Abstract— A design and its experimental result of a broadband equiangular spiral antenna for ultra-wideband (UWB) ground penetrating radar (GPR) applications are presented. Ultra-wideband antennas are one of the most critical parts of broadband GPR system. Dispersive or non-dispersive antennas have been commonly used for GPR systems, such as monopole, dipole or Bow-tie antenna, TEM horn antenna, Vivaldi or tapered slot antenna (TSA), and equiangular spiral antenna. The proposed antenna, which is fed by a vertically connected planar-type microstrip-to-coplanar stripline (CPS) balun, has ultra-wideband characteristics of the inherent equiangular spiral antenna. The curved microstrip-to-CPS balun transforms a unbalanced 50 Ω to a balanced 110 Ω of CPS impedance. The two conductors of the CPS strips are connected to the two arm radiators by utilizing vertical CPS substrate at the center. The spiral radiator consists of two identical arms which are shifted by 180° with respect to each other. The overall design of the spiral antenna is simply done by connecting between separately designed microstrip-to-CPS balun and two-arm equiangular spiral radiator. The calculated phase imbalance of the balun at feeding point was within 8° for whole frequency band. The implemented equiangular spiral antenna demonstrates wideband performance for frequency ranges from 2.9 to 12 GHz with the gain of 2.7 to 5.3 dB. The axial ratio is within 3 dB and the half-power beamwidth (HPBW) is more than 70°. Simulated radiation efficiency is about 90%. Good agreement was achieved between the simulations and the experimental results. This antenna can be widely applied to various UWB and GPR system applications.

Simulation on Power Handling Enhancement for the Ohmic Contact RF MEMS Switch with Micro-spring Structure

Zhuhao Gong, **Huiliang Liu**, **and Zewen Liu**
Institute of Microelectronics, Tsinghua University, Beijing 100084, China

Abstract— This paper presents a RF MEMS (Radio Frequency Micro-electro-mechanical System) switch which is capable of handling high power. By optimizing the design of its contact configuration and cantilever structure, the RF current distribution becomes more uniform through each contact of the multi-contact switch. The novel design of micro-spring cantilever structure also ensures a good contact between the contacts and top electrode when the switch is in the "on" state. The simulation results demonstrate the RF MEMS switch has excellent microwave performance: insertion loss < 0.15 dB, return loss > 31.6 dB and isolation > 14.5 dB from DC to 40 GHz as well as the ability of handling 3.1 W RF power which means a 300% improvement in power handling capability compared with traditional cantilever switch.

To be specific, the mechanical and electromechanical performances are simulated using CoventorWare to compare the traditional cantilever switch with the proposed micro-spring cantilever switch in the 2×2 contact configuration. The result shows the advantage of micro-spring cantilever structure in providing a good contact interface with multiple contacts. Fig. 1 shows the simulated S-parameters of the original switch and the proposed switch by full-wave EM simulator-Ansoft HFSS as well as the measured S-parameters of the original switch which implies a good consistence with the simulated results. To analyze the RF current distribution through each contact, the maximum RF current density through each contact in different contact configurations is simulated, as shown in Fig. 2. Simulation results demonstrate that the adoption of optimized 2×2 contact array ensures a more even current distribution between each contact in high frequency and therefore greatly improves its power-handling capability.

Abstract— Today, energy saving has become increasingly important and use of compact fluorescent lamps (CFL) has become widespread in structures such as shopping malls, offices, factories, hotels, houses, schools, hospitals and so on in order to provide more efficient lighting and conserve electrical energy. There are many commercial brands on the market. In recent years, electromagnetic interferences (EMI) problems induced by CFLs are investigated. In this study, EMI emitted by CFLs has been investigated in accordance with CISPR-15 which is an international standard.

It has been known that transmission emissions of lamps with different trademarks are also different; some of them don't provide the requirements of CISPR-15 standards and act as contaminants in the electric supply system. As an example of the analysis conducted, considering the limit, which is 66 dBμV, of CISPR-15 at 166.216 kHz frequency; it has been seen that the effect of CFL produced by Company A at 166.216 kHz frequency is 81.56 dBμV, whereas the effect of CFL produced by Company B at 166.216 kHz frequency is 50 dBμV, respectively.

In this case, the suitable filter was designed within scope of the study in order to prevent and minimize the risks created by commonly used brands in terms of energy quality, EMI and health; and solutions were presented to suppress CFL-induced noise transmitted to the electric grid.

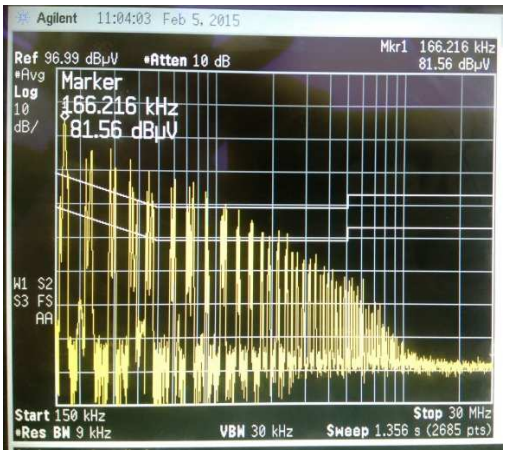

Figure 1: Interference values of CFL of A.

Analysis of the SMOS, MODIS and GCOM-W1 Data during the Growing Season in the Southern Part of the Western Siberia

P. P. Bobrov, A. S. Lapina, and A. S. Yashchenko
Omsk State Pedagogical University, Omsk, Russia

Abstract— The microwave emission of the soil covered with vegetation mainly depends on the following parameters: soil moisture and water content in the vegetation, temperature of the surface , and soil roughness. The SMOS Soil Moisture Retrieval Algorithm estimates vegetation attenuation (optical depth) at L-band by MODIS data (LAI and NDVI) using semi-empirical equations [1]. However, MODIS data that refer to the territory of the SMOS footprint often include cloudy areas. It makes difficulties in using optical sensor data.

This paper presents an analysis of the SMOS level 2 optical depth data, normalized microwave polarization difference index (MPDI), microwave vegetation index (MVI) derived from GCOM-W1 data and optical vegetation indexes (LAI and NDVI). We found that dependence between the data sets is determined by the type of surface. The best correlation for any type of the surface is between the optical and microwave indexes calculated according to the GCOM-W1 data. Among them, the best dependence was observed for indexes (MVI and MDPI) calculated according to the data at 6.9 and 10.7 GHz for the forest-steppe zone. It was also found that relationship between the optical depth (SMOS Level 2) and LAI, NDVI for any type of surface is very weak.

We also compared LAI and NDVI with ground-based measurements of the vegetation water content (VWC) taken from the southern part forest-steppe and steppe zone. The relation between them was extremely low. However the dependency between VWC and MDPI at frequencies of 18 GHz 23 GHz was significantly better.

Thus, GCOM-W1 data in frequency band can be used to retrieve the state of vegetation canopy instead of the MODIS data.

A Spread Spectrum Clock Generator Using Discontinuous Modulation Technique for Reduction of Time Interval Errors

Taiming Piao, **Jae-Kyung Wee**, **Inchae Song**, **and Boo-Gyoun Kim**
School of Electronic Engineering, Soongsil University, Seoul, Korea

Abstract— spectrum clock generator with a low maximum time interval error (MTIE) and low electromagnetic interference (EMI). The proposed circuitry was fabricated with 0.35 µm CMOS process and operated with 3.3 V supply voltage at the average center frequency of 100 MHz. The measured results showed the MTIE of 11.59 ns with the EMI reduction of 14.57 dBm.

Multi-wavelength Erbium-doped Fiber Laser Based on Distributed Rayleigh Scattering Feedback

Abstract— A multi-wavelength erbium-doped fiber (EDF) laser based on random distributed feedback through backward Rayleigh scattering in a 20-km-long single-mode fiber and a polarization-maintaining fiber loop mirror (PMF-LM) is demonstrated. 7 lasing lines with wavelength spacing of 0.8 nm is obtained at room temperature. Due to the half-opened laser cavity design and the efficient gain from the pumped EDF, the measured threshold power is only 20 mW, and the pump efficiency is up to 14%.

Analysis of the Induction Motor Drive Predictive Control Method and Its Comparison with the Fundamental Direct Torque Control Method

Jiri Lettl and Pavel Karlovsky
Faculty of Electrical Engineering, Department of Electric Drives and Traction
Czech Technical University in Prague, Technicka 2, 166 27, Prague 6, Czech Republic

Abstract— Thanks to their simplicity, low price and high reliability, induction motor drives are one of the most common in many applications nowadays. Many ways of their control strategies have been developed since launching of mass production of the modern semiconductor devices of high power at high switching frequency. These methods include not only standard frequency control but also modern techniques of field oriented control or direct torque control.

The fundamental direct torque control method of induction motor drive, using two hysteresis controllers to maintain the asked stator flux amplitude and generated torque values, is simple and efficient, however, in some applications relatively high torque ripple can be seen as its disadvantage. That is why various modifications of the method, such as direct torque control with space vector modulation, multilevel inverter application or some forms of predictive algorithms have been performed reduce the torque ripple.

The paper presents suggested predictive direct torque control method of induction motor drive based on predicting the most suitable inverter output voltage vector for the next control step. The prediction calculation is proceeding from torque and stator flux reference values, motor parameters, and actual values estimated from voltage and current measurements. In the paper theoretical analysis of the method is performed, mathematical description of the system is created and the functionality of the proposed control algorithm is verified both by simulation in MatLab/Simulink environment and by measurement on the real induction motor drive. Comparison of the designed predictive control method with the fundamental direct torque control method developed by Takahashi is presented, too.

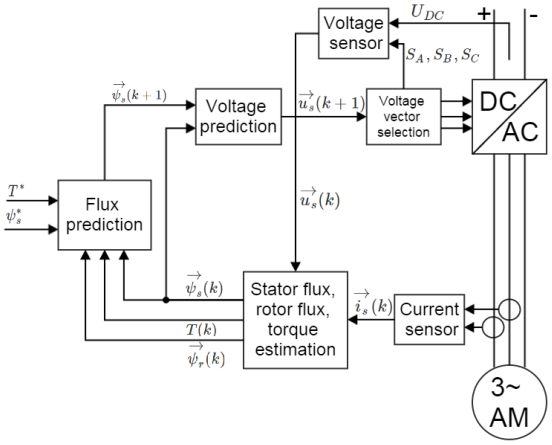

Figure 1: Block diagram of the proposed predictive direct torque control method.

Effect of Neutral Grounding Methods on the Earth Fault Characteristics

Abdallah R. Al-Zyoud[1], **A. Alwadie**[2], **A. Elmitwally**[2], **and Abdallah Basheer**[3]

[3]National Electrical Power Company, Jordan

Abstract— Medium voltage (MV) distribution systems use different methods for grounding the neutral point. Influences of these grounding methods on the single line to ground (SLG) fault characteristics are discussed in this paper. Jordanian MV network is used as a case study. The network has both underground cables and overhead lines. Simulation models are implemented in both MATLAB®/SIMULINK®, and DigSilent/Power Factory® softwares. The models allow detailed investigation of the different fault factors and grounding methods. Results are obtained to evaluate the impact of each grounding method on the SLG fault features. Isolated neutral, solid grounding, resistance grounding and Petersen coil (Arc suppression coil) grounding are compared for different fault locations, fault incidence angles, and fault resistances. Current and voltage waveforms, as well as symmetrical components are used to describe the fault case.

Wheel Speed Measurement of Traction Locomotive under Wheel Slip Conditions

O. Zoubek, P. Pichlík, and J. Zděnek
Czech Technical University in Prague, Czech Republic

Abstract— Wheel speed of heavy freight train locomotive under non-ideal traction conditions was measured with very high resolution and fine precision. Many authors published papers in this area over a past century, but only recent advance in information technology enabled measurement in such extent and resolution at the same time.

Most modern locomotives have the speed sensor coupled with the traction motor. Unlike many other authors doing research in area of wheel-slip, the wheel speed was measured directly on the wheel, not indirectly on the traction motor. This allowed to directly observe the wheel speed without requirement to implement motor — wheel model, which can carry inaccuracies.

Thanks to an independent method of determining train speed using sensitive GPS receiver, wheel slip speeds were accurately identified regardless of synchronous slip phenomenon.

Despite adhesion theory, three types of operation were identified: Stable traction with negligible slip without oscillations, semi-stable traction with evident slip and oscillations and prominent wheel slip. As the wheel speed was measured directly on the wheel, a much larger oscillations than ever published were revealed. The source of the oscillations is discussed.

A simple MATLAB model of rotational masses was constructed and tuned to match the measurements. Eigenvalues and eigenvectors of the model are discussed. The rotational masses model is completed with adhesion model to perform simulations. The simulation results are presented with comparison to the results of the measurements.

Electric Vehicle Drive Control Based on GPS and GSM Path Parameters

T. Haubert, Z. Čeřovský, P. Mindl, and P. Mňuk
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technická 2, 166 27, Prague 6, Czech Republic

Abstract— Minimizing of energy consumption is important task which is solved at all vehicles. In the case of electric vehicles (EV), energy stored on board in chemical accumulators must be used very effectively. For this purposes mathematical model of EV and real journey data used for energy consumption calculation must be used. On the basis of journey regime optimization lower energy consumption will be achieved.

Optimal journey regime is calculated by means of known road data, obtained by means of GPS and GSM navigation system. From the road horizontal and vertical data basic route elements are calculated. Basic route elements are compared with needed torque, generated by driver's pedal. All this information's are processed, optimized, and needed mechanical torque is transmitted to the control unit of electric drive.

For model implementation the dSpace DS1103 has been used. The DS1103 dSpace platform is used as a simulator of the electric vehicle in laboratory and it is used for HIL (Hardware In the Loop) tests. The DS1103 device is covered in the AutoBox with Ethernet communication interface and Autoboot option enabling usage of Compact Flash card. The complete EV mathematical model is loaded in DS1103 device.

For laboratory verification special testing bench has been built. Testing bench consists of permanent magnet synchronous motor, power inverter and power sources. The load is substituted by the dynamometer. Both machines are controlled by master controller. Hardware structure of the laboratory stand is depicted on Fig. 1. In the first step journey simulation required torque of EV drive in the single path elements has been calculated. Real path data obtained within the journey were generated by means of GPS and GSM mobil-phone and stored in the memory.

Stored data were used as EV simulation model input data. Then for needed driving torque, actual power and consumed energy are calculated. With respect to the obtained results optimized path elements strategy calculation has been developed.

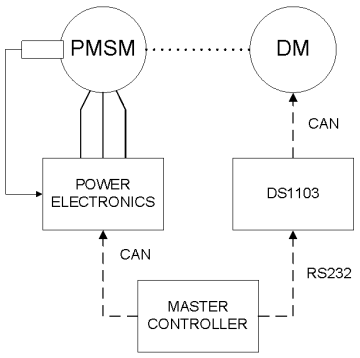

Figure 1: Hardware structure of the laboratory stand.

A Novel Ultrathin CdS/CdTe Solar Cell with Conversion Efficiency of 31.2% for Nano-area Application

M. Sabaghi[1], **A. Majdabadi**[1], **S. Khosroabadi**[2], **and S. Marjani**[1, 3]

[1]Laser and Optics Research School
Nuclear Science and Technology Research Institute (NSTRI), Tehran, Iran

[3]Department of Electrical Engineering, Ferdowsi University of Mashhad, Mashhad, Iran

Abstract— Due to limited availability and the rising price, the layer thickness reduction of solar cells is an attractive prospect. In this paper, we investigated a thin high efficiency structure of CdTe solar cells for nano-area application The proposed structure, achieved by rotating 90° in the base line structure, suggests high efficiency due to high current density. The proposed structure showed acceptable efficiency which is quite noteworthy in reducing the amount of material used and associated losses. The result showed a considerable improvement over the 15% efficiency of the reference sample. Under global AM 1.5 conditions, the designed cell had a V_{oc} of 866 mV, a J_{sc} of 74.84 mA/cm^2, and a FF of 48.2%, corresponding to a conversion efficiency of 31.2%.

The starting point of this work was the baseline case as reported in [1, 2]. In brief, the CdTe device model in the base line case consists of a 4 µm-thick CdTe absorber layer, a 100-nm thick CdS window layer, and a 500-nm-thick SnO_2 buffer layer. At the next step, this structure was modified by rotating 90° of the structure without dimension variation. Figure 1 illustrates the CdTe baseline case structure and the modified structures investigated in this study. The proposed structure has many advantages such as high photogeneration and low recombination rate. The J_{sc} of the cell can be improved by reducing the carrier recombination losses at the back contact or increasing the photogeneration rate in the absorber layer. Because the light inters to layers independently, the photogeneration rate is high in each layer. Figure 2 shows the comparison the photogeneration rate between conventional and proposed structure.

In addition, using less semiconductor material by thin cells is one of the main goals of today's solar cell research. Also, the thinning will reduce the recombination loss as well as lower production time and the energy need to produce solar cells. Consequently, all of these factors will decrease the production cost. Hence, it is possible to reduce the dimension of proposed structure considerably and achieve better base line results, simultaneously. Figure 3 shows the current-voltage and power-voltage curves for comparison with the base line case. As it is shown in Figure 3, the conversion efficiency can be increased to 31.2% mostly due to improvement of J_{sc} compared to the base line case. Although FF is smaller than base line case because of the high difference between J_{sc} and maximum current of the cell, the important parameters of the solar cell are much more than base line case.

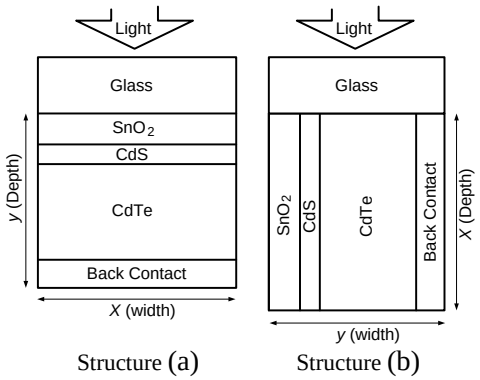

Figure 1: Structures of the CdTe solar cells: (a) baseline case structure and (b) modified cell structure for higher efficiency.

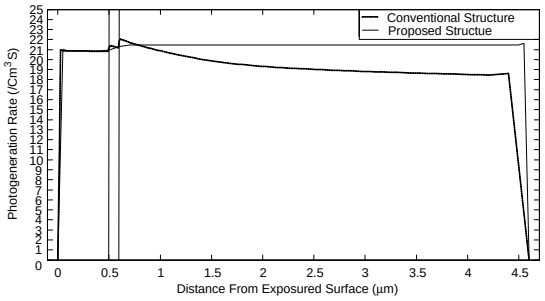

Figure 2: Photogeneration rate for the conventional and proposed structure.

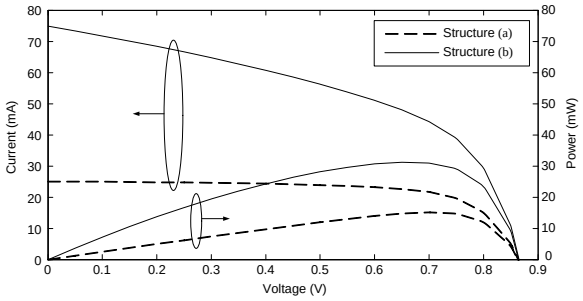

Figure 3: Characteristics of the (a) baseline case structure and (b) modified cell structure for higher efficiency.

Metasurfaces' Solutions for Polarization Spectroscopy, Optical Activity, Colored Phase Holograms and Compact Nano-cavities

Vladimir M. Shalaev, **Amr M. Shaltout**, **Jingjing Liu**,
Sajid Choudhury, **Alexandra Boltasseva**, **and Alexander V. Kildishev**

Purdue University, West Lafayette, IN 47907, USA

Abstract— Tremendous efforts have been done over the last decade to produce 3D optical metamaterials that transcend properties of natural materials. However, the realization of the hoped-for 3D devices is challenged by large absorptive losses and complex and cost-ineffective fabrication. Metasurfaces have been introduced to overcome these two major challenges. They provide simple, compact and power efficient solutions to problems of immense importance. In our work, we use metasurfaces to obtain circular dichroism (CD) spectrometer, polarization rotator, color hologram, and subwavelength nano-cavities.

CD spectrometers are typically used to sense chiral molecules which are highly recurrent in biological structures and organic compounds. These spectrometers measure the differential absorption between circular polarizations of light (or different spins). A typical CD spectrometer takes sequential measurements of spin components which require complex hardware for switching laser source and managing data acquisition. Instead, we implement a metasurface that employs photonic spin Hall Effect to spatially separate spectra of different spins. This is a real-time CD spectrometer, and the smallest to our knowledge. Applications include bio-sensing, DNA structural analysis and stereochemistry.

We also used metasurfaces to perform optical rotation of linearly polarized light — used in secure quantum communications. Using natural materials will necessitate a long optical path to accumulate the differential phase-shift between spin components required for optical rotation. Ultrathin metasurfaces have shown the ability to split these components, and introduce the required phase-shift through a single deep-subwavelength layer.

Another metasurface generates a polychromatic holographic image with a broadband white source. This is done by using nano-slit antennas that can simultaneously control phase and wavelength of transmission. Antennae size controls wavelength (color), while antennae orientation manipulates Pancharatnam-Berry phase allowing for concurrent generation of arbitrary RGB images.

In addition to previous applications, we design subwavelength Fabry-Pérot cavities by replacing conventional mirrors with reflecting metasurfaces that introduce arbitrary phase-shifts compensating for reduced accumulated phase through the ultra-small cavity. 100-nm cavities showed resonance in the range (0.6–1.1 μm). Applications include nano-lasers, spontaneous emission enhancement (Purcell effect) and single photon sources.

Metasurfaces have proven to be applied efficiently to the areas of bio-medical optics, coherent optics, optical imaging and quantum nanophotonics, and many other applications are yet to be explored.

Controlling the Polarization State of Light with Metastructures

Mu Wang, **Shang-Chi Jiang**, **Xiang Xiong**, **Ren-Hao Fan**, **and Ru-Wen Peng**
National Laboratory of Solid State Microstructures and School of Physics
Nanjing University, Nanjing 210093, China

Abstract— In this talk, we present our recent work on controlling the polarization state of light with metastructures. First, we illustrate an approach to tune efficiently the phase difference of light in two orthogonal directions by controlling the time retardation with a microstructured surface. Second, we demonstrate the general mechanism to construct the dispersion-free metastructure, in which the intrinsic dispersion of the metallic structures is perfectly cancelled out by the thickness-dependent dispersion of the dielectric spacing layer. By selecting the structural parameters, the polarization state of light can be freely tuned across a broad frequency range, and all of the polarization states on the Poincaré sphere can be realized dispersion free. Third, we present a freely tunable polarization rotator for broadband terahertz waves using a metastructure, which can conveniently rotate the polarization of a linearly polarized terahertz wave to any desired direction with nearly perfect conversion efficiency. The investigations provide some guidelines to control the polarization state of light at subwavelength scale.

Manipulating Surface Waves by Metasurfaces

Luigi La Spada and Yang Hao
Queen Mary, University of London, United Kingdom

Abstract— Surface waves on dissimilar interfaces have been extensively studied during the years [1]. Controlling these surface waves is of great interest in several new areas of technology including applications for surface wave suppression [2], improved antenna performances [3], wireless communication technologies, microwave circuits [4] and military applications among the others. In this regard, the properties of these surface waves supported on thin structured surfaces, known as metasurfaces, have been recently studied. In particular, a family of surface waves may be supported by pillar or crossed slit structures [5]. TM surface modes associated with a square array of metal patches on a dielectric coated ground plane and a "mushroom" metasurface were shown in [6]. By engineering the dimensions of metasurface elements across the array, the phase velocity of the surface mode can be controlled [7], and the propagation of the surface mode manipulated. Unfortunately, all such methods are highly dispersive, intrinsically narrow-band, lossy and anisotropic. The objective of this paper is to present a new metasurface-based design for surface waves manipulation.

The proposed structure consists of a metallic object, hidden underneath a dielectric structure above a ground plane, surrounded by a planar metasurface-based structure. This work has been divided into two main parts. The first part deals with the analytical formulation and the design of surface wave cloak. The second part will examine the simulation results of the proposed structure in the frequency range 8–10 GHz. The most significant findings from this study is that the proposed structure is polarization independent (it works for any impinging wave polarization: TE and TM), has wide-band and multi-band behaviour and it is easy to fabricate.

Extremely Confined Gap Surface-plasmon Modes in Metallic Metasurfaces Probed by Electron Energy-loss Spectroscopy (EELS)

Nicolas Stenger[1, 2]

[1]Department of Photonics Engineering, Technical University of Denmark
DK-2800 Kgs, Lyngby, Denmark
[2]Center for Nanostructured Graphene (CNG), Technical University of Denmark
DK-2800 Kgs, Lyngby, Denmark

Abstract— Applying EELS to ultra-sharp convex grooves in gold, we directly probe extremely confined gap surface-plasmon (GSP) modes excited by swift electrons in nanometer-wide gaps, down to approximately 5 nm.

We report an experimental study of GSPs in ultra-sharp gold convex nanogrooves using EELS [1]. The geometry of these nanogrooves is characterized by gradual and relatively slow variations in the gap width when moving deeper inside a groove. This means that the groove GSP modes can be considered as being formed by local metal-insulatormetal (MIM) GSP modes (that is, by GSP modes supported by constant-gap MIM configurations) that are weighted accordingly, a representation which is widely used in integrated optics and plasmonics for effective-index approximation. In EELS experiments (Fig. 1), the strongly confined electrical fields of moving electrons excite thereby local MIM GSP modes, corresponding to the position of the electron beam inside the groove. Note that a sample should necessarily be thin along the groove (Fig. 1) in order to be transparent for an electron beam, but not too thin with respect to the GSP wavelength. Overall, the considered groove geometry is ideal for studying MIM GSP modes, as the width of the insulating layer (gap size) decreases as the position of the electron probe is moved down the nanogroove, thus allowing us to map the evolution of MIM GSP modes for varying gap size in a single groove. We intentionally propagate the electron beam along the axis of the groove within the mirror-symmetry plane (yz plane, cf. Fig. 1) in order to allow for probing of modes near the groove bottom and to study the optically dark modes. We verify experimentally the existence of the MIM GSP mode in the crevice of the groove, i.e., at extremely narrow gaps of only 5 nm.

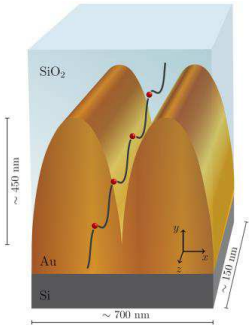

Figure 1: Artistic impression of the gold nanogroove studied in this work, with the electron probe moving parallel to groove axis. The groove is filled with silicon dioxide and the substrate is silicon. The groove height, depth and periodicity are approximately 450 nm, 150 nm and 350 nm, respectively.

Abstract— Surface plasmon polaritons (SPPs) have recently found numerous applications in photonics, but traditional devices to excite them (such as grating and prism couplers) all suffer inherent low-efficiency issues, since the generated SPPs can decouple back to free space and the reflection at the device surface can never be avoided. Here, based on a transparent gradient metasurface, we propose a new SPP-excitation scheme and numerically demonstrate that it exhibits inherently high efficiency (94%), since the designed meta-coupler kills both the decoupling and the reflection at its surface. As a proof of concept, we fabricate a meta-coupler in the microwave regime, and combine near- and far-field experiments to demonstrate that the achieved SPP-excitation efficiency reaches 75%, which is several times higher than all other available devices. Our findings can inspire the designs and realizations of high-performance plasmonic devices to harvest light-matter interactions.

Meta-line and Meta-surface for Cloaking

Hong Chen Chu, **Jie Luo**, **and Yun Lai**
Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology, College of Physics, Soochow University, Suzhou 215006, China

Abstract— Meta-surface has not only shown extraordinary ability to control the reflection and refraction of waves [1], but also the ability to change propagating waves into surface waves along the surface [2].

Here, we investigate the 1D counterpart of a meta-surface: meta-line, i.e., a one-dimensional structure with gradually changing parameters [3]. Our study shows that such a line is also capable of converting incident propagating waves into guided localized waves along the line. In such a way, propagating waves in space can be collected at a high efficiency.

The other topic that we investigate is the application of meta-surface for cloaking.

Few-layer Metasurfaces for High Efficiency Linear Polarization Conversion and toward Planar Flat Optics

Hou-Tong Chen, **Nathaniel K. Grady**, **Jane E. Heyes**, **Dibakar Roy Chowdhury**, **Yong Zeng**, **Matthew T. Reiten**, **Abul K. Azad**, **Diego A. R. Dalvit**, **and Antoinette J. Taylor**
Los Alamos National Laboratory, USA

Abstract— The properties of metamaterials are determined by their structures rather than the materials being used. They enable electromagnetic functionalities by design, which are applicable to the entire electromagnetic spectrum from microwave to visible. Bulk metamaterials often suffer from high resonant losses and three-dimensional fabrication challenges, particularly when approaching the optical frequency regime where metals become lossy and structural dimensions are on the micro- or nano-scale. Single layer planar metamaterials — metasurfaces — are relative easy to fabricate using modern micro- and nano-fabrication technologies, and at the same time minimize their losses. However, their interactions with electromagnetic waves are limited, resulting moderate device performance and insufficient for many real world applications.

When a few layers of metasurfaces are added together and separated by subwavelength dielectric spacers, the overall response could be dramatically different from the simple addition of individual metasurface layers. Taking advantage of the tailored resonance (dispersion) and anisotropic response, we achieve few-layer terahertz (THz) metamaterials for efficient linear polarization conversion over a broad bandwidth more than two octave [1]. The few-layer THz metamaterials consist of two orthogonal metal gratings and an array of subwavelength anisotropic metal resonators in between, which are separated by polyimide spacer. Similar to the metasurface structures previously demonstrated [2], the phase of the cross-polarized waves depends on the geometry and dimensions of the resonators being used, spanning the entire 2π range. This enables the creation of spatial phase profile for arbitrary wavefront shaping. For instance, a thin-film-like flat metamaterial with appropriately arranged resonators can deflect the transmission waves to a specific frequency-dependent angle, a function could be otherwise only accomplished using a bulk prism. Other flat optics can be designed using the demonstrated few-layer metamaterials, for instance, for beam focusing/collimation.

Abstract— The terahertz (THz) band of the electromagnetic spectrum is conveniently sandwiched between the microwave and infrared regions that allows one to combine both optical and microwave techniques in THz instrumentation and to synthesize unique instrumental solutions. Such a synthesis is proven to be very effective when planar metallized microstructures of subwavelength topology, commonly referred to as frequency selective surfaces (FSSs) or measurfaces (metaFSS), are used for manipulating amplitude, polarization and phase characteristics of quasi-optical THz beams. In microwave engineering, the phase control is of great importance in the technology of low-profile reflectarray antennas, whose conventional design implies exploiting a grounded-dielectric-slab-backed FSS with spatial-depended reflection phase. Transferred to the THz band, this approach is estimated to be promising for beam-shaping and beam-focusing techniques as it allows creating purely flat, thin and lightweight reflectors capable of properly manipulating the wavefront through the control of the FSS unit cell geometry. Due to relative simplicity in photolithographic fabrication, such kind of reflectors serve as an attractive alternative to the conventional diffractive optical elements (DOEs) based on cost-consuming structures with profiled surfaces.

In this contribution we demonstrate feasibility for high performance reflective focusing of THz beams using flat DOEs based on metaFSS-inspired holographic reflectarrays (HRAs), whose design is accomplished using a combined technique involving:

a) a computer-generated holography method to synthesize an appropriate distribution of the reflection phase $\varphi_{\mathrm{HRA}}(x, y)$ over the metasurface;

b) a full-wave-electromagnetic-analysis-based method to control the complex reflectance ρ_{HRA} (x, y) of the HRA at any local point (x, y) of its surface via proper morphing the metaFSS unit cells geometry from metallic patches to U-shaped and split-ring resonator elements.

We present the experimental results of testing different planar focusing devices designed with the aforementioned technique and optimized for the operation frequency of 0.35 THz. The devices are implemented on basis of polypropylene substrates with the thickness of 190 μm and provide radiation focusing into simple and sophisticated shapes including single and multiple spots, as well as Latin letters. The overall diffraction efficiency up to 80% is demonstrated that outperforms similar characteristics of many metaFSS-based analogues working at THz frequencies.

Abstract— Near-field imaging optics, including scanning near-field optical microscope, near field proximity lithography and super lens, have always been suffering from the issue of near field diffraction limit, which implies that the obtainable resolution is strongly dependent on the light wavelength and the distance between objects and lens or fiber tip's apex. This results in great troubles in practical applications, like the physical abrasion of near field mask patterns. A method of plasmonic metalens going far beyond the near field diffraction limit was proposed and demonstrated experimentally in our recent investigations. The plasmonic metalens is composed of silver-photoresist-silver structure and applied with high numerical aperture off-axis photons illumination and surface plasmons illumination, generated by hyperbolic metamaterial of multiple metal-dielectric films. The air working distance between mask patterns and metalens could be significantly elongated far beyond of the near field diffraction limit, benefitting from sub-diffraction imaging information enhancement due to the cavity metalens structure and the shift of Fourier components of nano patterns. As examples, nano patterns of half pitch 60 nm are successfully resolved with 365 nm light wavelength and 100 nm air gap distance, about four times that in conventional near-field imaging or superlens scheme. Much Deeper subwavelength resolution with half pitch 4× nm, 3× nm and 2× nm are demonstrated theoretically and experimentally as well. The method is believed to significantly improve the compatibility of plasmonic lithography application as a cost effective, nano-fabrication way.

Transparent Conducting Oxides as Plasmonic Component in Near Infrared

Abstract— Research on alternative plasmonic materials is becoming an important step to improve the performance of plasmonic and nanophotonic devices for many applications. Our study focuses on transparent conducting oxides which have great potential for enabling high performance, tunable, semiconductor compatible plasmonic devices.

The development of new plasmonic materials enables novel optical devices, and they in turn assist in the progress of optical communications. As a result of the significant attention in searching for alternative materials, transparent conducting oxides (TCOs) have been proposed as promising plasmonic compounds in near infrared (NIR) regime, especially at telecommunication wavelengths [1]. They are eminently practical materials because they are CMOS-compatible, can be grown on many different types of substrates, patterned by standard fabrication procedures, and integrated with many other standard technologies. In addition, like any other semiconductor, the optical properties of TCOs can be tuned by changing the carrier concentration/doping. Thus, TCOs form an obvious choice as alternative plasmonic materials in the NIR.

In our studies, we have demonstrated that simple TCO structures patterned by electron beam lithography support strong plasmonic resonances in the NIR, and such resonances are easily adjustable with post processing such as thermal annealing [2]. These characteristics of TCOs provide the capability to design essential optical components for nanophotonic systems. For example, we recently demonstrated a TCO based metasurface which functions as a quarter wave plate with a 200 nm bandwidth at the 1.55 μm wavelength [3].

TCOs can be used not only as an alternative to metal, but also as epsilon near zero (ENZ) materials since they naturally offer ENZ properties in the NIR regime. From our recent study of the behavior of nanoantennae sitting upon a TCO substrate, we found that TCOs can be a potential optical insulating media in nanophotonic systems due to the high impedance of TCOs at the ENZ frequency.

In addition, the optical properties of TCOs can be varied by optical or electrical means. Current research is focused on studying the ultrafast carrier dynamics in doped zinc oxide films using transient pump-probe spectroscopy. We have shown that CMOScompatible doped zinc oxide films can achieve a 40% change in reflection (30% in transmission) with ultrafast dynamics (< 1 ps) under a small fluence of $3\,\mathrm{mJ/cm^2}$. Consequently, TCOs are shown to be extremely flexible materials, enabling fascinating physics and unique devices for applications in the NIR regime.

Abstract— Photonic spin hall effect (PSHE), that spin-polarized photons can be laterally separated in transportation, gains increasing attention from both science and technology, but available mechanisms either require bulky systems or exhibit very low efficiencies. Here we demonstrate that a giant PSHE with $\sim$ 100% efficiency can be realized at certain meta-surfaces with deep-subwavelength thicknesses. Based on rigorous Jones-Matrix analysis, we establish a general criterion to design meta-surfaces that can realize 100%-efficiency PSHE. The criterion is approachable from two distinct routes at general frequencies. As a demonstration, two microwave meta-surfaces are fabricated and then experimentally characterized, both showing $\sim$ 90% efficiencies for the PSHE. Our findings pave the road for many exciting applications based on high-efficiency manipulations of photon spins, with a polarization detector experimentally demonstrated here as an example.

Control of Ultrafast Coherent Nonlinear Response of Plasmonic Metasurfaces

Abstract— Nonlinear phenomena are widely studied in nano-optics, and are often implemented in synergy with plasmonic effects to provide strong field enhancement. Research on arrays of plasmonic nanostructures can form the basis for the development of efficient, active metasurfaces with designed coherent and ultrafast optical functionalities. These can be useful in applications requiring for example frequency conversion or efficient integrated quantum sources. This work is developed within this context and aimed at gaining the understanding necessary to develop coherent nonlinear metasurfaces rationally.

The unit cell of the metasurface we study (Fig. 1(a)) is a 30 nm high Au cut disc. It is designed to support plasmonic resonances at both fundamental and harmonic frequencies. The extinction spectrum (Fig. 1(b)) exhibits a Fano resonance in the visible and a magnetic dipole resonance in the near-IR, both optically active due to the presence of the slit [1] and at the basis of the strong coherent response of the metasurface.

We experimentally study and discuss the dispersion of both second and third-order nonlinear processes produced by this structure with a particular focus on the mechanisms enabling their optically-controlled modulation at the sub-picosecond time scale. The experiments, including pump-probe spectroscopy, are rationalized using theoretical considerations and numerical computations.

Abstract— Polarization is one of the fundamental properties of electromagnetic radiation. Based on the measurement and interpretation of the polarization of light waves, polarimetry has found its applications in many areas of science and technology, ranging from ellipsometry, remote sensing to polarization light scattering and ophthalmic polarimetry. Although the traditional measurement systems bring distinguished functionality in measuring speed and accuracy, their applications are still limited due to the various polarization elements and complicated data processing system adopted, which result in large volume and high cost. What's more, the miniaturization of measurement systems currently used to characterize the polarization state of light is limited by the bulky optical components used such as polarizers and waveplates. We propose and experimentally demonstrate a simple and compact approach to characterize the polarization state of light using an ultrathin (40 nm) gradient metasurface. A completely polarized light beam is decomposed into a left circularly polarized (LCP) beam and a right circularly polarized (RCP) beam, which are steered in two directions by the metasurface consisting of nanorods with spatially varying orientations. By measuring the intensities of the refracted light spots, the ellipticity and handedness of various incident polarization states are characterized at a range of wavelengths and used to determine the polarization information of the incident beam. Interestingly, since the refracted LCP and RCP light diverge naturally from each other, the metasurface can also be used as a circular polarization beam splitter, whose split angle is determined by controlling the spatial distribution of the nanorods in the metasurface.

Waveform-selective Metasurfaces to Distinguish Different Waves at the Same Frequency

H. Wakatsuchi[1, 2]

[1]Center for Young Innovative Researchers, Nagoya Institute of Technology, Japan
[2]Department of Electrical and Electronic Engineering, Nagoya Institute of Technology, Japan

Abstract— In general the responses of materials to an electromagnetic wave depend on the composite molecules and incoming frequency. Although the advent of metamaterials [1, 2] allowed us to obtain electromagnetic properties independent of composite molecules, still none of materials has permitted sensing different waves at the same frequency unless they had nonlinearity [3]. However, such nonlinearity was controlled by the magnitude of the incoming wave or bias. Recently we have reported circuit-based metasurfaces composed of circuit components including schottky diodes, capacitors, inductors and resistors. These metasurfaces allowed us to distinguish different surface waves even at the same frequency in response to their waveforms or pulse widths [4–7]. In this paper we demonstrate that such a new capability termed *waveform selectivity* is not limited to surface waves but can be applied to controlling different types of incoming waves including free space waves normal to the metasurfaces. The metasurfaces demonstrated here are composed of periodically deployed square patches, ground plane, and dielectric spacer (Rogers3003). In each gap between square patches, a set of four diodes is deployed to play a role of a diode bridge and to convert the incoming frequency component to zero frequency. This frequency conversion is used together with the time domain response of capacitors or inductors deployed inside diode bridges, which ends up with sensing specific waveforms even at the same frequency. Under these circumstances, capacitor-based metasurfaces more effectively absorb short pulses, while inductor-based metasurfaces absorb longer pulses or continuous waves. The use of such waveform-selective metasurfaces gives us a new capability to control electromagnetic properties and thus is expected to develop new kinds of microwave applications and technologies, e.g., waveform-selective wireless communications [8].

Optimization of Second Harmonic Generation in Plasmonic Nanostructures by Mode Matching

Gabriel D. Bernasconi, Jérémy Butet, and Olivier J. F. Martin
Nanophotonics and Metrology Laboratory (NAM)
Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne 1015, Switzerland

Abstract— In the dipolar approximation, second harmonic generation (SHG) is forbidden in the bulk of centrosymmetric nanostructures (such as gold) but can arise at the interface thanks to the breaking of inversion symmetry. As a consequence, SHG is an appropriate tool to acquire information about nanostructures surfaces. In this presentation, we will show that SHG can also provide information on the underlying modes supported by a given structure. Furthermore, a combination of modes at the fundamental frequency can generate a SH wave supported by modes that cannot be excited at the fundamental frequency, the so-called dark modes. This optical nonlinear process can then be used to measure the radiation pattern of those dark modes. When the fundamental frequency matches a resonance of the structure, the high field enhancement will yield a high SHG. Additionally, if the SH frequency matches another higher frequency mode, the SH emission will be stronger and thus more easily measurable. Hence, being able to optimize the structure so that both SHG and fundamental frequencies match resonant modes is very useful for practical applications.

Using a surface integral equation method (SIE) to describe 3D nanostructures, we study the behavior of the eigenvalues of the corresponding matrix $\mathbf{M}(\omega)$ where ω is the frequency. First we consider the equation relating the surface currents j_{surf} to the excitation field E_{inc}

$$\mathbf{M}(\omega) j_{surf} = E_{inc}. \tag{1}$$

Then, by setting the incident field E_{inc} to zero, we can find the (non-trivial) solutions that don't need any external excitations to exist. This is done by re-writing Equation (1) as

$$\mathbf{M}(\omega) V_i = \lambda_i V_i = 0. \tag{2}$$

Looking for the frequencies ω where one of the eigenvalue λ_i of $\mathbf{M}(\omega)$ tends to zero, it is possible to find the eigenmodes. The frequency ω thus corresponds to the resonant frequency, and the eigenvector V_i associated to the current distribution (and so to the charge distribution) corresponds to the eigenmode. By scanning the complex frequency plane, we can find the multiple resonances supported by a given nanostructure.

This approach is especially interesting since dark modes cannot be found by considering a plane wave excitation. Indeed, the scattering spectrum can be used as prior knowledge of the resonant frequency (both its real and imaginary parts, the latter being related to the losses and the width of the resonance) at which the bright modes can be excited. Having the mode structure in mind allows optimizing the geometry in order to reach the most efficient SHG at the nanoscale, as will be demonstrated with different experimental configurations.

Linear and Nonlinear Spectral Signatures of Surface Plasmon Polaritons

S. A. Ponomarenko, L. Wang, and F. Che
Department of Electrical and Computer Engineering, Dalhousie University, Halifax, NS, B3J 2X4, Canada

Abstract— We explore spectral behavior of the fundamental and sum-frequency fields generated in thin metal films upon reflection of polychromatic light and elucidate a surface plasmon polariton role therein.

The field of plasmonics has lately experienced a truly explosive growth [1]. Much research in plasmonics has so far been focused on linear light-matter interaction modalities [2], owning largely to the success of plasmonic-based sensors as a powerful tool for probing surfaces [3]. However, resonantly enhanced local electric fields bring about pronounced enhancement of nonlinear responses of plasmonic materials as well [1].

Although the vast majority of work in plasmonics deals with quasi-monochromatic light, there has been growing interest in spectral signatures of plasmon enhanced electromagnetic fields. In particular, the linear optical response of homogenous [4] and inhomogeneous — periodic or random [5] — plasmonic nanostructures, probed with broadband light beams, has been recently examined. However, to the best of our knowledge, plasmon-enhanced *nonlinear* optical processes, excited by polychromatic light sources, have not yet been studied. In this context, it is especially instructive to learn whether plasmon polaritons, excited on the surface of a conducting material or nanostructure, leave any signatures in the far-field spectra of generated second-order nonlinear waves. The affirmative answer to this question can trigger new developments in surface nonlinear spectroscopy, microscopy, and surface morphology studies.

In this work, we investigate the spectral behavior of the fundamental and sum-frequency waves in the surface SFG from a thin metal film with the polychromatic (pulsed) incident light. The wide bandwidth of the source makes it possible to realize SFG with a single source: any pair of monochromatic components within the source spectrum gives rise to a sum-frequency wave through the surface SFG process. We assume a wellcollimated broadband light source such that its output can be treated as a plane wave. The source plane wave is assumed to be incident on a thin metal film, arranged in the Kretchmann configuration at a plasmon coupling angle.

For symmetric source spectra in the Kretchmann geometry, one would expect the SFG spectrum to peak at half the carrier wavelength of the source. We show, however, that at the incidence angle corresponding to light coupling to the SPP, the reflected sum-frequency wave (SFW) spectrum gets blue-shifted from the expected maximum whereas the reflected fundamental wave has a spectral hole at the carrier frequency. We further demonstrate that the magnitude of the effect depends on the bandwidth of the source spectrum and the incidence angle: The shifts of SFW spectra become more pronounced as the source bandwidth increases, while at a certain angle a spectral switch is observed. Also, as the incidence angle deviates from the plasmon coupling angle, all spectral changes disappear. The appearance of large SFW spectral shifts and switches can serve as an unambiguous plasmon signature in nonlinear surface spectroscopy.

[3]Institute of Physical and Theoretical Chemistry, Eberhard Karls University Tuebingen, Germany

Abstract— The search for time-stable and tunable point light sources with ultra-small dimensions constitutes a challenging task since the early days of nano-optics. Quantum dots, single molecules, or NV-centers in nano-diamonds may manifest ultimately small point light sources. Nevertheless, many such emitters suffer from blinking or photo-bleaching. In contrast, plasmonic nanostructures or pointed metal tips exhibit more stability even when illuminated with focused laser beams for strong field enhancement. In particular nonlinear effects such as second-harmonic generation (SHG) may benefit greatly from the strong and highly localized near-fields.

Using specially developed techniques, we fabricate plasmonic nanocones from thin films of different metals on glass/ITO and on silicon [1]. The cones with a tip radius down to less than 10 nm act as optical antennas [2, 3]. The external electric field is concentrated near the cone tip, leading to a narrow region of high near-field enhancement, which can be employed for SHG as well as tip-enhanced Raman spectroscopy [4] or molecule sensing [5, 6]. The geometry of the metallic nanocones breaks the centro-symmetry, thus providing stronger second-harmonic polarizability along the direction of symmetry-breaking, and concentrates the field energy via both plasmon oscillations and the lightning-rod effect into the cone tip. We demonstrate that plasmonic nanocones can act as nonlinear optical point-like sources for spectrally narrow second harmonic generation and a spectrally broad two-photon photoluminescence signal when excited by near-infrared femto-second laser pulses [7]. The nonlinear emission from cones of four different sizes is observed in two different setups (top and bottom illumination). Either the tip of the nanocones or the cone base is predominantly excited depending on the polarization of the excitation and of the respective plasmon resonance frequencies of the two modes. By size variation and choice of the illumination, the tip-to-base-edge ratio of the emission can be optimized. Such nanocones can thus potentially be used as nonlinear single point light sources for scanning near-field probing or lab-on-chip sensor applications.

Abstract— Finding a possibility to control the activation of a single molecule is interesting since it paves the way to realize logic devices as small as molecules. This can be achieved by carefully designed devices which can interface a single molecule and interact with it at the same size scale. Such devices can be of electrical, magnetic or optical origin [1] and may induce changes in the properties of a single or few molecules which can act as switching registers for data processing or data storage at the nanometer scale. Electrical devices at the single molecule size level include break-junctions, scanning tunneling junctions and molecular landers. Optical devices that can interface a single molecule among an ensemble of many molecules are yet lacking. The main difficulty lies in the diffraction limit of practically $\sim$ 150–180 nm focal size for a wavelength of 600 nm light. Compared to a few nm sizes of individual molecules, unambiguous activation of single molecules by means of absorption of light can only be possible for a device prepared from a sparse ensemble of molecules. Thanks to advancement in near-field optical instrumentation technology this main difficulty can be circumvented as the near-field light intensities typically have a very strong nonlinear dependence on distance (from $\sim r^3$ to $\sim r^6$). Strongly confined, highly intense fields of light called "hot spots," can be achieved by engineering the nanoscale environment of a single molecule. By utilizing plasmonic resonances of nanoscale metal structures, such spots can be arranged to occupy from a few down to a single molecule. Nevertheless in these schemes, a broad far-field background component of the activation wavelength is inevitably superposed on to the near-field of the nanoparticles. This imposes limitations on single molecule activation experiments to be performed with high fidelity.

In this study we propose a method which is feasible for deterministic activation of few molecules. We demonstrate effective background-free continuous wave nonlinear optical excitation of enhanced yellow fluorescent protein molecules that are sandwiched between asymmetrically constructed plasmonic gold nanoparticle clusters [2]. We observe that infrared photons are converted to visible photons through efficient plasmonic second harmonic generation. Our theoretical model and simulations demonstrate that nonlinear conversion of continuous wave light becomes possible by Fano resonance in the nonlinear response. We show that nonlinearity enhancement of plasmonic nanostructures via coupled quantum mechanical oscillators such as molecules can be several orders larger as compared to their classical counterparts [3, 4]. Our numerical simulations demonstrate that observation of second harmonic generation with continuous wave laser becomes possible owing to the cooperative action of conversion enhancement through Fano resonance, hybridization in the plasmon absorption spectrum and the size asymmetry of nanoparticle dimers.

We further investigate the Fano resonances in intrinsic nonlinear optical response of single or coupled metal nanoparticles. We show that Fano resonance conditions can be tuned to enhance nonlinear optical conversion. When a bare metal nanoparticle is coupled with a plasmonic nonlinear converter, second harmonic generation can be enhanced by several orders of magnitude. This phenomenon emerges due to path interference effects. It is shown that second harmonic generation enhancement in hybrid structures can be obtained even in the absence of coupled quantum emitters [5]. This is an important simplification for facilitating the use of purely metal nanoparticles with appropriate functionality.

Abstract— We theoretically and computationally demonstrate that a plasmonic metamaterial containing split-ring resonators exhibits a strong toroidal resonance at the second harmonic (SH). The electric dipole, magnetic dipole, electric quadrupole, and toroidal dipole determined by the charge and current distributions at the SH are determined by firstly calculating the electric field at the fundamental frequency (FF) and, subsequently, the corresponding nonlinear polarization (nonlinear currents) induced by the FF field. In addition, the total transmission, reflection and absorption spectra for this structure, both at the FF and SH, are presented and the connection between the spectral features of these optical coefficients and those of the electromagnetic multipoles are discussed.

Toroidal dipoles, first discovered by Zel'dovich in 1957, are formed when the magnetic dipoles of a system form a closed loop, all pointing in the toroidal direction. Although it is often neglected due to its small contribution, this dipole moment can, in a similar fashion to the other electromagnetic moments, be considered as a source term of a multipolar expansion of charge and current distributions. In this work, four gold split-ring resonators embedded in a dielectric background constitute the basis for our metamaterial. In order to induce a resonant electromagnetic response in each ring, the incident light impinges at an angle of 45° with respect to the planes of the rings. The electromagnetic interactions of our metamaterial with the incident light were simulated at the FF using the rigorous coupled-wave analysis method whereas the optical response at the SH was analyzed using a nonlinear version of the generalized source method. In particular, after parameters were enhanced to ensure a strong resonance we computed the spectral dependence of the total reflection, transmission, and absorption coefficients from 2 μm to 4 μm, a resonance being apparent at $\lambda = 2.5\,\mu\text{m}$.

The generated polarization at the SH, which induces the nonlinear toroidal dipole, is a result of a nonlinear optical process occurring primarily at the surface of the metallic rings embedded in the dielectric background. As every electromagnetic moment is dependent upon the nonlinear polarization (or equivalently, via the continuity equation, the corresponding current density), this physical quantity must be calculated in order to fully analyze the multipole moments. To this end, the unit cell of our metamaterial was covered by a three-dimensional computational grid, with the electric field being calculated for every grid point. This field at the FF was then used to calculate the distribution of the nonlinear polarization, which was subsequently employed to compute the nonlinear electric dipole, magnetic dipole, electric quadrupole, and toroidal dipole.

Surface Polaritons in a Negative-index Metamaterial with Active Raman Gain

Abstract— We propose a scheme to realize stable propagation of linear and nonlinear surface polaritons (SPs) by placing a N-type four-level quantum emitters at the interface between a dielectric and a negative-index metamaterial (NIMM). We show that in linear propagation regime SPs can acquire an active Raman gain (ARG) from a pump field and a gain doublet appears in the gain spectrum of a signal field induced by the quantum interference effect from a control field. The ARG can be used not only to completely compensate the Ohmic loss in the NIMM but also to acquire a superluminal group velocity for the SPs. We also show that in the nonlinear propagation regime a huge enhancement of the Kerr nonlinearity of the SPs can be obtained. As a result, ARG-assisted $(1+1)$- and $(2+1)$-dimensional superluminal surface polaritonic solitons with extremely low generation power may be produced based on the strong confinement of the electric field at the dielectric-NIMM interface.

Session 2P2b
FocusSession.SC2: Plasmonic Nanolasing

Plasmonic Stopped-light Nanolasing

Ortwin Hess
The Blackett Laboratory, Department of Physics, Imperial College London
Prince Consort Road, London SW7 2AZ, United Kingdom

Abstract— Every Laser has two vital components: a (laser) again material and a light-feedback mechanism. In normal lasers feedback is provided by placing the gain material between mirrors — i.e., inside a cavity. Going beyond traditional cavity-concepts, recently conceived nanolasers employ plasmonic resonances for feedback, allowing them to concentrate light into mode volumes that are no longer limited by diffraction [1]. The use of localized surface plasmon resonances as cold-cavity modes, however, is only one route to lasing on subwavelength scales. Lasing, in fact, does not require modes predefined by geometry but merely a feedback mechanism [2].

Here we demonstrate that the concept of dispersion-less stopped-light [3] allows by combination of nanoplasmonics with quantum gain materials [4] *stopped-light lasing* in hybrid nanoplasmonic heterostructures.

In a stopped-light laser, photons are trapped and amplified in space just at the point of their emission. It will be discussed that, at the stopped-light point, a stable lasing mode can form over a finite region of gain material due to the arising local (cavity-free) feedback in the form of a sub-wavelength optical vortex.

The remarkable spatio-temporal dynamics of nanoplasmonic stopped-light lasing is studied on the basis of a Maxwell-Bloch Langevin approach [4]. Moreover, a new rate-equation framework is shown to grasp the particular physics of stopped-light lasing involving [4]. The observed high-β characteristics and picosecond relaxation oscillations of cavity-free stopped-light lasing can potentially allow for the design of thresholdless plasmonic laser diodes that can be modulated with THz speeds.

Metal Nanoantennas: Nonlinear Response and Enhanced Light-matter Interaction

Rudolf Bratschitsch
Institute of Physics, University of Mnster, Münster D-48149, Germany

Abstract— Metal nanoantennas have been demonstrated to work as optical analogues to their well-known counterparts at radio and microwave frequencies. We investigate the nonlinear optical properties of these plasmonic nanosystems. Using few-cycle femtosecond light pulses for excitation we find strong third harmonic generation from single nanoantennas and study the emission characteristics of the created harmonics [1, 2]. Nanoantennas are also well suited to enhance the light-matter interaction. We couple nanoantennas to atomically thin semiconductors and present the exceptional optical properties of this hybrid system [3].

Ultrafast Plasmonic Lasers at the Surface Plasmon Frequency

Themistoklis P. H. Sidiropoulos[1], **Robert Röder**[2], **Sebastian Geburt**[2], **Ortwin Hess**[1], **Stefan A. Maier**[1], **Carsten Ronning**[2], **and Rupert F. Oulton**[1]

Abstract— Light-matter interactions are generally slow as the wavelengths of optical and electronic states differ greatly. Surface plasmon polaritons, the electromagnetic excitations at metal-dielectric interfaces, have generated significant interest because their spatial scale is decoupled from the vacuum wavelength, promising accelerated light-matter interactions. In principle, the acceleration of the dynamics in recently demonstrated surface plasmon lasers [1] can also be achieved [2]. In this talk, we report the observation of sub picosecond pulses from plasmonic zinc oxide (ZnO) nanowire lasers [3]. Operating at room temperature, ZnO excitons lie near the SPP frequency in such silver-based plasmonic lasers, leading to accelerated spontaneous recombination, gain switching, and gain recovery compared to conventional non-plasmonic ZnO nanowire lasers.

The plasmonic lasers consist of ZnO nanowires separated from a Silver substrate by a thin 10 nm LiF gap layer in a so-called hybrid geometry. The nanowires were optically pumped (150 fs pulses @ 800 KHz) at 355 nm and their emission was monitored spectrally at room temperature. Evidence for the lasing of plasmonic modes arises from a range of tests including emission polarization, reduced cut-off diameter where laser action ceases as well as temporal dynamics.

We have measured the temporal characteristics of these plasmonic lasers using a novel double-pump approach that exploits the natural non-linearity of the laser itself to expose its own dynamics. We find that gain recovery times in the very smallest diameter lasers occurs on ~ 1 ps time scales (Fig. 1(b)). Furthermore,we see extremely strong acceleration of the optical processes with decreasing nanowire diameter for plasmonic lasers consistent with increasing mode confinement. Nanowires without a metal substrate however, become slower with decreasing nanowire diameter, which we attribute to the loss of mode confinement.

Our study shows that plasmon pulses can be as fast as gain the thermalization process of excitons in ZnO (< 800 fs), which seems to preclude lasing in the thinnest and fastest devices (diameter < 120 nm). The capability to combine surface plasmon localization with ultra fast amplification provides the means for generating extremely intense optical fields with applications in sensing, non-linear optical switching, as well as potentially in the physics of strong field phenomena.

Investigation of Superradiant Surface Plasmon Mode Generated in Ag Slit Array/InGaAsP at Room Temperature

Kwang Jun Ahn[1], **Seung-Hyun Kim**[2], **and Ki-Ju Yee**[2]

[1]Department of Energy Systems Research & Department of Physics
Ajou University, Suwon 443-749, Korea
[2]Department of Physics, Chungnam National University, Daejeon 305-764, Korea

Abstract— A well-known method to generate surface plasmon (SP) is the SP amplification by stimulated emission (SPASER) [1]. Similar to conventional lasers for generating coherent photons, the operation of SPASERs is also accomplished by stimulated emission of excited light emitters.

In this study, we generated SP radiation with a completely different approach. A strong burst of the SP mode was created by a cooperative radiation process called superradiance (SR) [2]. Fluctuating electromagnetic fields resulting from highly excited light emitters and their reabsorption by the emitters build a phase-locked macroscopic polarization as a source of the SR. In Fig. 1(a) we schematically illustrate our sample structure. A 100 nm-thick silver slit array was fabricated on a 700 nm-thick InGaAsP bulk semiconductor grown on an InP substrate. The sample was optically pumped by a femtosecond pulse laser at a center wave length of 800 nm, and time-resolved emission from samples was measured by using frequency up-conversion technique. By varying the slit period Λ, the fill factor FF (the ratio of the slit width to the period), and temperature we were able to control the emission wavelength in a 400 nm-wide telecommunication band ($\lambda \sim 1.5\,\mu$m) at room temperature. Furthermore, our samples with $\Lambda > 430$ nm support for the simultaneous generation of the SP and a pure photonic (waveguide) mode (WG). Even though the SP mode has larger losses than the WG mode does, we experimentally and theoretically found that the SP mode overwhelms the WG one in a high excitation regime (Fig. (b)) on account of the enhanced dipole moment of the gain medium due to its mirror image. We expect that our new SP source can be applied for optical information processing as a mesoscopic quantum light source and investigating cooperative interaction of bosons in solid state many-body system.

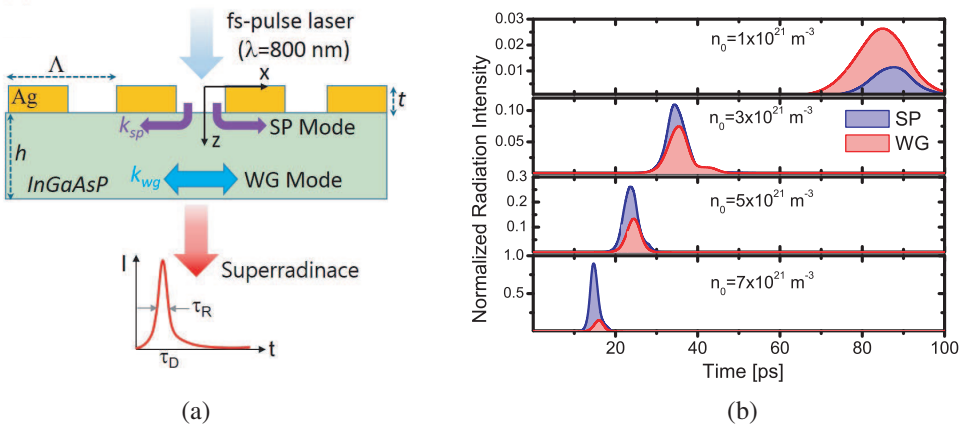

Figure 1: (a) Schematic illustration of the sample structure. (b) Simulated superradiant pulse profile of surface plasmon (SP) and waveguide (WG) modes depending on the excited carrier density (n_0) at $T = 300$ K.

Influence of Gold Nanoparticles on the Lasing Properties of Rh6G-PMMA Material

Abstract— Surface plasmons is a hot topic in the scientific world due to effect of local field enhancement. At the same time, continual research progress is ongoing in the laser industry. New materials are tested in order to create new laser types and to improve performances of the existing ones. In this study, two main trends of the research were combined to get the maximum benefits from both of them. In this paper, we analyze the influence of localized surface plasmons existing on the Au nanoparticles (NP) on the properties of dye molecules Rh6G in PMMA.

There are permanent debates about either localized surface plasmons produce quenching or enhancement of photoluminescence of the active media [1, 2]. In order to clarify the situation, Au NPs were placed in the matrix of Rh6G in PMMA. The size of the NPs was chosen in such a way that localized surface plasmon resonance band overlaps with absorption band of the laser medium. We found that the presence of Au nanoparticles caused several effects. The first one is the change of radiation and non-radiation rates in comparison with the pure samples of Rh6G in PMMA. The second one is the absorption efficiency of the doped samples was significantly increased in comparison to the undoped ones (Fig. 1). The third one is the influence of the gold concentration on the emission properties of the material. The varying stripe line method [3] used in our experiments showed exponential growth of the emission intensity depending on the distance light traveled inside the media symbolizes existence of optical gain. This dependence changes its behavior at the certain length where the lasing threshold occurs, that corresponds to the theory [4]. The measured emission spectra show the existence of the random laser (Fig. 2). At high concentration of Au NPs, the quenching of the luminescence by NPs introduces losses exceeding the amplification value that leads to the drop of optical gain and, consequently, stimulated emission. Energy transfer between dye molecules and Au NPs was shifted towards to NPs what caused strong quenching of luminescence. However the previous research done for the liquid solution of Rh6G in ethanol with Au NPs showed the possibility of the optical gain enhancement [5]. Therefore, optimized concentrations ratio between the dye molecules and nanoparticles has to be established. Also we surmise that the metal nanoparticles cause the temperature redistribution inside the material under pumping that influences on the optical gain value and leads to refractive index anisotropy.

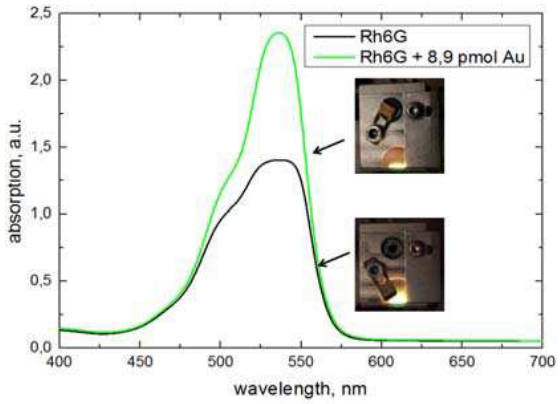

Figure 1: Absorption spectra for the sample of Rh6G with/without Au NPs. Inset: the photo of the samples.

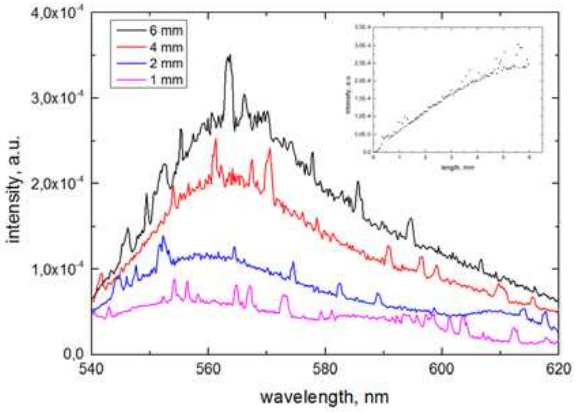

Figure 2: Measured emission spectra at different distances light traveled inside the media. Inset: Dependence of emission intensity at 575 nm wavelength from the length.

Abstract— Magnetic effects find their applications in modern data recording, storage and readout devices, optical isolators and etc.. In particular, modern hard disks use magnetic effects in ferromagnetic layers separated by thin layer of nonmagnetic dielectric. Direction of magnetization in domains of ferromagnetic layers encodes storage information. Thus, novel methods of the magnetization control and the enhancement of magnetic effects are required for the further development of technology. An employment of magneto-optical (MO) effects seems to be a very promising approach. MO effects mean that the magnetization of material essentially depends on the intensity and polarization of the light passing through the material. We are focused on the intensity MO effects like transverse magneto-optical Kerr effect (TMOKE). Such effects can be significantly enhanced by the excitation of surface plasmon-polaritons (SPPs) at the surface of ferromagnetic dielectric. In Ref. [1] it was investigated the influence of SPPs propagating along the interface of ferromagnetic dielectric film and the nanoscaled grating of noble metal on the TMOKE. SPPs increase the interaction area of light beam and magnetic material, and therefore enhance the MO effect in both reflected and transmitted light.

However, it is well-known that SPPs dissipate their energy through the interaction with metal that limits their propagation length. In our structure ferromagnetic material containing iron ions contributes additional losses. Thus, the problem of loss compensation and amplification of SPPs is crucial for the further enhancement of the MO effect.

Loss compensation and amplification of surface plasmon-polaritons have been investigated deeply in active nonmagnetic materials, like dye solution, or PMMA doped by quantum dots, etc. (see review [2]). Amplified spontaneous emission of surface plasmon polaritons can be observed at the interface with a resonant amplifying medium. In our work we consider a ferromagnetic film doped by Cr ions or ions of rear-earth elements, like Yb, Er, Nd. We address a magnetoplasmonic crystal of one dimensional gold grating deposited on the doped iron garnet grown on top of the non-magnetic gadolinium gallium garnet substrate. Transmittance and reflectance spectra and enhancement of magnetooptical effects were demonstrated on the value of the gain parameter and on the geometrical parameters of the magnetoplasmonic crystal and type of the dopants. Experimental observation of this phenomenon is discussed.

Classical Spaser

V. G. Bordo
Nanosyd, Mads Clausen Institute, University of Southern Denmark, Denmark

Abstract— A spaser is a hybrid plasmonic device which generates coherent surface plasmon polaritons (SPPs). The underlying mechanism of its operation is stimulated emission which occurs under an intensive optical or electrical pumping of a gain medium incorporated into the plasmonic structure. There is, however, a fundamental question: Is stimulated emission the only way to achieve an avalanche of SPPs?

In this talk, a principally new avenue to SPP generation will be considered. It is based on the utilization of a feedback mechanism which exists for an oscillating dipole moment in close vicinity (within a wavelength) from a reflecting surface. Such a dipole is driven by its own reflected field that modifies essentially its dynamics [1]. In particular, its damping constant is renormalized in accordance with the imaginary part of the reflected field at the dipole position. In the case where the latter quantity is negative the reflected field performs a positive work on the dipole oscillations thus providing a positive feedback. If an ensemble of dipoles is located nearby a surface their mutual interaction mediated by the reflected field can cause a collective polarization instability which is accompanied by lasing in the system [2]. This effect can occur, in principle, in any subwavelength structures. In the case of a dipole in/at a metal cavity the dipole field launches SPP modes acting back on the dipole polarization and thus establishing a feedback loop which can lead to self-excitation of surface plasmons (SESP). The considered mechanism is an essentially classical effect. It does not imply stimulated emission in the structure and hence does not require a population inversion in the dipole.

A possible implementation of the SESP effect in the cavity formed by a nanogap between two metals will be discussed in this talk. It is assumed that the gap material contains polarizable inclusions with resonance frequency being in the SPP frequency band. Basing on the dyadic Green's function of the structure, the equations for the SPP mode field in the cavity are investigated. It is shown that under certain conditions the field becomes unstable that leads to its self-excitation. The threshold criterion for self-excitation as well as the frequency of self-oscillation are derived in an analytical form. Calculations are carried out for a dielectric slab containing metal nanoparticles enclosed between Ag, Au and Cu surfaces.

Abstract— Chirality in soft matter is emerging as a tool to address innovative concepts in materials science, colloidal systems, optical and photonics devices, optomechanics, optofluidics etc..

Two examples are presented; the first one refers to chiral optofluidics devices and the second one to optofluidics strategies for nanoparticles assembling and manipulation.

We investigate the optical forces and torques on spherical polymeric particles with chiral arrangement of the inner structure consisting of supramolecular helices (left or right-handed). The methodological approach used for micro-particles preparation is such that the helical arrangement self-organizes in precursor cholesteric liquid crystal droplets by proper selection of a chiral dopant. The helical pitch is adjusted from nanometre to micrometre range by means of the dopant concentration. The helicoidal arrangement can leads to a shell structure of the refractive index and to a selective Bragg phenomenon that makes them to behave as chiral spherical reflectors for light propagating along the helical axis and wavelength within the stop band. The circularly polarized light component having the same handedness of the chiral arrangement is reflected leaving its spin state unchanged. On the contrary, the light having opposite handedness is transmitted unaffected. The sign and strength of the optical force depend on the particles reflectance. Moreover, in contrast to conventional reflecting particles, these chiral particles can be set in rotation because of the transfer of spin angular momentum. We investigate the tunability and the coupling of the optical forces and torques by controlling the amount of the reflected light. Several approaches have been adopted: particle size, optical tweezers wavelength position within the stop band and light ellipticity. Chirality-controlled optical trapping and manipulation opens novel strategies for optomechanics and optical sorting.

We exploit chiral photosensitive materials to move nanoparticles-charged disclination lines in anisotropic chiral fluids. We demonstrate the ability to trap nanoparticles and to manipulate them at large range by low power incoherent light. The chirality is introduced at two levels, by the boundary architectures and by a photosensitive chiral dopant. The first permits to design the topological defects templates, the second to move nanoparticles-charged disclination lines without disrupting them. Full reconfigurability and time stability make this strategy attractive for future developments and practical applications.

Abstract— Microfluidics represent the science and technology that process or manipulate small amount of fluids (10^{-9} to 10^{-18} liters) with dimensions of tens to hundreds of micrometers in microfluidic chip. Optofluidics or micro-opto-fluidic-systems (MOFS) aim at manipulating light and fluid at microscale and exploiting their interaction to create highly versatile devices that is significant scientific and interests in many areas. The novelties of the optofluidics are twofold. First, fluids can be used to carry substances to be analyzed in highly sensitive optical microdevices. Second, fluids can also be exploited to control optical microdevices, making them tunable, reconfigurable and adaptive. It is a new breakthrough research area that can provide new solutions and opportunities for a wide range of traditional photonic devices allowing tuning and reconfiguration at the micrometer scale using microfluidic manipulation. This new innovation allows scientists and researchers to tackle many classical problems with new tools and new research ideas.

Among many novel innovations have been demonstrated, such as liquid-liquid waveguide, liquid lens, liquid bubbles grating and microfluidic waveguide laser etc., the manipulation and sorting of a small size of particle and molecule with dimensions of tens to hundreds of nanometers in a microfluidic chip is one of the most significant research approaches. In this talk, light is shaped effectively to generate distinctive interference patterns in the optofluidic chip, which can be used to sort and assemble biological samples. For example, the optical field can be switched from the Bessel profile for particle sorting to various discrete interference patterns for particle assembly.

Light-induced Bulk Flows

Jean-Pierre Delville, **Hamza Chraibi**, **David Riviere**, **and Ulysse Delabre**
Université of Bordeaux, CNRS, LOMA, UMR 5798, Talence F-33400, France

Abstract— Light waves exchange momentum with or transfer energy to matter. A force density results from this interaction whenever photon momentum undergoes a modification in amplitude and/or in direction. This force produces bulk flows in liquids. Flows may also result from the light energy deposited in the liquid. Here we aim at reviewing the different origins of this opto-hydrodynamics. On the one hand, an incident beam may lose forward momentum during its propagation by photon absorption in absorbing liquids or by elastic scattering in transparent turbid liquids. As a consequence, momentum conservation produces a density force within the fluid along the propagation axis and triggers centro-symmetric flows. This density force is proportional to the wave momentum nI/c, the so-called radiation pressure (where n is the index of refraction, I the beam intensity and c the light celerity), and to the beam attenuation $(-1/I)dI/dz$ represented by either the absorption or the turbidity. On the other hand, an incident beam may lose energy due to optical absorption. Energy deposition heats the liquid which in turn produces a pressure gradient that induces bulk convection. These bulk flows can be characterized by Particle Imaging Velocimetry or by the stresses they may produce on a liquid interface. Finally, a tangential shear stress can be triggered by interfacial tension gradients at the interface between two fluids, thus setting up Marangoni flows on both sides of the interface. These gradients of interfacial tension may be triggered optically by light-induced concentration (soluto-capillarity) or thermal (thermo-capillarity) gradient at the interface. Optocapillary flows can as well be characterized Particle Imaging Velocimetry or by the interface deformation resulting from the induced flows. These different ways to drive microflows prove to be a nice and accurate alternative to actuate bulk liquids by light in a contactless manner for optofluidic applications.

Liquid Crystal Photonics

Abstract— When liquid crystals are dispersed in an immiscible fluid, microdroplets of liquid crystal [1] are spontaneously formed in a fraction of a second. They have optically anisotropic internal structure, which is determined by the ordering of liquid crystal molecules at the interface. Spherical droplets of a nematic liquid crystal can function as whispering-gallery-mode microresonators [2] with an unprecedented width of wavelength tunability by an electric field. WGM pulsed lasing in dye-doped nematic microdroplets is sensitive to strain, temperature and presence of molecules [3, 4] that change molecular orientation at the interface. Omnidirectional 3D lasing was demonstrated in droplets of chiral liquid crystals that form 3D Bragg-onion resonators [5, 6]. We showed that anisotropic and topologically nontrivial fibres could be self-assembled from smectic liquid crystals [7], which could support Laguerre-Gaussian modes. We present recent progress in this field, including electric tuning of 3D lasing, resonant transport of light between waveguides and liquid crystal resonators [8].

Organic Dye DFB Laser Sensor Arrays for Image Refractometry

Christoph Vannahme, **Kristian Tølbøl Sørensen**, **Petur Gordon Hermannsson**, **Martin Dufva**, **and Anders Kristensen**
DTU Nanotech, Technical University of Denmark, Kongens Lyngby 2800, Denmark

Abstract— This paper describes the design, fabrication, and experimental validation of optically pumped, solid state organic dye distributed feedback (DFB) laser intra-cavity sensor arrays. The DFB dye lasers are low-cost and highly sensitive refractive index sensors. The lasers are fabricated by UV-nanoimprint lithography into Pyrromethene doped Ormocomp thin films on glass, and the surface refractive index sensitivity is enhanced by a factor of up to five by subsequent deposition of a thin titanium dioxide (TiO_2) waveguiding layer. The multiple wavelength laser arrays presented here enable high frame-rate and highly sensitive imaging of refractive index changes on a $2 \times 2\,\mathrm{mm}^2$ surface, without moving parts, providing a detection limit of $8 \cdot 10^{-6}$ RIU in combination with spatial resolution of 25 µm. The omission of moving parts in the setup improves the robustness of the imaging system and allows a very high frame rate of up to 12 Hz, limited by the CCD camera. The laser sensor arrays are applied for visualizing and studying the dynamics of dissolution, mixing, and biological processes without the need for labeling. The unique multi-wavelength DFB laser structure comprises several areas with different grating periods. Imaging in two dimensions of space is enabled by analyzing laser light from all areas in parallel with an imaging spectrometer. With this multi-resonance imaging refractometry method, the spatial position in one direction is identified from the horizontal, i.e., spectral position of the multiple laser lines which is obtained from the spectrometer CCD array. The orthogonal spatial position is obtained from the vertical spatial position on the spectrometer CCD array as in established spatially resolved spectroscopy. Here, the imaging technique is demonstrated by monitoring the motion of small sucrose molecules upon dissolution of solid sucrose in water.

Light at Work: Optical Delivery, Sorting and Self-assembly of Microobjects

P. Zemánek, **O. Brzobohatý**, **P. Jákl**, **L. Chvátal**, **S. Simpson**, **and M. Šiler**

Abstract— Illumination of a colloidal suspension by laser beams leads to a force interaction between the light and microobjects. Spatially structured illumination of microobjects enables their sorting according to their sizes, shapes or composition, delivery by the principles of optical "tractor" beam or conveyor belt, self-arrangement into structures kept together by the scattered light. Recent results and applications of this topic will be presented.

Introduction: A single tightly focused laser beam, referred to as the optical tweezers represents now the most famous optical micromanipulation tool. However, since this invention more complex spatial distributions of laser beams can be dynamically generated using spatial light modulators. If more particles are illuminated at the same time, they interact with each other by scattered light and so called optical binding occurs. It results in formation of stable structures composed of microparticles kept together by light. Optical forces acting upon objects depend on particles properties and can be effectively used for separation of different components of heterogeneous suspensions or even optically self-arranged structures [1].

Conclusion: Several examples of optical sorting of microobjects in traveling interference patterns will be presented. We also explain the principle of optical "tractor" beam and its utilization for particles delivery, separation (see Fig. 1) and self-arrangement of optically bound structures.

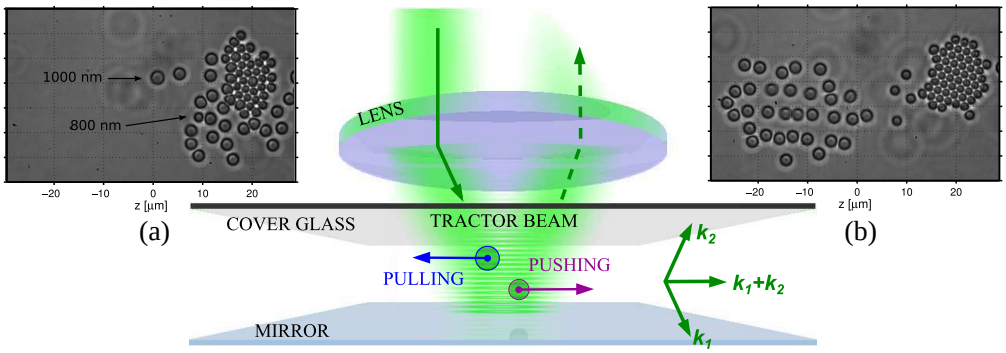

Figure 1: Geometry of the "tractor" beam experiment. Larger particle scatter light differently than a smaller particle and thus moves in opposite direction. Images show separation of polystyrene particles of radii 400 nm and 500 nm using the same geometry by switching the polarization of the beam from (a) p to (b) s polarization.

A Nanophotonic Platform for High-throughput Precision Single Biomolecule Manipulation

Michelle D. Wang
Department of Physics, Laboratory of Atomic and Solid State Physics, Howard Hughes Medical Institute
Cornell University, Ithaca, New York 14853, USA

Abstract— Optical trapping has been proven to be a powerful manipulation and measurement technique widely used in the biological and materials sciences. A prominent example of the application of optical trapping techniques is in the study of single biological molecules, in which the mechanical behavior of a molecule can be investigated. These techniques make it possible to disrupt protein complexes with piconewton forces and track motor proteins with nanometer and millisecond resolution. However, conventional optical trapping instruments are only capable of manipulating one molecule at a time, which limits their throughput. Miniaturizing optical trap instruments onto optofluidic platforms holds promise for high-throughput lab-on-a-chip applications. We have been developing novel nanophotonic platforms for precision manipulation and measurements of a bio-molecular array. In addition to on-chip optical trapping, we demonstrate that such a platform can be integrated with fluorescence and laminar flow cells, substantially enhancing its utility. We anticipate that this approach will make single molecule measurements broadly available.

Localized Fluorescence Enhancement with Gold-coated Microtools

Pál Ormos, Badri L. Aekbote, Gaszton Vizsnyiczai, and Lóránd Kelemen
Institute of Biophysics, Biological Research Centre, Temesvári krt. 62, Szeged, Hungary

Abstract— There is an increasing interest in functionalized complex microstructures for micro- and nanotechnology applications in biology. Particularly in imaging, metal-enhanced fluorescence (MEF), achieved by microscopic surfaces coated with metal nanoparticles (NPs) or films has been applied recently on cells observing otherwise weakly detectable signals [1, 2]. We introduce the combination of microstructures made of SU-8 photoresist by two-photon polymerization and gold nanoparticles or thin gold layers as fluorescence signal enhancers. The polymer microstructures serve as platforms and can be tailor made into any shape with sub-diffraction resolution required by the actual application. We coated these platforms either with 80 nm gold nanoparticles (NP) at various surface density [3] or sputtered gold layers of high reflectivity. We demonstrated localized MEF by NP-coated microstructures equipped with tips of 250 nm radius of curvature that provided enhancement factor of more than 3. The NP-mediated enhancement factor was as high as 6 over areas of several square-micrometers when flat microstructures without tips were used. We attributed the enhancement effect to reflection of the excitation and emitted light, what is demonstrated with the use of tilted polymer platforms. According to this observation, highly reflecting gold thin films were also used for coating and provided enhancement up to 8.

The coated microtools are further developedfor optical tweezers actuation.These microtools can be held and positioned in holographic optical tweezers. This gives the possibility of targeted local fluorescentenhancement at desired locations.

Abstract— The development of simple and low-cost miniaturized fabrication methods has been very important for the advancement of microfluidics technology. Despite recent advances in the lab on a chip samples, in particular for biomedical applications, the increasing need of high sensitivity and performance of the devices is not yet satisfied. The fulfillment of these requirements makes necessary the fabrication of complex 3D fluidic structures that allow analysis of physico-chemical properties of micro amount of sample by optical techniques. This involves being able to achieve levels of integration and control of photonic signals not yet reached in the advanced opto-fluidics platform. With the aim of designing a way to integrate optical signal in lab on a chip systems, an investigation on novel optofluidic laser microcavities has been performed in view of getting tuning capability exploiting by liquid crystal orientational properties.

Although planar micro-fabrication approach based on photolithography is well established and is suitable for surface micro-fabrication, multilayer and multistep processes, including stacking and bonding of different substrates, are required to form true three-dimensional (3D) microstructures. An innovative, simple and maskless technique is the femtosecond laser micromachining, which allows a 3D fast prototyping thanks to its inherent ability to fabricate buried microstructures. Taking advantage from ultrashort-pulse laser, it is possible to realize surface (ablation) or internal (nanocracks) modification of the transparent materials or a high localized photo-polymerization of sensitive polymeric materials, in the focus of the laser beam. Since both the microfluidic channels and waveguides in glass can be fabricated by the same tool on the same substrate, it is easy to create integrated and vibration-free optofluidic devices. After the volume laser irradiation, the optofluidic circuit is obtained by chemical etching removing the laser modified areas.

Taking advantage from this new fabrication technique, different geometries of the laser cavity with excellent flexibility can be fabricated. Many geometries has been fabricated and investigated although the digging out of two empty "basins" located close to the dye recirculation microchannel has been the basic configuration. Covering their side walls with a thin film of conductive ink, two broadband micro reflectors have been recorded (one partially and the other fully reflective). Exploiting the potential of inkjet printing technology, the micro mirrors are also electrodes allowing the tuning of the stimulated light emission by control the alignment of the liquid crystal in the microchannel. A fine control of reflectivity from 30% to 100% has been achieved, even in useful no-planar geometries (curved mirrors). A selective microlaser wavelength imprinting Bragg reflectors into two empty "basins" previously filled with the photopolymerizable mixture can be obtained exploiting the full potential of holography. Either way an integrated broad band fibers optic completes the microcircuit design in order to outcouple the emitted light.

Optofluidic Platforms for Miniaturized Biomedical Analysis Systems

Abstract— Polymers are a popular material platform for low-cost, mass-producible optofluidic sensing applications. However, due to the low refractive index contrast between various polymer materials, the efficiency of such devices is often limited. The most elegant way to achieve maximum refractive index contrast, not only in polymer photonic devices, is to use air as cladding layers. We exploit a novel polymer-onto-polymer lamination method that enables air-suspended polymer photonic devices and the merging of microfluidic channels and photonic functionalities in one layer. Polymer films with thicknesses down to single-mode condition for waveguided light can be transferred onto microchannels of several hundred microns in width and centimeters of length by using a simple PDMS stamp. This allows firstly to achieve highly efficient polymer grating couplers due to the high refractive index contrast and secondly the embedded microchannel can be exploited for transporting analytes. Combining a microchannel for fluid handling with photonic structures enables research towards a large range of applications, such as optofluidics, biosensing, biomedical analysis, environmental investigations and renewable energy. Here, we report on the modeling, progress towards experimental realization and characterization of air-suspended photonic structures (such as grating couplers) as well as a resulting optofluidic refractive index sensor.

Furthermore, in the context of biomedical analysis, absorption spectroscopy-based portable blood analysis systems are highly desirable for improved patient care. In this regard, air-suspended polymer integrated circuits — consisting of input and output grating couplers and a waveguide that is probing an embedded analyte channel (see Fig. 1) — are a promising platform.

Apart from the actual sensing device, many biomedical analysis methods require blood plasma as an analyte. Typically, this blood plasma is obtained through centrifugation of relatively large volumes of blood in a central lab. This method is not practical for mobile point-of-care devices, therefore an effective miniaturized method of plasma extraction is required to enable portable lab-on-a-chip based point-of-care devices.

In this contribution, we also report on a new method of blood plasma extraction that fulfils the requirements for a mobile point-of-care blood analysis device. This system is enabled by repulsive dielectrophoresis forces actively unblocking a cross flow filter.

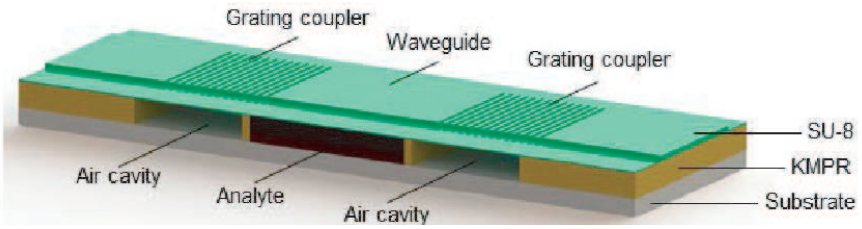

Figure 1: Vision of an optofluidic biosensor exploiting air-suspended grating couplers for light coupling and an embedded microchannel to transport an analyte sample.

Optofluidic Devices and Platforms for Sensing Applications

Abstract— Optofluidics is an emerging research field that combines the advantages of microfluidics and optics on the same platform towards highly functional and compact devices. This approach offers innovative design in order to increase performances and optical functionalities of sensing devices. In particular, the possibility to use a fluid as an optical material and guiding light through it offers very interesting solutions enabling unprecedented sensitivity and limit-of-detection.

In this work we present the design, fabrication and characterizations of optofluidics devices and microsystems for sensing applications that ranges from biosensing to environmental monitoring.

The confinement properties and the strong light matter interaction between light and fluids occurring in optofluidics waveguides, like Antiresonant Reflecting Optical Waveguide (ARROW) or liquid jet waveguide, have been exploited to realize simple but effective and sensitive microfluidic sensors. The use of optofluidic waveguides for spectroscopy methods like absorption, fluorescence, Raman is illustrated showing that the optofluidic approach permits to overcome the sensitivity problems related to the reduced the interaction length of light with fluid due to device miniaturization. Besides the use of the waveguides itself as optofluidic sensor, we show that more sophisticated devices can be realized by using liquid core ARROWs. In particular, we demonstrate that single mode ARROWs provide the opportunity to implement sensor devices which make uses of interferometric phenomena that are very attractive for sensing applications as they combine high sensitivity with compactness and low-production cost. We show that, despite ARROWs are leaky waveguides high performance liquid core Mach-Zehnder interferometers (MZI) and Ring resonator could be realized.

Finally we demonstrate the possibility to combine solid core with liquid core ARROWs and microfluidic devices in a single sensing platform. This represents a significant step towards an effective realization of chip scale integrated system. The integration of planar optofluidic components with microfluidic tools at the chip scale represents the future trend of sensing systems for point-of care diagnosis or in situ monitoring. Increasing the synergy between these technologies can lead to highly reliable and portable systems.

A Tunable Nano-optofluidic Polymer Filter Based on Guided-mode Resonance

Guohui Xiao and Chongjun Jin
State Key Laboratory of Optoelectronic Materials and Technologies
School of Physics and Engineering, Sun Yat-sen University, Guangzhou 510275, China

Abstract— Optical filters with reconfigurable spectral properties are highly desirable in a wide range of applications. We propose and experimentally demonstrate a tunable nano-optofluidic polymer guided-mode resonance (PGMR) filter. The device is composed of a periodic grating sandwiched between a high index waveguide layer and a low index capping layer, which integrates nano-fluidic channel arrays and PGMR filter elegantly. A finite difference time domain (FDTD) methods is employed to understand the spectral properties and determine appropriate device parameters. We fabricate the polymer guided-mode resonance filter with a method combining two-beam interference lithography, floating nanofilm transfer and thermal bonding techniques. Experimental results show that our tunable nano-optofluidic PGMR filters can provide a broad spectral tuning range (13.181 nm), a narrow bandwidth ($<$ 2.504 nm), and a high reflection efficiency ($>$ 85%) in the visible region. Such nano-optofluidic PGMR filters are highly compatible with existing nano/microfluidic technologies and would be valuable for the integrated flexible optical system.

Single Microbial Cell Manipulation in a Three Dimensional Microfluidic Chip

Heriot Watt University, Edinburgh EH14 4AS, UK

Abstract— Novel microfluidic devices with integrated optical waveguides can be used to enable sorting, culture and testing of cells from very small volumes of biological samples [1]. Controlled flow and optical manipulation of cells within a femtosecond laser machined and chemically etched microchannel using optical scattering force has been demonstrated in our previous work [2] and by others [3].

In this paper we present the design and fabrication of a three dimensional microfluidic device fabricated using femtosecond laser micromachining combined with selective chemical etching. We use the device to focus microbes in a hydrodynamic flow and then use optical scattering forces to deflect single cells from the flow for downstream analysis and culture of the isolated cells. Taking advantage of method simplicity and three dimensional capability of femtosecond laser micromachining, 3-dimensional microfluidic structures that are capable of implementing hydrodynamic focusing were fabricated in a fused silica substrate. Hydrodynamic flow focusing inside the microfluidic channel enables the sample to be focused into a narrow stream and has been previously demonstrated by others within a cell counter device [4]. The three dimensional hydrodynamic focusing capability of our device was demonstrated by focusing dye, polystyrene beads of 7 micrometre diameter and 2 micrometre diameter and a range of biological cells (bacteria, yeast, microalgae cells) inside the microfluidic channel. Waveguides were integrated into the device to provide an optical scattering force to deflect cells into a side channel. Our experimental results highlight the potential for single cell isolation by integrating 3-dimensional hydrodynamic focusing of samples and the deflection of cells within a femtosecond laser micromachined and chemically etched device.

Abstract— Conversion of photons energy into mechanical work usually requires intermediate, energy-expensive steps, which make not convenient the use of light to generate work. In order to bypass these steps, different approaches have been proposed. Here we focus on light-induced gradients of surface tension to generate motion of small objects floating on supporting fluids. These phenomena fall into the general framework of the Marangoni effect [1]. It has been shown how a composite object made by poly-dimethyl-siloxane and carbon nano-tubes can be easily moved on the fluid surface driven by light absorption by using IR radiation [2]. Other approaches concern the possibility of moving micro-droplets of oil in micro-channels by light induced-pH gradients [3] or through a photo induced cis-trans isomerization effect [4]. In this work we present a simpler complementary approach to the problem based on the possibility of generating objects motion and to control in real time their trajectories on any supporting fluid. We use low power visible light to induce motion of any floating objects. An object able to absorb the impinging radiation can be asymmetrically heated and moved on the liquid surface whereas transparent objects can be moved by a suitable doping of the supporting fluid and irradiating the fluid surface near the floating object. Light-induced displacement versus time of the floating object has been recorded on different supporting fluids as function of the dopant concentrations and impinging light intensities.

Atomic Layer Lithography for High-throughput Fabrication of Sub-10-nm Plasmonic Gap Arrays

Xiaoshu Chen, **Hyeong-Ryeol Park**, **Daehan Yoo**, **and Sang-Hyun Oh**
Department of Electrical and Computer Engineering
University of Minnesota, Minneapolis, MN 55455, USA

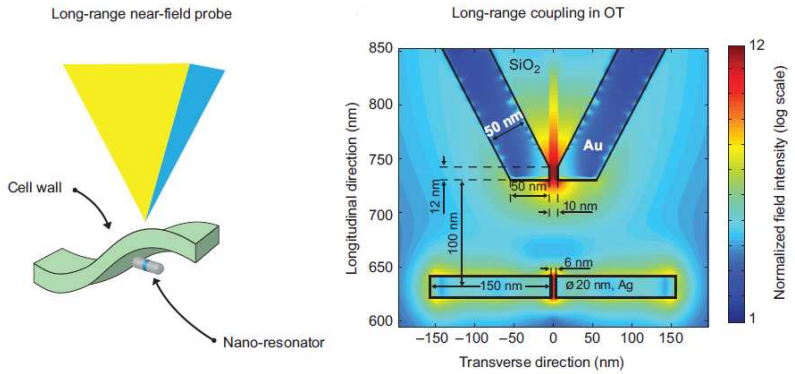
Abstract— The research field of nanoplasmonics has progressed along with advances in nanofabrication technologies. This presentation will focus on the development of a new technique to create ultra-thin nanogaps in metal films using atomic layer deposition (ALD). ALD has been widely used for conformal coating of metal oxides on a wide variety of surfaces. Recent work demonstrated a new scheme to transform sub-nanometer thickness control of ALD into sub-nanometer patterning resolution. Using this technique, called atomic layer lithography, it is now possible to create plasmonic nanogaps that are sub-1-nm in width but as long as 1 cm. These high-aspect-ratio nanogap structures can exhibit a series of strong optical resonances, which can be utilized for sensing and spectroscopy in broad frequency ranges. Some applications of these ALD-patterned nanogap structures will be demonstrated.

Plasmonic Optical Transformer as Scanning Probe Microscopy: Status and Perspectives

Aleksandr Polyakov, **Mauro Melli**, **Wei Bao**, **Alexander Weber-Bargioni**, **P. James Schuck**, **and Stefano Cabrini**
Molecular Foundry, LBNL, One Cyclotron Road, Berkeley, CA, USA

Abstract— The expansion of nanoscale optics and nanofabrication capabilities has generated a variety of scanning probe geometries that yield spatial resolution below 10 nm. Efficient conversion of photonic to plasmonic energy is important for nano-optical applications, particularly imaging and spectroscopy. Recently a new generation of photonic/plasmonic transducers has been fabricated on top of an optical fiber combining the concepts of optical transformer and adiabatical compression to be used as optical near field scanning probes. Those devices, called the 'campanile' probes [1], have been developed that overcomes many shortcomings of previous near-field probes by efficiently merging broadband field enhancement with bidirectional coupling of far- to near field electromagnetic modes. Field confinement, enhancement, and polarization near the apex of the probe are evaluated relative to local fields created by conical tapered tips in vacuum and in tip-substrate gap mode [2]. Campanile design has similar field enhancement and bandwidth capabilities as those of ultra-sharp metallized tips, but without the substrate and sample restrictions inherent in the tip-surface gap mode operation often required by those tips.

We will present a physical model for coupling far-field radiation to plasmonic modes on the surface of a scanning probe [3], and propose a scheme for extending the working distance of such a probe. In a subsurface application, an optical transformer at the tip of a probe can be coupled to a remote near-field antenna placed inside the sample at a distance away from the surface, expanding the effective working distance up to 100 nm.



(a) (b)

Figure 1: (a) The effective working distance of a near-field probe can extended beyond the typical 3 nm by placing a resonator some distance away from the apex of the OT. (b) In this configuration, the electric field couples between the probe and the resonator establishing an efficient channel for locally exciting the sample at the location of the resonator hotspot and collecting the resulting signal from it. OT, optical transformer.

Quantum-dot Plasmonics

David J. Norris
Optical Materials Engineering Laboratory, ETH Zurich
Leonhardstrasse 21, Zurich 8092, Switzerland

Abstract— Quantum optics involves the coupling of quantum emitters to their electromagnetic environment. Because this coupling is related to the concentration of the optical field, it is typically constrained by the diffraction limit of light. One way to circumvent this is by moving to quantum plasmonics, which uses surface plasmon polaritons (SPPs) instead of photons. SPPs are surface waves that arise from the coupling of photons to electronic oscillations. They allow light to be concentrated well below the diffraction limit. However, despite this capability, quantum plasmonics has not yet been thoroughly exploited. This can be attributed to challenges in fabricating high-quality systems that combine robust efficient emitters with well-defined plasmonic structures. To address this, we have recently fabricated quantum-plasmonic systems that consist of active colloidal quantum dots precisely placed in the mode of a passive plasmonic resonance. Since material quality is critical, we optimized both the active and passive components. For the active part, quantum dots were synthesized with stable fluorescence quantum yields above 90%. For the passive part, finite-element simulations were used to identify suitable structures. These were then fabricated by combining template stripping with a cryogenic deposition process to yield ultrasmooth silver patterns with previously unattainable performance. Countable numbers of quantum dots were placed into the plasmonic modes of these structures with nanometer precision using an electrohydrodynamic printing technique. The result is an ideal system for exploring fundamental physics in quantum plasmonics.

DNA-based Functional Plasmonic Particle Assemblies

Tim Liedl
Physics, Ludwig-Maximilians-University of Munich, Munich, Germany

Abstract— We use the DNA origami method [1] for the fabrication of functional self-assembled nanoscopic objects and materials [2]. In DNA origami, a virus-based 8 kilobase-long DNA single-strand is folded into shape with the help of ~ 200 synthetic oligonucleotides. The resulting DNA nanostructures can be designed to adopt any two- and three-dimensional shape. By offering attachment sites for active nano-components on these DNA objects, we have realized complex and nanometer-precise assemblies of organic fluorophores as well as of fluorescent and plasmonic nanoparticles.

With this method in hand we are able to build plasmonic metamolecules that freely float in solution and exhibit striking optical properties such as switchable optical activity in the visible range [3, 4]. The metamolecules can also be tethered to surfaces to be operated by external stimuli [5]. The observed circular dichroism signals are reversible and in very good agreement with plasmonic dipole theory.

We are currently also exploring the possibility to create defined electric and magnetic responses at visible wavelengths with DNA-based plasmonic arrangements of sub-wavelengths sizes. By, e.g., positioning 40 nm gold particles in rings with a diameter of 65 nm we were recently able to observe signatures of magnetic resonances in such ring structures at the red end of the optical spectrum [6].

Abstract— We report on developments in fabricating nano and micro-structured volumetric plasmonic materials and metamaterials utilizing crystal growth techniques based on directional solidification and crystallization as the micro-pulling down method. Two types of materials will be discussed: (i) based on directional solidification of eutectic composites [1–3], and (ii) directional solidification of dielectrics nonchemically doped with functional nanoparticles [4, 5].

It has been shown that with self-organization mechanism during the eutectic crystallization the various shapes pertinent to metamaterials can be obtained as the 'split-ring resonator' geometry [1], rodlike structures which can be used as hyperbolic metamaterials, or for subwavlength transmission of electromagnetic waves [2, 6, 7], eutectic-based nanoplasmonic materials have been demonstrated for the first time [8], as well as anomalous transmission and enhanced second harmonic generation has been demonstrated [9].

On the other hand the novel method developed by us called NanoParticles Direct Doping, NPDD, enables doping dielectric matrices with various nanoparticles of various size, shape and chemical composition as well as various additional elements as rare earths [3].

The developments in this field will be reported.

Nanofabrication Approaches for Plasmonic Nanoantenna Design

Simon Dickreuter[1], **Emre Gürdal**[1], **Dominik Gollmer**[1], **Andreas Horrer**[1], **Dieter Kern**[1], **and Monika Fleischer**[2]

[1]Institute for Applied Physics, Auf der Morgenstelle 10, Tuebingen 72076, Germany
[2]Institute for Applied Physics, Eberhard Karls University, Tuebingen, Germany

Abstract— Metallic nanoparticles are under intense investigation as optical antennas for the local enhancement of electromagnetic fields,both in fundamental studies of light-matter interaction and for applications such as biosensors or opto-electronic devices.

Electron beam lithography is typically the method of choice for fabricating individual antenna shapes with high flexibility. Different approaches include standard lift-off processes as well as etch-mask transfer into a continuous metal layer [1, 2]. By varying the geometric parameters the plasmon resonance frequencies of the nanoantennas can be tuned over a wide range [3]. In order to maintain the high resolution and flexibility of e-beam lithography while simultaneously increasing the throughput of nanostructure fabrication, stamps can be patterned by e-beam lithography, where the patterns are subsequently transferred onto a substrate by nanoimprint. For device applications with following layer deposition it may be beneficial that the surface remains planar, such that the nanoantennas can be embedded into the surface [4]. In an alternative approach, nanosphere lithography can be applied for structuring larger areas in a parallel process, where the self-assembly of polystyrene spheres allows for patterning optical antennas with hexagonal or honeycomb order, using either mono or double layers of nanospheres as evaporation or etch masks [5].

Moving from top-down fabricated metal antennas to the flexible approach of self-assembled metal nanostructures, colloidal particles can be prepared in considerable quantities and purchased commercially. Such size-selected metal particles exhibit clear plasmonic resonances. The resonance properties strongly depend on the order and distribution of the nanoparticles, since coupling and grating effects can have a strong influence. In a fully self-assembled approach, diblock copolymers are applied to a substrate. Distinct patterns with dimensions pre-determined by the copolymer will formunder suitable treatment. After selective removal of one of the diblock components a surface topography emerges, which can serve as a template for ordering colloidal particles at defined distances. In a hierarchical approach combining e-beam lithography with capillary self-assembly of colloidal particles, oligomers containing a fixed number of colloids assemble in hole patterns created by e-beam lithography and development. Such oligomers of nanoantennas may provide coupling across narrow gaps, and offer antenna assemblies with distinct optical properties depending on the plasmonic modes of the individual particles, the morphology of the oligomer, and the respective excitation.

In this presentation different techniques, serial vs. parallel and individual vs. scalable, will be shown in their application for the fabrication of optical nanoantennas together with the scattering, extinction or Raman spectra of the resulting antenna structures.

Fabrication of Three-dimensional Metamaterials

Takuo Tanaka[1, 2]

[1]RIKEN Metamaterials Laboratory and Innovative Photon Manipulation Research Team, Japan
[2]Tokyo Institute of Technology, Japan

Abstract— Metamaterials is man-made materials using sub-wavelength resonant structures and have introduced a new paradigm to create unprecedented optical properties. Since the resonant element of metamaterial such as a split-ring resonator (SRR) is an analog of antenna and there is no ideal antenna that has isotropic radiation properties, the optical responses of metamaterials are inevitably anisotropic. In order to realize isotropic responses of metamaterials, three-dimensional symmetric alignment of metamaterial elements is employed at microwave frequencies, but in the optical regime, such isotropic metamaterials are still challenge due to the limitation of three-dimensional micro/nanofabrication. To this end, we present the first experimental realization of an isotropic metamaterial using fourfold-symmetric configuration of metallic nanostructures. Mass-productive formation of the assembled stereo-structures was achieved by a metal-stress driven self-folding method. Transmission spectrum of this three-dimensional metamaterial shows unambiguous isotropic characteristics for any lateral rotation, polarization, and incident angle up to 40°. The corresponding numerical simulations well re-produced the experimental results, revealing that the interplay of electric and magnetic interactions of the three-dimensional metamaterial structure plays a crucial role for the bi-anisotropic responses and it creates effective refractive index of 0.35, which is smaller than that of vacuum, at 32.8 THz. We anticipate our technique to be a breakthrough for introducing the concepts of metamaterials to real-components.

Three-dimensionally Structured Optical Metamaterials via Holographic Lithography and Eutectic Solidification

Paul V. Braun
Department of Materials Science and Engineering, University of Illinois at Urbana-Champaign
1304 West Green St., Urbana, Illinois 61801, USA

Abstract— Over the past few decades, three-dimensional structures have been widely proposed as a path to enhance light-matter interactions in devices such as solar cells and LEDs. While the sophistication of self and directed-assembly approaches for functional photonic structures has increased dramatically, application of these structures has remained elusive, in part because real structures almost always contain finite defect densities and cannot be produced from materials with the appropriate optical properties. We have now made considerable strides in integration of metallic and non-metallic material into ultra-low defect density three-dimensionally structured optical materials (e.g., epitaxially grown single crystal GaAs). We accomplish this by applying unique template-based and post-synthetic materials transformations in conjunction with powerful computational design tools. Our materials toobox now includes metals (e.g., Al and Ag), single crystal semiconductors (GaAs, GaP, and Cu_2O), and materials with variable refractive indexes (e.g., porous Si). We are particularly intrigued by the possibility of ultra-large volume processing strategies for the formation of deterministically structured materials, and have found eutectic solidification, in conjunction with a template which provides a structural driving force to limit the defect density in the material to be quite promising. Via eutectic solidification, dielectric structures with characteristic length scales as small at 100 nm have been formed in large volumes of material.

Wafer-scale 3D Nanofabrication for Sub-wavelength Nanophotonics

Peer Fischer[1, 2]

[1]Max Planck Institute for Intelligent Systems, Heisenbergstrasse 3, Stuttgart 70569, Germany
[2]Institute for Physical Chemistry, University of Stuttgart
Pfaffenwaldring 55, Stuttgart 70569, Germany

Abstract— We have recently developed a fast, parallel growth method that permits the fabrication of large arrays of nanostructures with control over their size, spacing and material composition [1]. Plasmonic metals such as silver, copper, or gold can be grown pure, or as alloys, or in combination with other materials, such as oxides, conducting or magnetic materials. The method allows us to grow structures that are of interest to nanophotonics at the wafer-scale on a large range of substrates, including transparent substrates. Several hundred billion nanostructures cover a wafer, where they form thin films with remarkable properties [2–4]. It is also possible to remove the nanostructures from the substrate and suspended them in solution, where they can form stable nanocolloidal solutions [1]. We have recently used the fabrication method to grow chiral plasmonically-active nanohelices, as small as 90 nm with two turns, that show record optical activities [2, 3]. Combination with magnetic materials can be used to grow hybrid plasmonic-ferromagnetic nanohelices [4]. We have demonstrated a resolution of 10 nm in the growth of the hybrid structures.

The growth method consists of a combination of block-copolymer micellar nanolithography (BCML) [5] with shadow growth physical vapor deposition (GLAD) [6]. First, a substrate which may be transparent, flexible, or (semi)conducting is patterned with an array of hexagonally close-packed gold (Ag or Pt) nanodots by spin-coating via block-coplymer micellar nanolithography [5]. In a subsequent plasma step the organic polymer is removed and the metal salt is reduced to a metal nanoparticle. The nanoseed are generally too small to show a plasmonic resonance (and hence field enhancement). However, a subsequent shadow growth step (glancing angle deposition) together with substrate manipulation and cooling [1] allows us to increase the size of the nanoseeds and to give them a 3D shape, including a helical shape. The nanoparticles' size, material composition and size can be tuned [1]. It is possible to grow high-density plasmonic nanodot arrays whose size and spectral response is tuned to different regions in the UV, visible, or NIR spectrum. Examples will be presented.

Nanofabrication of 3 Dimensional Taper Structures for Nanofocusing Purposes

Junlong Kou, **Zheng Li**, **and Hyuck Choo**
Electrical Engineering, Division of Engineering and Applied Science
California Institute of Technology, Pasadena, CA, USA

Abstract— We have demonstrated experimentally a highly efficient on-chip three-dimensional (3D) linearly tapered metal-insulator-metal (MIM) nanoplasmonic photon compressor (3D NPC) with a final aperture size of $14 \times 80\,\mathrm{nm}^2$. An optimized and linearly tapered MIM gap plasmon waveguide could theoretically reduce the excessive losses that would occur during nanofocusing processes. This nanofocusing concept has existed for some time, yet researchers had difficulty in realizing structures based on the concept because precisely fabricating the nanoscale waveguides that taper in three dimensions had been very challenging. In simulation study, this approach could enable nanofocusing into a $2 \times 5\,\mathrm{nm}^2$ area with the coupling loss and maximum E^2 enhancement of 2.5 dB and 3.0×10^4, respectively. We fabricated the 3D NPC on a chip employing electron beaminduced deposition and demonstrated its highly localized light confinement using a twophoton photoluminescence (TPPL) technique. From the TPPL measurements, we experimentally estimated an intensity enhancement of 400 within a $14 \times 80\,\mathrm{nm}^2$ crosssectional area and a coupling efficiency of -1.3 dB (or 74% transmittance).

Extremely Long Nanochannel Arrays Realized by PnP

Junyong Park, **Changui Ahn**, **Kisun Kim**, **Jerome K. Hyun**, **and Seokwoo Jeon**
Graphene Resarech Center, KINC
Department of Materials Science and Engineering, KAIST, Daejeon, Republic of Korea

Abstract— The realization of high resolution, large area nanopatterning has been demonstrated from numerous methods. Above all, Proximity field nanoPatterning (PnP) is a unique three dimensional (3D) patterning methods using optical interference from conformal phase masks that contact directly on top of the surface of photosensitive materials. The contact allows incomparable stability in the size of pattering area, resolution, and reproducibility. Extending the thickness and structural degree of freedom of patterned structure are essential topics of current research in my group. In this presentation, in-depth study of the influence of phase and diffraction on 3D Talbot image formed from binary phase masks is explained for achieving rational design of 3D nanopatterns, especially in the regime where the grating periodicity is close to the wavelength and where scalar treatments fail to accurately capture the phase optics. The ability to precisely control diffraction and interference in this regime is illustrated by tuning the grating height in the phase mask up to values that exceed a full phase cycle. Based on these understanding, two examples of unusual pattering will ensure the robustness of PnP. One is large area patterning of three-dimensional (3D) nano-architectures that serve as sacrificial templates for the realization of highly stretchable materials by infiltrating various materials, especially poly (dimethylsiloxane) (PDMS) in this work. The 3D networked PDMS enables 62% enhancement of stretchability compared to the constituent solid film. The 3D structural PDMS has stretched up to $\sim$ 225% at optimized elastic modulus and thickness. A stretchable conductor, which contain liquid metal inside the porous network of the 3D PDMS, show extremely high electrical conductivity of 24,100 S cm^{-1} at 220% strain with god cyclic properties. The other is extremely long ($>$ cm) nanochannel arrays ($>$ 30 by 30,000 in cross-section) whose hole size could be well below 100 nm. Those nanochannels can promise new applications in the field of nanofluidics and optical components in display.

Scalability of 3D Micro-printing: Issues in Diffraction Limited Parallel Writing

Erik Waller[1] **and Georg von Freymann**[1, 2]

[1]Department of Physics and Research Center OPTIMAS
University of Kaiserslautern, Kaiserslautern 67663, Germany
[2]Fraunhofer Institute for Physical Measurement Techniques (IPM)
Kaiserslautern 67663, Germany

Abstract— Direct Laser Writing, or in more modern terms three-dimensional micro printing, has seen a tremendous development during recent years. While it took up to several ten minutes to write one single photonic crystal roughly one decade ago [1], today many samples are fabricated in the same time. Micro-printed three-dimensional samples range from a few cubic micrometers to several cubic millimeters, covering more than two orders of magnitude in dimension with one single technique, allowing for hierarchical structures to be realized. Even larger structures just seem a matter of further increased writing speed. One possible avenue is parallelization of the writing process by generating multiple foci using spatial light modulators [2, 3].

Along these lines we find that closely spaced features vary in size depending on the order they are written. At first sight this is surprising as all foci are generated with same intensity and shape, but a closer look reveals that today's high writing speeds initiate features on a timescale smaller or comparable to the time needed to finalize the polymerization process. This could provide us with detailed knowledge about the different physical mechanisms driving this so-called proximity-effect and their relative strength.

We present simultaneous multi-foci exposures to study photoresist-specific polymerization processes. We generate different focus patterns, allowing to precisely tuning timing and spacing between different features. These patterns are calculated such that different physical mechanisms leading to the proximity-effect may be separated and characterized in their time and spatial dependence. Numerical modeling of the processes shows good agreement with our experimental observations.

Formulating Nanostructures to More Scalable and Functional Architectures via Assembling Hierarchical Hybrids and Adopting Continuous Nanomanufacturing Methods

Jong G. Ok
Department of Mechanical and Automotive Engineering
Seoul National University of Science and Technology, Seoul, Korea

Abstract— Recently there has been increasing interest in micro- and nano-scale materials, structures, and phenomena from both academia and industry. Many diverse fields including optoelectronics, photonics, bioengineering, and energy conversion have all shown significant increases in utilization of, and demand for, micro/nano-scale features. To meet this demand, more scalable, practical, and efficient methodologies for small-scale architecturing are called for. This talk will discuss these issues while focusing on two main topics: (1) how complementary micro- and nanoscale structures and materials can be hierarchically assembled into more functional hybrid architectures; and (2) how these nanoarchitectures can be engineered in a continuous manner towards commercially-feasible scales.

In part one of this talk, carbon nanotubes, graphene, and metal oxide nanowires (NWs) will be considered as small-scale building blocks. Assembling these complementary functional components, three-dimensional (3D) hybrid nanoarchitectures comprising ZnO and VOx NWs hierarchically integrated with CNT constructs will be demonstrated for advanced energy applications based on photonic and electrochemical conversion.

In the second part, a series of continuous and high-throughput micro/nano-manufacturing techniques will be presented based around roll-to-roll (R2R) lithography as well as seamless and template-free nanopatterning, along with direct photonic applications. R2R nanoimprint lithography (R2R NIL) and Photo Roll Lithography (PRL) will exhibit the scalable nanofabrication of various sub-wavelength-scale features by combining NIL and photolithography with continuous rolling principle. Further, the seamless nanopatterning enabled by continuous inscribing of a cleaved grating mold edge on a polymer substrate will be demonstrated, which will be followed by the template-free nanopattering via vibrational indentation of a simple flat edge over a softer substrate.

Moving forward, we will discuss how nanomaterials/nanostructures and nanopatterning methodologies can be mingled with each other towards more scalable and multidimensional nanoarchitectures. For instance, the mechanically-rolled 2D CNT sheets will be introduced for direct fabrication of NW/CNT hybrid thin-film devices. Then we will demonstrate PRL-fabricated metal mesh patterns can be incorporated to the transparent graphene films for flexible nanoelectronics. It will also be presented various 2D micro/nanopatterns can be continuously fabricated by sequential 1D patterning strokes enabled by nanoinscribing and vibrational indentation.

High-contrast Sensing Using Hyperbolic Metamaterials and Plasmonic Cavity Resonators

H. J. Lezec[1], **T. Xu**[1, 2], **A. K. Agrawal**[1, 2], **and W. Zhu**[1, 2]

[1]Center for Nanoscale Science and Technology
National Institute of Standards and Technology, Gaithersburg, MD, USA
[2]Maryland Nanocenter, University of Maryland, College Park, MD, USA

Abstract— Hyperbolic metamaterials, a class of artificially engineered materials with a highly anisotropic permittivity response originating from opposite signs of the principal components of the electric tensor, have attracted significant interest in recent years due to their ability to manipulate the propagation light in exotic ways [1]. Such materials enable distinctive optical phenomena such as negative refraction, super-resolution imaging, and enhanced spontaneous emission.

Here we exploit the hyperbolic iso-frequency characteristic of a planar type-II HMM (composed of a template-stripped [2] stack of alternating, 25-nm-thick, sputtered films of Ag and SiO_2) to achieve high-sensitivity proximity detection of nanoparticles in transmission. The iso-frequency surface of the HMM is unique in that propagation of light over the entire visible-range is allowed only for electromagnetic modes having tangential spatial frequencies k_x exceeding the free-space wavevector k_0 by over a factor of two [3, 4]. Due to its high sensitivity to nanoparticles in deep-subwavelength proximity to a surface, achieved without the use of dark-field optics, this HMM-based device hints at promising applications in bio-chemical sensing, particle tracking and contamination analysis.

High-contrast refractive-index-change sensors consisting of ultra-high quality factor open-cavity resonators for surface-plasmon polaritons will also be discussed. The resonator structures, fabricated using a combination of template stripping [2] and focused-ion-beam milling, are designed to overcome the intrinsically short plasmon lifetimes which typically limit the sensing performance of plasmonic systems strongly coupled to free space, such as sub-wavelength hole arrays in metal films.

Fabrication of a Nanoscale Plasmonic Fishnet Structure for the Enhancement of Absorption in Thin Film Solar Cells

Sayan Seal, **Vinay Budhraja**, **Liming Ji**, **and Vasundara V. Varadan**
Department of Electrical Engineering, University of Arkansas, USA

Abstract— Incorporating plasmonic structures in the back spacer layer of thin film solar cells (TFSC's) is an efficient way to increase the yield. The incoming light is scattered into the absorber layer and light is also trapped by total internal reflection from the top of the absorber layer. This light trapping results in increased efficiency and hence we can extract more power from the cell. The plasmonic fishnet structure is one such geometry using which this effect can be realized. Numerical simulations have shown the ability of these structures to bring about an enhancement in the short circuit current density of TFSCs. The fishnet should be designed to operate at wavelengths near the band gap of amorphous silicon, which is the absorber material in the TFSC. At these wavelengths, the absorption of light in amorphous Si is extremely low. We show that light absorption in the a-Si absorber layer is enhanced by a factor of 10.6 at the design wavelength of 690 nm due to the presence of the fishnet structure. Furthermore, the total absorption over all wavelengths was increased by a factor of 3.2. The short circuit current densityof the TFSC was increased by 30% as a result of including the fishnet. No deterioration at lower wavelengths occurred unlike what happens with plasmonic particulate structures.

This paper presents the fabrication process of the fishnet structure. A fishnet structure made of silver was fabricated using a combination of electron beam lithography and thermal evaporation. A complete TFSC was fabricated using PECVD to deposit a-Si on the fishnet structure. In effect, the fishnet was placed in the back spacer layer preventing shadowing effects. The final structure optically resembled a TFSC in all respects except that there were no doped layers. The fishnet structure is essentially a mesh of linewidth 100 nm, and a thickness of 20 nm. The process for fabricating such a fine structure is challenging, especially if a repeatable process is desired. The adhesion of this structure to the substrate is also a matter of concern since there is more processing that follows the fabrication of the fishnet. The procedures leading up to the establishment of a repeatable process for the fabrication of the fishnet structure will be presented. The designed solar cell was optically characterized using spectroscopic ellipsometry. The measured results were in agreement with those predicted by full wave electromagnetic simulations.

Light Carrying Orbital Angular Momentum: Theory and Applications

Magneto-optics with Light Carrying Orbital Angular Momentum

Thomas Bose[1], **Roy W. Chantrell**[1], **and Jamal Berakdar**[2]

[1]University of York, York, UK
[2]Martin-Luther-University, Halle, Germany

Abstract— The design and fabrication of ever smaller and faster magnetic devices for data storage, sensorics and information processing necessitates the development of efficient tools to control the dynamic behavior of the magnetization. In particular, femtosecond laser-induced magnetic excitations, originating in thermal and non-thermal effects, were demonstrated for magnetic systems [1, 2]. A key element in the underlying mechanism in this case is the material spin-orbit interaction that facilitates the coupling of the electric field component of the laser to the magnetic degrees of freedom of the material under study. A more general approach is to structure the laser beam. For this purpose we demonstrate here the potential of optical vortices, i.e., laser beams designed as to carry transferrable orbital angular momentum (OAM) in addition to the light polarization (associated with the photon spin) [3–5].

We predict a non-thermal magneto-optical effect for magnetic insulators subject to intense light carrying orbital angular momentum (OAM) [6]. Using a classical approach to second harmonic generation in non-linear media with specific symmetry properties we find a significant nonlinear contribution to the local magnetic field triggered by light with OAM. The resulting magnetic field originates from the displacement of electrons driven by the electric field (with amplitude E_0) of the spatially inhomogeneous optical pulse, modeled here as a Laguerre-Gaussian beam carrying OAM. In particular, the symmetry properties of the irradiated magnet allow for magnetic field responses which are second-order ($\sim E_0^2$) and fourth-order ($\sim E_0^4$) in electric-field strength and have opposite signs. For sufficiently high laser intensities, the terms $\sim E_0^4$ dominate and generate magnetic field strengths which can be as large as several Tesla. Moreover, changing the OAM of the laser beam is shown to determine the direction of the total light-induced magnetic field, which is further utilized to study theoretically the non-thermally induced magnetization dynamics. Pump-probe experiments [2] may be used to verify the effect.

Illumination of Optical Vortices Forms Chiral Nanostructures

Takashige Omatsu
Graduate School of Advanced Integration Science, Chiba University
1-33 Yayoi-cho, Inage-ku, Chiba 263-8522, Japan

Abstract— Optical vortices, e.g., the Laguerre-Gaussian modes, have been widely investigated in various fields, such as optical telecommunications, and super resolution microscopes, because they have unique properties, such as annular intensity profiles due to a phase singularity. They also carry an orbital angular momentum characterized by an integer (a topological charge) due to the helical wavefronts and a spin angular momentum associated with a helical electric field.

Their orbital and spin angular momenta, causing orbital motion of submicron particles in optical tweezers, will have the potential to control the dynamics of compositional elements (a melted matter or a vaporized matter) produced by irradiation of laser pulses. However, there is no reports concerning the angular momentum effects of optical vortices on the laser ablation, so far.

In recent years, we and our co-workers have found that the optical vortices enable us to twist an irradiated material through an ablation process, so as to form chiral nanostructures. The resulting nanostructures show the chilarity (twisted direction) determined by the sign (handedness) of the the optical vortices. Such chiral nanostructures will have the potential to open the door to a variety of research opportunities, such as micro-electro mechanical systems, planar metamaterials, chiral selective nanoscale imaging systems and chemical reactions on plasmonic nanostructures.

In this paper, we present the state of art of the chiral nanostructures fabrication based on illumination of the optical vortices. The chiral metal nanoneedles with a twisted conical surface had a minimum tip curvature of $< 40\,\mathrm{nm}$ ($< 1/25$ of the laser wavelength (1064 nm)).

Such chiral metal nanoneedle formation can be understood as follows. The metal melted by irradiation of the optical vortex pulse then receives the total angular momentum from the optical vortices, to rotate azimuthally around the dark core of the optical vortices. Subsequently, the melted metal is directed and confined in the dark core (stable equilibrium position) by the optical scattering force, so as to establish the chiral nanostructures.

We also address chiral azo-polymeric materials formed by the illumination of green optical vortices. The irradiation of a green optical vortex makes the softer cis azo-polymer arising from trans-cis photo-isomerization of the azo-polymer. Subsequently, the cis azo-polymer is forced to revolve in a clockwise (or counter-clockwise) direction owing to the total angular momentum transfer, and it is directed toward the dark core of the optical vortices owing to the mass transport driving force, resulting in the chiral surface relief formation.

Abstract— Angular momentum transfers between light and material object induces optical torque. In 1936, Beth measured the optical torque acting on a centimeter sized birefringent plate using circularly polarized light. Here, we showed that a pair of parallel birefringent slabs not only preserve the magnitude of the torque and the broadband nature of the birefringence, but also shows up novel effects that a single plate can never achieve. Examples include, but not limited to, a large torque beyond the limit of a single plate, controllable counter or parallel rotation of the two plates, and a high torque extraction rate from light.

To zeroth order, the plates convert the polarization of the light, and receiving a torque in response. Multiple scattering between the plates further opens up additional possibilities. We optimize and engineer the structure for better torque extraction by introducing a dielectric (e.g., oil) between the plates (to enhance counter rotation), fine tuning the light frequency, and using different birefringent refractive indices (to enhance the torque).

We then turn our attention to bilayer plasmonic particle clusters. In addition to the functionalities stated above, the hybridized modes of the plasmonic particles enabled strong counter rotation that is an order of magnitude stronger than the single layer torque. Another disadvantage of a single resonance plasmonic structure is its reliance on large extinction cross section, which requires the particle to be isolated. In contrast, the bilayer structures allows strong torque with high torque per unit extinction cross section, allowing a very high efficiency in torque extraction from light.

Extreme Nonlinear Optical Processes with Beams Carrying Orbital Angular Momentum

Abstract— Light beams carrying an isolated point singularity with a screw-type phase distribution are called an optical vortex (OV). The fact that in free space the Poynting vector of the beam gives the momentum flow leads to an orbital angular momentum (OAM) of the photons in such a singular beam, independent on the spin angular momentun [1] There are many applications of optical OAM shown in literature that would benefit from the availability of optical vortex beams in all spectral regions. For example it was shown that transitions forbidden by selection rules in dipole approximation appear allowed when using photons with the additional degree of freedom of optical OAM [2]. However, the common techniques of producing new light frequencies by nonlinear optical processes seem problematic in conserving the optical vortex when the nonlinearity becomes large. We show that with the extremely nonlinear process of High Harmonic Generation (HHG) it is possible to transfer OVs from the near-infrared to the extreme ultraviolet (XUV) [3] at wavelengths down to $\sim 30\,\mathrm{nm}$. The observed XUV light was examined spatially and spectrally. The spatial profile showed the expected singular behavior, a dark region in the centre. A phase feature that showed a shift of π on opposing sides of the beam profile was found with a wavefront splitting technique. A screw-like phase evolution around the profile was also verified by employing a Hartmann type measurement. The generated spectrum revealed that in all Harmonic orders an OV was present. The profile however looked the same in all orders, indicating identical topological charge, which runs counterintuitive to the assumption that the phase of $\exp(-il\varphi)$ is multiplied by the order of the nonlinearity.

Space-time Mapping of Variable Vortex Pulses

Martin Bock, **Thomas Elsaesser**, **and Ruediger Grunwald**
Max-Born-Institute for Nonlinear Optics and Short-Pulse Spectroscopy, Germany

Abstract— The adaptive generation and diagnostics of ultrashort coherent light pulses carrying an extrinsic orbital angular momentum enables to exploit specific degrees of freedom for applications like plasmonics, communication or materials processing. We report on recent experiments in which few-cycle vortex pulses were simultaneously shaped and detected by a tandem of sequentially arranged liquid-crystal-on-silicon (LCoS) spatial light modulators (SLMs) [1]. The pulses to be shaped were emitted by a Ti : sapphire laser oscillator. Because of the significant coupling between spatial and temporal features, the pulse characterization in few-cycle range is non-trivial and requires a resolution in time and space. In the shaping part of the setup, variable phase patterns like single or arrayed spiral phase plates are programmed into the phase map of a HoloEye SLM. The detection part works as a second order wavefront autocorrelator. It combines (i) the spatial resolution and robustness of a reconfigurable, SLM-based Shack-Hartmann sensor with programmable axicons, (ii) the high time-resolution of a Michelson interferometer, (iii) a nonlinear conversion in a thin (10 µm) BBO crystal, and (iv) the high quantum efficiency of an EMCCD camera. The detailed analysis of the twisted Shack-Hartmann patterns reveals the vortex structure and indicates the tunable topological charge. Together with the spatially resolved nonlinear autocorrelation, one obtains also the relative pulse front travel time map. The results enable to reconsider the concepts of optical propagation for vortex pulses and related types of structured beams.

Generation of Twisted Light via Metallic Nanospirals

A. Sprafke[1], **R. Kamrla**[1], **R. B. Wehrspohn**[1, 2], and **J. Berakdar**[1]

[1]Institute of Physics, Martin Luther University Halle-Wittenberg, Halle 06120, Germany
[2]Fraunhofer Institute for Mechanics of Material IWMH, Halle 06120, Germany

Abstract— Light can carry an orbital angular momentum (OAM). Light with OAM exhibits a corkscrew-like rotation of the maximum of the electric field around the axis of propagation. Therefore, such light is also called twisted light. Twisted light has been suggested for a number of applications, e.g., for optical tweezers to trap and rotate microparticles, atoms, molecules, and Bose-Einstein-condensates, for light-control of magnetic fields as well as for novel approaches for photovoltaics. The amount of OAM is experimentally tunable. Hence, the use of twisted light is particularly interesting for strongly enhanced data transmission rates. Light beams carrying no OAM are commonly converted into twisted light beams by either a macroscopic spiral phase plate, a holographic grating, a spatial light modulator, or by mode conversion inside a laser resonator. It was shown recently that twisted light can transfer its OAM to metal surfaces and transform planar metal surfaces into chiral nano needles. In this work, we numerically and theoretically investigate the reverse problem: Can a chiral metallic structure, such as a metal spiral that has feature sizes in the range of the wavelength, transform plane waves into structured light beams carrying OAM? We show that light reflected by small metal spirals indeed carries OAM provided that the geometrical properties of the spiral, such as height to wavelength ratio, or spiral turns per wavelength, are properly adjusted. Furthermore, we discuss the robustness of our suggested system, e.g., with regard to the angle of incidence, spiral size, and generated beam size and divergence. These finding are important in so far, as they suggests a new route to transfer locally and temporally angular momentum, e.g., by depositing the metal nanospiral on the tip of a scanning tunneling microscope which is irradiated by a Gaussian laser beam. Such a device offers qualitatively new possibilities to explore the local dynamics of spin and/or orbitally ordered matter.

Nonlinear Vortex Light Beams Resistant to Dissipation

Miguel A. Porras[1] **and Carlos Ruiz-Jiménez**[2]

[1]Complex Systems Group, Technical University of Madrid, Rios Rosas 21, Madrid 28003, Spain
[2]Complex Systems Group, Technical University of Madrid, Ciudad Universitaria s/n, Madrid 28040, Spain

Abstract— The research on light beams carrying orbital angular momentum, and in particular those with screw topological wave front dislocations or vortices, was initially focused on Laguerre-Gauss beams, but quickly spread to other vortex beams, many of them endowed by the property of being non-diffracting, as high-order Bessel beams in the linear regime of propagation, vortex solitons in transparent nonlinear media, and dissipative solitons in media with gain and losses. In this work we describe a novel class of vortex beams that we have called nonlinear vortex Bessel beams with the unique feature that can propagate without any change, including any attenuation, while continuously dissipating energy and orbital angular momentum in the host medium via multiphoton absorption. This "self-healing" property makes these beams particularly attractive in applications requiring optical pumping of angular momentum. Nonlinear vortex Bessel beams are easily generated in practice from standard axicon-generated high-order Bessel beams. Recent studies in the highly nonlinear regime indicate that they are also involved in a new type of light filamentation with tubular geometry. Contrary to many vortex solitons, nonlinear vortex Bessel beams do not require Kerr-type nonlinearities to exist, but only nonlinear absorption, and therefore are not affected by Kerr-induced instabilities.

Controlling Atomic Transparency with Structured Light

S. Franke-Arnold[1], **N. Radwell**[1], **T. W. Clark**[1], **B. Piccirillol**[2], **and S. M. Barnett**[1]

[1]University of Glasgow, SUPA, UK
[2]Universitá di Napoli Federico II, Italy

Abstract— Electromagnetically induced transparency (EIT) is a curious but well-established effect that can drastically change the optical response of an atomic medium. Atoms can become transparent to a resonant probe laser if they are simultaneously exposed to a suitable control light beam. Here we show that the opacity of atoms can vary across the beam profile, dictated by the local phase and polarisation of the light [1]. We use a single probe beam with an azimuthally varying polarisation and phase structure, generated by a q-plate [2]. Its right and left polarisation components, which carry opposite orbital angular momenta, provide the probe and control beam for the EIT transition. We measure the transmission of our structured light beam through cold rubidium atoms and observe an azimuthal variation of the absorption profile, with alternating regions of transparency and opacity.

Conventional EIT systems do not exhibit phase sensitivity. We show, however, that a weak transverse magnetic field closes the EIT transitions, thereby generating phase dependent dark states [3] which in turn lead to phase dependent transparency, in agreement with our measurements.

Tailored spatial atomic dark states could provide a potentially robust storage mechanism, offering an alternative to coherence based quantum memories [4].

Spontaneous Formation of Square Optical Vortex Lattice in a Transverse Section of Broad-area Laser

A. A. Krents[1, 2], **A. V. Pakhomov**[1, 2], **D. A. Anchikov**[1], **and N. E. Molevich**[1, 2]

[1]Samara State Aerospace University, Samara 443086, Russia
[2]Lebedev Physical Institute, Samara 443011, Russia

Abstract— The paper studies the spontaneous formation of square optical vortex lattice (SVL) in broad-area lasers theoretically. The possible motion of vortices is also studied. The nonlinear interaction of numerous transverse modes in broad-area lasers can lead to the spontaneous formation of complex spatiotemporal optical structures including the SVL. The SVL is experimentally observed in the Nd:YVO_4 laser, in a broad-area CO_2 laser operating at a single longitudinal mode, in the solid-state laser with optical pumping on a chip $LiNdP_4O_{12}$, in a Na_2 laser, in the vertical cavity surface emitting laser.

We studied the formation of SVL both analytically and numerically using the full Maxwell-Bloch model:

$$dE/dt=\sigma\,(P-E)+ia\Delta E;\; dP/dt=-\,(1+i\delta)\,P+DE;\; dD/dt=-\gamma[D-r+0.5\,(E^*P+EP^*)],\quad (1)$$

where Δ is the transverse two-dimensional Laplace operator, E, P are, respectively, the dimensionless electric field and polarization amplitudes, D is the dimensionless population inversion. σ, γ are the dimensionless electric field and inversion decay rates, respectively, r is the pump parameter, δ is the detuning.

In case $\delta > 0$, we have shown analytically that the SVL is solution of the full Maxwell-Bloch model. Also, the SVL solution was found numerically (Fig. 1). For numerical simulation of Equation (1), we used the split step Fourier method. Random initial conditions were used. A distance between neighbor vortices was calculated analytically: $d = \pi\sqrt{a/\delta}$. This value is in a good agreement with our numerical results.

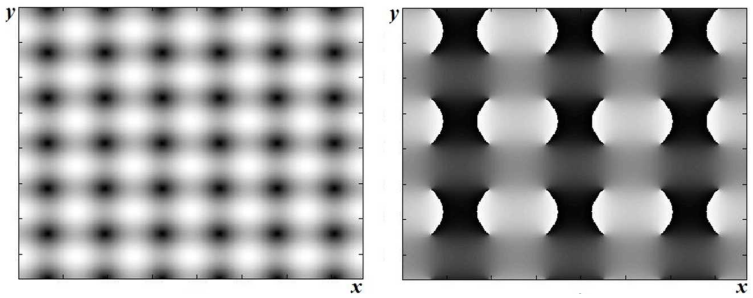

Figure 1: Stationary square vortex lattice: (a) Intensity distribution and (b) phase distribution.

By increasing the pump parameter r, the SVL becomes unstable. Each vortex oscillates around the steady state. The frequency of vortex oscillations is calculated analytically: $\omega = \delta/(\sigma + 1)$. This value is in a good agreement with our numerical results.

Superpositions of Three-dimensional Diffraction-free Asymmetrical Bessel Beams

A. A. Kovalev, V. V. Kotlyar, and A. P. Porfirev
Image Processing Systems Institute of the Russian Academy of Sciences, Russia

Abstract— We considered physical properties of superpositions of the diffraction-free asymmetrical Bessel beams. These beams differ from a conventional symmetrical Bessel beams by arbitrary complex shifts along both the Cartesian coordinates. The intensity distribution of the asymmetrical Bessel beam has a form of a crescent. We derived an equation, which allows to obtain from the values of the complex shifts the position of the n-fold phase singularity of the beam (n is the topological charge, the order of the Bessel function), as well as orientation angle of the crescent on the diffraction pattern.

Using representation of the complex amplitude via the angular spectrum of plane waves, a general analytical expression was derived for the orbital angular momentum (OAM) of the superposition of a finite number of the asymmetrical Bessel beams, each of them having its own complex shifts along the Cartesian coordinates (although the topological charge of the beams in superposition supposed to be the same).

Using the obtained expression for the OAM, we proved that the beam, composed of arbitrary number of the same-order symmetrical Bessel beams located at the arbitrary points in space, has the OAM equal to the topological charge of each beam.

Using the same equation, we considered the OAM of the beams composed of three or four asymmetrical Bessel beams located at the vertices of the equilateral triangle (triple beams) or the square (quadruple beams). For triple beams, we obtained a closed-form expression for the OAM without any integrals and series. For both triple and quadruple beams, we obtained the condition when the OAM is equal to the topological charge of each constituent beam (like is the case for the conventional Bessel beams). For example, we calculated the intensity distribution of quadruple beams with their pattern composed of the light square instead of the circle. Such beam consists of four 5-order Bessel beams and the OAM of the superposition is also equal to 5.

We also showed that the diffraction pattern of a superposition of the infinite number of the symmetrical Bessel beams with their centers located on a circle coincides with the diffraction pattern of one Bessel beam located at the center of the circle.

Abstract— Light reflection at the boundary of two different media is one of the fundamental phenomena in optics, and optical antireflection is desirable in many optical systems such as cameras, telescopes, displays, and solar cells. Traditionally, optical antireflection has been accomplished using single- or multiple-layer dielectric films and graded index surface relief structures. However, these approaches either impose strict requirements on the refractive index matching or involve complicated fabrication processes that are difficulty for device integration. Here we report a demonstration of a new strategy of antireflection coating employing metasurfaces with designer surface optical properties in the mid-wave infrared. Our results show that the metasurface antireflection coating can completely eliminate optical reflection and enhance light transmission over a broad spectral bandand a wide range of incidence angle.

Structured Conductive Zinc Oxide for Mid-IR Perfect Light Trapping

Abstract— Plasmonic assisted mid-infrared (MIR) light trapping using 1D grating microstructures patterned in gallium doped ZnO films is investigated. The resonant absorption due to the excitation of surface plasmon polaritons in the highly conductive ZnO film can be controlled with a proper choice of grating period and film thickness. Lumerical finite-difference time-domain (FDTD) simulations show resonant modes resulting in close to 100% light trapping observed as reflection dips in the 4–8 µm wavelength regime. Experimental demonstrations of the perfect trapping is accomplished using a 1.3 µm thick Ga doped ZnO film deposited on high resistivity Si substrate by pulsed laser deposition. The achieved film was nominally $Zn_{0.974}Ga_{0.026}O$ with a doping level of $\sim 10^{21}\,cm^{-3}$ as determined by IR ellipsometry. The 1D grating structures of different periods are fabricated using standard photolithography followed by reactive ion etching. When comparing experimental resonant reflection dips with FDTD simulations, unanticipated low-wavelength roll-offs where found. Films that had undergone the etch processing where again characterized via IR ellipsometry and notably showed a decreasingly negative permittivity versus the un-etched counterpart. Analysis via further simulations shows the etch has the effect of making a thin layer on top of the structure less metallic which is likely due to a local annealing process. Incorporating a thin layer over the entire structure in the simulation using the less metallic optical constants then gives a good qualitative fit to experimental light trapping resonances. By tuning the grating parameters these perfect light trapping device structures could easily be extended to the long wavelength IR in the range of 8 to 12 microns. Such structures have potential uses in IR sensing and filter applications.

Broadband Metamaterial Absorber Based on Multiple Resonances of Fundamental and Second Harmonics

Chang Long, **Sheng Yin**, **Wei Li**, **Wei Wang**, **and Jianguo Guan**
State Key Laboratory of Advanced Technology for Materials Synthesis and Processing
Wuhan University of Technology, Wuhan 430070, China

Abstract— Metamaterial absorbers (MMAs) may show perfect absorption and adjustable absorption frequency from microwave to visible light band by simply tuning the parameters of the artificial structured unit cells. However, the absorption bandwidth is usually so narrow that the practical applications are strongly limited.

In this work, we design an ultra-broadband, thin-thickness metamaterial absorber by alternatively assembling two different sized quadrangular frustum pyramids containing multiplexed resonance cavities in a backplane metal. Unlike the traditional methods that simply mix resonances by horizontal or vertical integration [1, 2], we make full use of both fundamental (TE/M_{10}) and second order harmonics (TE/M_{21}) of the structure. The modes of the resonance are verified by square waveguide theory [3] and simulated electromagnetic field distribution. By arranging big pyramids in the "white blank" of the chessboard, TE/M_{21} modes are enhanced because of the unevenness of the units. Meanwhile, TE/M_{10} modes remain the same though the other half of the chessboard are empty. So dual-band absorption are obtained. The gap of the two bands is connected by the TE/M_{10} modes of the small pyramids and a broadband absorption are acquired when they are arranged in the "black blank" of the chessboard.

Above all, the fundamental and second order harmonics of the multiplexed resonance cavities are both excited in this design, so that the MMA shows $\geq 90\%$ absorption in the whole 6.8–18 GHz range, triple bandwidth of that based on the single sized counterpart at the same total thickness (h) of 4.36 mm. Though the MMA are not strictly symmetrical, it is still insensitive to the polarization. The as-proposed design idea is flexible, and can be manipulated to meet the absorbing requirements in other frequency by simply changing the characteristic dimension of the MMAs. The design strategy provides a novel route to exponentially extend the absorption bandwidth of MMAs without increasing h.

Thin Film Dielectric Gradient Optical Structures for Space Photonics

O. Volpian[1], **A. Kuzmichev**[2], **G. Ermakov**[1], **Yu. Obod**[1], **N. Silin**[3], **and S. Shkatula**[1]

[1]Scientific-Manufacturing Enterprise "Fotron-Auto Ltd.", Moscow, Russia

[3]Far Eastern Federal University, Vladivostok, Russia

Abstract— Optical devices and photonics, in general, play an important role in space and aviation technology. The basis for many devices is layered interference systems and huge challenge is to ensure resistance and spectral characteristics stability of the interference systems against action of the cosmic environment factors, including intermittent high-intensity heating and deep cooling, and of the factors related to the functioning of spacecraft (in particular, laser radiation with high power density ($W > 10^9\,\mathrm{W/cm^2}$ and plasma). Authors' experience in the design and manufacture of precision optical coatings and lasers shows that these problems can be solved by use of gradient optical structures instead of the conventional multilayer interference systems with an abrupt change in the refractive index at the boundaries of each layer.

Design, technological aspects and test results of gradient optical coatings for space and aviation photonics are considered in the contribution. The magnetron sputtering facilities for deposition of the dielectric coatings with gradient/nanogradient of refraction index $\mathrm{grad}_z\ n(z)$ along light direction **z** has been designed and built. The sputtering unit contains two magnetrons with metal sputtered targets. The programmable movement of substrates over the magnetrons allows obtaining the desired composition variation and refraction index profile of coating material along **z**. The pulse mid-frequency mode of magnetron discharge provides stable deposition process in reactive gas medium ($Ar + O_2$ is used). An oxygen activator is used for better oxygenation of the deposited material. The special facilities for testing the manufactured optical structures in situ also has been designed and built. The gradient structures with different refraction index profile (simple "one-periodical", multi-periodical, rugate-like, with apodization, etc.) with excellent properties, including gradient optical metamaterials [1] for devices based on transformation optics, have been produced.

The experiments showed the gradient and nanogradient refraction index profiles provide wide-band or narrow-band and wide-angle working spectral characteristics (antireflective and others) in the visible and near IR field of the full-dielectric low-loss coatings and their stability against high-power laser radiation, thermal, mechanical and space environmental factors. Thus, the perspectives of pulse magnetron sputtering technology of gradient optical structures for space photonics are confirmed.

Harnessing the Nano-optics of Silicon and Germanium Nanowires for Color and Multispectral Imaging

Kenneth B. Crozier
The University of Melbourne, Australia

Abstract— Given the considerable interest that has existed for nanowires lately, it is surprising how little attention has been generally paid to dramatic influence that waveguide and resonance phenomena can have upon their optical properties. The presentation reviewer recent work by the author and his research group on the optical properties of silicon and germanium nanowires, and there use for imaging applications. We demonstrate that vertical silicon nanowires take on a surprising variety if colors covering the entire visible spectrum, in marked contrast to the gray color of bulk silicon [1]. We demonstrate that embedding silicon nanowires into polydimethylsiloxane (PDMS) presents a means for adding color, i.e., provides filtering at visible and near-infrared wavelengths [2]. We report the demonstration of a compact multispectral imaging system that uses vertical silicon nanowires to realize a filter array [3]. We fabricate pixels consisting of vertical silicon nanowires with integrated photodetectors, demonstrate that their spectral sensitives are governed by nanowire radius, and perform color imaging [4]. We demonstrate the fabrication of arrays of vertical Ge nanowires with different diameters [5]. Measured reflection spectra show dip features for which electromagnetic simulations predict enhanced absorption.

Semiconductor Nanowires: New Opportunities for Light Trapping and Surface Enhanced Raman Scattering

I. Alessandri
INSTM and Chemistry for Technologies Laboratory, Mechanical and Industrial Engineering Department
University of Brescia, via Branze, 38, Brescia 25123, Italy

Abstract— Raman microspectroscopy gives access to key information for detection and analysis of several chemical species, including environmental pollutants, explosives, drugs and biomolecules. However, the very low Raman cross-section of most of the analytes asks for a strong intensification of the local electromagnetic field (Surface Enhanced Raman Scattering, SERS) to improve sensitivity and detection capabilities. This goal is typically achieved by exploiting surface plasmon resonances of coinage metals (Au, Ag, Cu and, more recently, Al) in form of nanoparticles or nanostructures. However, in most of the cases, this approach is affected by low reproducibility, owing to the strong perturbation of the local environment of the systems under analysis.

On the other hand, SERS in semiconductor-based nanostructures is an attractive alternative to conventional, metal-assisted SERS active materials [1, 2]. In particular, semiconductor nanowires (NWs) allow for efficient light trapping and stimulation of morphology-dependent optical resonances. Thanks to these optical resonances, surface evanescent fields can be exploited to achieve enhanced Raman sensitivity with low invasiveness [3, 4].

This talk will be organized in two parts. First,we will discuss the Raman response of chemically-etched Si NWs, which are usually investigated as antireflective substrates for solar cells or artificial leaves. The influence of morphology on light trapping and, as a consequence, Raman scattering, will be evaluated over both the substrate itself (self-diagnostics) and detection of molecular species (organic molecules) and thin films (TiO_2). In the case of thin films, the formation of Si/TiO_2 core/shell heterostructures allows for a direct experimental evaluation of the spatial extension of the local near-field, suggesting the intriguing possibility to probe analytes over a long range [5].

In the second part we will give some examples of recyclable Raman substrates based on semiconductor nanorods and nanowires. Here the photocatalytic activity of the semiconductors is exploited to remove the analytes after each measurement, allowing reuse of the same chip for multiple cycles. The coupling with plamonic nanoparticles will be also discussed [6].

Nanophotonics in III-V Nanowire Arrays

Nicklas Anttu
Division of Solid State Physics and the Nanometer Structure Consortium (nmC@LU)
Lund University, Box 118, Lund S-22100, Sweden

Abstract— We have studied how light interacts with arrays of vertical nanowires made of the optoelectronically important III-V materials. Our combined theoretical and experimental investigations [1–7] have yielded guidelines for efficient light-management in these arrays. With proper tuning of the nanowire geometry, the absorption per volume semiconductor material can be 20 times higher than in a planar geometry [1]. At the same time, the arrays show low reflection losses, thus combining anti-reflection properties with light-trapping to enhance the absorption. Based on these guidelines, we have fabricated solar cells of InP nanowires [2]. These arrays show an efficiency of 13.8% under the AM1.5 solar spectrum illumination and convert more than 70% of above-bandgap photons into electric current, despite covering only 12% of the surface. Finally, we have shown through electromagnetic modelling that the Shockley-Queisser efficiency limit for an optimized nanowire array solar cell is higher than for a conventional, planar solar cell [8].

Abstract— Gallium nitride (GaN) and its related alloys are technologically important for applications in short-wavelength LEDs, lasers, photodetectors, and power electronics. GaN is a piezoelectric material. As a result, when it is strained, a strong built-in electric field is generated which has profound impacts on its applications in LEDs and lasers. In these devices, strained InGaN heterostructures are routinely employed as the light-emitting active region. The strain induced built-in electric field can significantly lower the emitter efficiency, cause efficiency droop and undesirable wavelength drift. Nanowires can effectively relax the strain and nanowire LEDs have attracted substantial interests in recent years. In this work, we showed that by controlling and engineering the strain in GaN nanowires via a top-down fabrication scheme, not only can one realize benefits arised from strain relaxation, new degrees of control can be obtained which have potential applications for display, communication, and sensing. In this talk, I will discuss two of these applications: (1) on-demand single photon sources with highly pure and programmable polarization states; (2) monolithically integrated multi-color light emitter chips.

From Subband Structure to Single Electron Devices in Semiconductor Nanowires

Jonathan Baugh and Gregory Holloway
University of Waterloo, ON, Canada

Abstract— Controlling the electronic transport properties of semiconductor nanowires can benefit technologies ranging from optoelectronic sensors to spin-based quantum information processing. We investigate the subband structure of InAs nanowires due to radial confinement, exploiting the coupling of orbital angular momentum to an axial magnetic field. The magnetoconductance is shown to contain signatures that allow precise identification of subbands, and also reveals the nature of the radial potential [1]. We show that these effects are indeed manifested experimentally in InAs FET devices studied at low temperatures. Next, we turn to a study of the superconducting proximity effect by considering a Nb-InAs-Nb nanowire junction. These experiments reveal rich Andreev physics and span two distinct regimes: the S-N-S junction regime in which a supercurrent is realized and is modulated with field and gate voltage [2], and the S-dot-S regime in which Andreev transport competes with the dot charging energy. Finally, we discuss the controlled realization of quantum dots, tunable down to single electrons, for confining and manipulating electron spin qubits for future quantum information processors.

Dielectric Parameters Estimation Using Global Optimization Techniques

Ilja Merunka, **Ondrej Fiser**, **and Jan Vrba**
Department of Electromagnetic Field, Czech Technical University in Prague, Czech Republic

Abstract—

Introduction: In this contribution we present a method for dielectric parameters estimation of human breast tissue phantom. There are many papers focused on this topic and a lot of methods are presented [1]. We focused on a method based on global optimization techniques, more specifically genetic algorithm [2–4].

Material and Methods: Numerical model was prepared in COMSOL Multiphysics (Burlington, MA 01803, United States) simulation platform. The model is only two dimensional and consists of circle (cross section of simplified human breast) and eight ports placed equally in distance of 2 cm from human breast phantom (Fig. 1). The ports with diameter of 2 mm excite electromagnetic field in direction of z axis (i.e., perpendicular to the plane of the model) and also record the scattered field. Thus, the scattering matrix can be simply computed and exported after simulation. Built in frequency solver was used to simulate electromagnetic field. Circle representing the cross section of human breast phantom was firstly virtually filled by only one material (arithmetic mean of dielectric parameters of human breast fat and gland). Secondly, numerical phantom of tumour represented by circle of diameter 2 cm were added into the region on the specific position and again only dielectric parameters of these two materials were estimated. We used the simple euclidean distance as the cost function to evaluate the overall correspondence between s-parameters virtually measured and s-parameters extracted from results of simulations of the model with updated parameters. Genetic algorithm was employed in the optimization procedure. The process is implemented in MATLAB 2013a (The MathWorks, Inc., Natick, Massachusetts, United States) where the global optimization toolbox is used.

Results: Dielectric parameters of the tissues were estimated. However, the total computational time is very long. It is primarily caused by the relative long computational time of the forward solution (2 s per one port, 16 s per all ports). The regularization term will be included in the cost function in our next work.

Analysis and Evaluation of Waveguide Methods to Measure the Dielectric Properties of Biological Materials

L. Farrugia[1], **P. Schembri Wismayer**[2], **L. Zammit Mangion**[1], **and C. V. Sammut**[1]

[1]Department of Physics, University of Malta, Msida, Malta
[2]Department of Anatomy, University of Malta, Msida, Malta

Abstract— Accurate knowledge of the dielectric properties of biological tissues is of crucial importance for both numerical and dosimetric studies. There are many ways to accurately measure the dielectric properties of a material, and the choice of method is highly dependent on the type of material under test (MUT). Nowadays, the coaxial probe technique is very often used for broadband measurements of the dielectric properties of biological tissues. The latter is very difficult to use with solid or semi-solid materials such as bone because of poor measurement repeatability. In this study we analyse the use of an alternative broadband method to perform dielectric measurements using a waveguide structure. Both reflection and transmission waveguide measurement methods are reviewed and the various methods to convert from the S-parameters to the complex permittivity are presented. Both reflection and transmission methods were studied numerically for materials with known dielectric properties and the values obtained were in very good agreement with both published and measured data obtained by coaxial probes. Furthermore, we carried out a detailed and systematic investigation of the minimum sample size required for accurate determination of the reflection coefficient with the rectangular waveguide method, and present an alternative numerical method to calculate the complex permittivity which compares well with the analytical solution of the waveguide structure.

Easy-to-produce Stable-in-time 3D-printed Breast Phantoms for Microwave Imaging

Centrale Supelec, UPSud, France

Abstract— In recent years, quantitative microwave imaging systems have been investigated as a future alternative mammography technique. At the present time, there are several dozen-research teams around the world working on this topic [1]. The major potentials of using microwaves are, first, the significant contrast in dielectric properties between cancerous and normal healthy breast tissues [2] and, secondly, the non-ionizing nature of microwaves, which reduces the risk linked to frequent diagnoses during a screening program. The validation of inversion algorithms, used to build up images of the breast in microwave imaging systems, needs measurements of experimental data in controlled configurations, on realistic and stable-in-time reference breast phantoms. Oil-in-gelatin phantoms have been intensively investigated [3] since their dielectric properties are close to that of various breast tissues over a wide frequency range. However, if not properly sealed from the environment, such phantoms are not stable over time. On the other hand, we have already shown that liquid mixtures based upon Triton X-100 and salted water solutions are also able to mimic the various breast tissues and tumors in the 0.5–6 GHz frequency band [4]. These mixtures are easy to produce and their electromagnetic parameters are stable over time. Furthermore, their permittivity can be predicted as a function of Triton X-100 and salt concentrations, by means of a binary fluid mixture model that uses one pole Debye models. Thus, an adjustment of Triton X-100 and salt quantities can be obtained by fitting the Debye models corresponding to the different healthy or cancerous breast tissue types. In this work, such liquids are used to fill up 3D printed complex structures. This process allows us to produce realistic phantoms stable and adjustable in time, since liquids can easily be replaced or modified. Figure 1 displays two 3D models, used for printing phantoms dedicated to the test of 3D (a) and 2D (b) inversion algorithms, respectively. The 3D interior structure is very similar to realistic distributions of fibro-glandular (G_2) and adipose (G_3) tissues, surrounded by skin (G_1). The STL format file corresponding to the 3D phantom is produced from the one developed in [5], which is available at: https://uwcem.ece.wisc.edu/phantomRepository.html. The next step will be the dielectric characterization of these phantoms and, then, their test with microwave breast imaging systems.

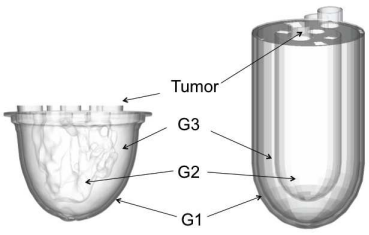

Figure 1: 3D printed phantoms to be filled up with Triton X-100-salted water mixtures dedicated to the test of (a) 2D and (b) 3D inversion algorithms.

Abstract— This paper introduces the prototype of a scanning system operating in the microwave range 0.5–4 GHz with strong potential in biomedical applications such as breast cancer detection or to assess shape-discontuinity in bones. Based on the research outcomes in [1], a fully automated scanner was designed to reduce mechanical uncertainties and data acquisition time. Accurate positioning and synchronization with data acquisition enables a rigorous proof-of-concept for the microwave imaging procedure.

The system can remotely control two printed antipodal Vivaldi antennas that scan a phantom across a set of positions arranged in cylindrical coordinates. For antenna miniaturization and improved coupling, the antennas, interface and phantom are immersed in a coupling medium that offers electric properties similar to adipose tissue. The antenna positioning, data acquisition and post-processing are automated. In the current version the reflection coefficients are measured by a Vector Network Analyzer (VNA). The integration of dedicated electronics attached to each antenna will replace the VNA to speed up data acquisition. Without any difficult *a priori* antenna characterization, the system is capable of detecting distinctive dielectric contrast in the phantom enclosed regions. By processing measured reflection coefficients with an interferometric version of the Multiple Signal Classification (MUSIC) algorithm [1], the detection of inserted targets in three-dimensional reconstructions is successful. The achievable performance obtained by I-MUSIC is then compared with two other methods in the literature: the non-coherent migration [2] which is a particular version of beamforming, and the standard wideband MUSIC technique [3]. From experimental results carried out on a multi-layer phantom made of glass and pork fat, a metallic bar of diameter equal to 8 mm was used as a target for a preliminary characterization of the scanning system.

UWB Waveguide Breast Tumor Detection System Based on Delay and Sum Reconstruction Algorithm

Ondrej Fiser, **Ilja Merunka**, **and Jan Vrba**
Department of Electromagnetic Field, Faculty of Electrical Engineering
Czech Technical University in Prague, Czech Republic

Abstract— The main objective of this contribution is the breast tumor detection using four double ridged horn antennas system. Signals are obtained in time domain and "delay-and-sum" method is used.

Antenna, antenna configuration and breast phantom: For imaging purposes the UWB double-ridged horn antenna intended for medical imaging was adopted from [1]. Total four antennas are placed equidistantly around a breast model (see Fig. 1). The whole antenna system is immersed in canola oil. A simple homogeneous breast phantom with a thin skin layer was used. This used breast phantom is based on a phantom published in [2]. In this phantom spherical phantom of diameter 30 mm at various positions was inserted. The values of relative permittivity and conductivity of fat, skin and malignant tumor tissue has been taken from [3].

Simulation and image reconstruction: The reconstruction algorithm for delay and sum was implemented. The transmitting antenna sends a RF pulse through the breast model. Transmitted signal is Gaussian pulse with the central frequency 4.5 GHz and bandwidth 8 GHz. The place of the change in dielectric parameters of material (canola oil X skin X fat X tumor) scatters the incident wave. The scattered wave can be received in all antennas which are placed around the breast. The method consists of two phases. In the first phase scan of scattered field of breast without the tumor is performed. In the second phase (e.g., after 1 year in next medical examination) second scan is made. For all signals Hilbert transformation is applied and prepared signals with/without tumor are subtracted from each other. Obtained differential signals are reflections from changes which have occurred (e.g., tumor). From the knowledge of the average velocity wave propagation in the breast from measured time difference peak of the transmitted signal (from transmitting antenna) and received signal peak the distance of the reflections from each antenna is found (assumed tumor position). Position of the wave diffuser is on the circle with the center in the antenna power probe. For tumor localization must be measured distance even from other antennas. Then it is possible to calculate intersections of the circles defining the distance of the tumor from each antenna. For high accuracy it is good to use all antennas as transmitters sequentially. In the case of uncertain tumor position (in case that in signal sometimes appears more than one peak) we can rotate the whole antenna system by 30 degrees and thus increases the localization accuracy. Used method seems to be very promising for breast tumor detection. Its disadvantage is the need to have signals from the breast at a time when the tumor did not occur.

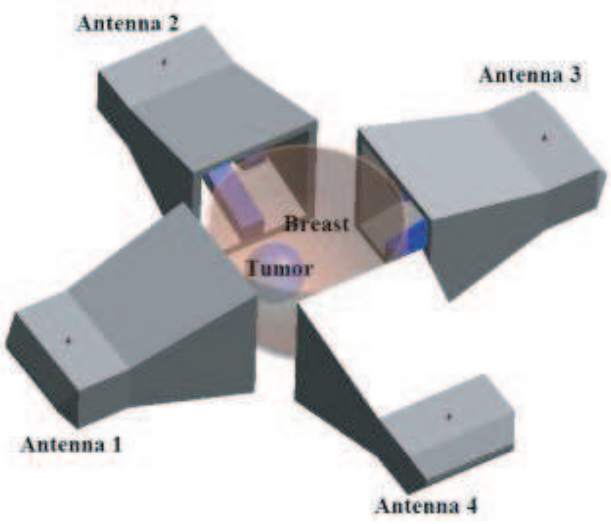

Figure 1: Antenna configuration with homogenous breast and spherical tumor.

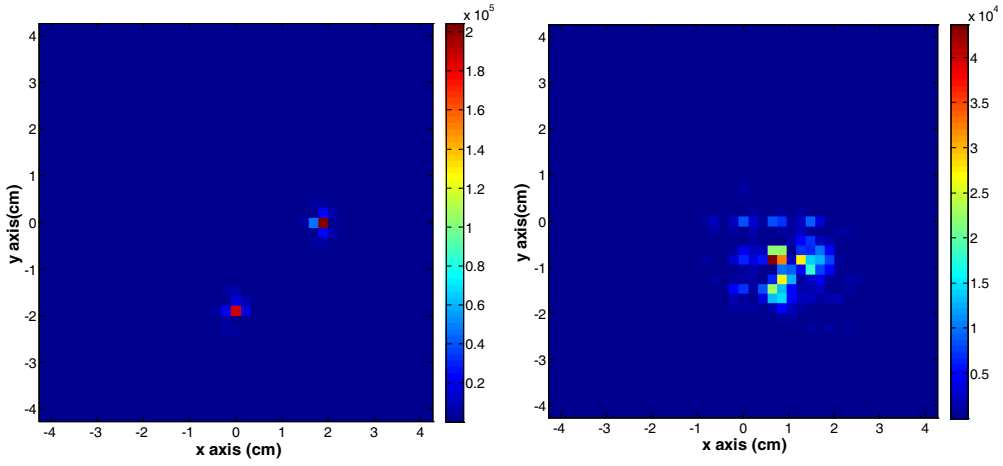
Abstract— In the last ten years, Ultra Wide Band (UWB) radar has been proposed as a complimentary imaging modality for breast cancer detection [1]. This technology is based in the significant dielectric contrast between healthy and malignant breast tissues (at least 2 to 1 according to the latest in vivo studies) [2]. UWB radar has a number of features that can be quite desirable from a clinical perspective, such as the use of low power non ionizing radiation and the lack of compression during the imaging procedure.

An area of particular interest in the last couple of years is the use of cylindrical or hemispherical multistatic scan geometries for UWB radar. Multistatic scan protocols exhibit an increased detection rate when compared to monostatic scan procedures [3]. Nevertheless, multistatic images may present artifacts for some transmission-reception scan location positions [3]. In this paper, the source of these artifacts will determined by performing a frequency domain analysis in the multistatic signal model. Let consider the multistatic signal spectral coverage band for a cylindrical scan geometry:

$$\Omega_q = \frac{k \cdot R \cdot r_q \cdot \sin(\phi_q - \theta)}{\sqrt{R^2 + r_q^2 - 2 \cdot R \cdot r_q \cdot \cos(\phi_q - \theta)}} + \frac{k \cdot R \cdot r_q \cdot \sin(\phi_q - \varphi)}{\sqrt{R^2 + r_q^2 - 2 \cdot R \cdot r_q \cdot \cos(\phi_q - \varphi)}}\Big|_{(\phi_q - \theta) = \pi/2} \quad (1)$$

where Ω_q is the spectral support band of the qth target in the scan region, k is the wavenumber, R is the radius of the scan geometry, (r_q, ϕ_q) are the polar coordinates of the qth target, and θ, φ are the angular locations of the transmitter and receiver respectively.

In the full paper, the complete procedure to derive (1) was will be given. Notice how the spectral coverage band reduces as the separation between the receiver and transmitter antenna increases. This result on the formation of a larger point spread function in the spatial domain. This will result in a possible loss of spatial resolution in the reconstructed image, which would limit the abilities to resolve individual targets. To validate this hypothesis, a set of two reflectors were created using the radar simulator described by the authors in [4] and their corresponding images were formed using the reconstruction approach presented in [5]. A representative example of this



(a) (b)

Figure 1: (a) Reconstructed multistatic image from a dataset where the transmitter and receiver separation is 45 degrees, (b) reconstructed multistatic image from a dataset where the transmitter and receiver separation is 135 degrees.

effect is shown in Figure 1. Figure 1(a) shows the reconstructed image of the two target reflectors when the antenna separation between transmitter and receiver is 45 degrees. Figure 1(b) shows the reconstructed image of the two target reflectors when the antenna separation between the transmitter and receiver locations is 135 degrees.

Notice how the targets can be resolved in 1(a) while in Figure 1(b) the signatures of both targets are fused due to the larger point spread function. In conclusion, these preliminary results show the effect of the angular separation between the transmitter and recording location on the point spread function of the targets in multistatic UWB radar images acquired along cylindrical scan geometry. The complete paper will explain the mathematical model in full and will also provide additional examples and a full quantitative analysis to describe the relationship between the transmitter-receiver locations and the point spread function of the targets in the reconstructed image.

Microwave Imaging of the Breast: Investigating Tumour Response with Classification

R. C. Conceição[1, 2], D. Byrne[3], J. A. Noble[1], and I. Craddock[3]

[1]Institute of Biomedical Engineering, University of Oxford, Headington, Oxford OX3 7DQ, UK

[3]Department of Electrical & Electronic Engineering, University of Bristol, UK

Abstract— In this study we evaluate the feasibility of using machine learning algorithms to investigate the scattering of breast tumours using ultra wideband radar microwave imaging. In particular, we aim to aid in differentiating between normal breast tissue (a "miss") or tumour tissue (a "hit") within data obtained from a radar scan of the breast. A machine learning algorithm (e.g., Support Vector Machines) will be trained with a database of series of measurements of both "hits" and "misses" in realistic breast phantoms, which have been performed with the microwave imaging prototype at the University of Bristol.

Introduction: Microwave Imaging of the breast has been thoroughly studied in the past years, with some recent studies addressing the use of classification algorithms (such as Linear Discriminant Analysis, Quadratic Discriminant Analysis, Support Vector Machines [1], Spiking Neural Networks [2] and Self-Organising Maps [3]) with the aim of estimating the size and shape of benign and malignant tumour phantoms.

In this study we further extend the use of classification algorithms to investigate the scatterings recorded in microwave radar breast imaging. We will estimate the likelihood of tumour occurrence at each synthetic focal point in resulting energy profiles of the breast.

Methodology: The measurement data used in this study are captured with the microwave imaging prototype at the University of Bristol. This comprises a Rohde-Shwarz ZVT 8 port VNA (frequency bandwidth: 3–8 GHz) and a conformal array of 60 wide-slot antennas [4].

Several breast phantoms are developed, some of which contain multiple targets. For all breast phantoms, the chest-wall is accounted for by maintaining a liquid to air interface at the base of the breast phantom. Synthetic focal points of 36 different phantoms are considered. The database considered for this study consists of a total of 1,925,455 measurements of "hits" and "misses" from 779 synthetic focal points corresponding to "hits", and 779 synthetic focal points corresponding to "misses".

A number of features are extracted from the measured data related to "hits" and "misses". The data is then divided into a training, a testing and a validation set in order to test the performance of classification algorithms. Performance is evaluated by metrics, including sensitivity, specificity, positive predictive value, negative predictive value and accuracy. The Receiving Operating Curve (ROC) for each classification algorithm is calculated.

Conclusions: The features extracted from the measured data and the performance of the classification algorithms will be discussed.

Axiomatics of the Blondel-Park Transformation

G. F. Crosta[1] and G. Chen[2]

[1]University of Milan Bicocca, Italy
[2]Texas A & M University, USA

Abstract— The doubly-fed induction generator (*DFIG*) is a key constituent of energy conversion plants. The control of a *DFIG* is a challenge, whenever the primary energy supply (e.g., the wind velocity field) is characterised by intermittency. The mathematical model and control of a *DFIG* rely on the Blondel-Park transformation, which is known to simplify the governing equations. The distinctive feature of this contribution consists of showing how the Blondel-Park transformation derives from a set of conditions to be met by a group. Such a group is shown to exist and to continuously depend on one parameter. The uniqueness of its infinitesimal generator is also shown. As an application, the well-known electric torque theorem is proved in a simple way, which relies on a "product of matrices" formula. The latter, in turn, is a by-product of the axiomatic deduction of the Blondel-Park transformation.

Nonlinear Goubau Line: Numerical Study of TE-polarized Waves

E. Yu. Smol'kin[1] **and Yu. V. Shestopalov**[2]

[1]Penza State University, Russia
[2]University of Gävle, Sweden

Abstract— A conducting cylinder covered by a concentric dielectric layer called the Goubau Line (GL) is the simplest type of open metal-dielectric waveguides. A complete mathematical investigation of the spectrum of symmetric surface modes in a GL is performed in [1]. Papers [2, 3] develop the theory of wave propagation in layered nonlinear dielectric waveguides. However, there are very few results concerning the analysis of wave propagation in a GL with an external concentric layer having variable, nonlinear, or variable and nonlinear permittivity. We aim this study to fill this gap and consider the problem of electromagnetic TE (transverse-electric) wave propagation in a GL with nonlinear permittivity $\varepsilon = \varepsilon(\rho) + f(|\mathbf{E}|^2)$ of the dielectric medium filling the GL layer (here $\varepsilon(\rho)$ is a function of inhomogeneity which depends on the radius of the waveguide, f is a function that models nonlinearity, and $\mathbf{E}$ is the complex amplitude of the electric field). We consider only the intensity-dependent permittivity. The determination of TE waves is reduced to a nonlinear transmission eigenvalue problem for Maxwell's equations, which is then reduced to a system of nonlinear ordinary differential equations. Numerical experiments are carried out for two types of nonlinearities:

- $\varepsilon = \varepsilon(\rho) + \alpha u^2$ (Kerr law) and
- $\varepsilon = \varepsilon(\rho) + \alpha(1 - e^{-\beta u^2})$ (nonlinearity with saturation),

where $\varepsilon(\rho) = \frac{1}{\rho}$, const, or ρ. Comparison with linear homogeneous (inhomogeneous) and nonlinear homogeneous (inhomogeneous) cases are performed. Calculations are carried out for various frequency and parameter ranges.

Numerical Path-integration Computation of the Capacity and Electric Polarizability Tensor of Complex-shaped Particles

Jack F. Douglas
Materials Science and Engineering Laboratory, NIST, Gaithersburg, MD 20879, USA

Abstract— Many boundary value problems arising in materials science modeling involve complicated boundary shapes and boundary data, making analytic solution based on conventional partial differential equation methods difficult. In particular, it is important to develop effective computational methods for calculating the electromagnetic and transport properties of nanoparticles for understanding their interaction with electromagnetic radiation to allow their manipulation with optical traps and separation with fields. These properties are also basic to characterizing particle and polymer geometry and interparticle interaction through solution property measurements. This class of problems is made challenging by the fact that large ensembles of objects having rather complex shape must be considered an ensemble averaged properties must be determined. As illustrative examples, we discuss specific systems such as carbon nanotubes and graphene, proteins, DNA and Au nanoparticles with grafted with DNA. These problems are daunting since there is still no accurate analytic theory for calculating basic transport properties (e.g., diffusion coefficient and intrinsic viscosity) and electromagnetic properties (capacity and polarizability) of even simple objects like a cube or stochastically defined objects such as random walk polymer chains modeling polymers in solution. In many cases, finite elements are also found to be intractable when the geometry shape becomes highly complex. As a step towards attacking this broad class of problems, we focus on the problem of calculating the self-capacity and electric polarizability tensor of conductive particles having essentially arbitrary geometry based a novel computational method involving path-integration. The basic concepts behind the method are described and the method validated in cases where exact analytic, or at least highly accurate numerical estimates, are known for comparison. Some applications of the program are then given for some non-trivial situations, such as the nanoparticle and polymer systems mentioned before. The path-integration method is evidently a powerful tool for computing basic electromagnetic and transport properties of complex-shaped polymers and should find wide application in polymer science, engineering, nanotechnological applications and medical and biological applications.

Unified Description of Chirped Gaussian Pulse Propagation of Arbitrary Initial Width in a Multiple Resonance Lorentz Medium

Constantinos M. Balictsis
Hellenic Telecommunications and Post Commission
60 Kifissias Avenue, Maroussi, Athens 15125, Greece

Abstract— Research interest regarding the reproducible generation, compression and characterization of ultrashort, pulse-modulated signals whose duration is comparable to the carrier oscillation cycle, is on the rise and spans various frequency domains [1–3]. Increased emphasis is placed on their dynamical evolution as they propagate through, and interact with, various material media due to the diverse and important applications, among others, in optical communications, radar systems and pulse compression. Pertinent theoretical efforts commonly invoke the slowly varying envelope approximation (SVEA) and are inapplicable in the sub-cycle pulse regime [1, 3]. A different stream of rigorous theoretical efforts to pulse propagation problems employs asymptotic techniques. These efforts have elucidated the dynamical evolution of the propagated field due to rapid rise and/or fall time or exponentially varying input pulses and their accuracy has been validated upon comparison with purely numerical results [1].

Recently, modern asymptotic techniques have been utilized in order to obtain an accurate uniformly valid description of Gaussian pulse propagation in a single-resonance causally dispersive, absorptive [4] or amplifying [5], Lorentz medium. Here, the unified asymptotic approach is applied to the important case of an input Gaussian pulse envelope modulated chirped harmonic wave whose envelope has a fixed but otherwise arbitrary initial full width $2T$ centered around $t_0 > 0$, and it modulates a harmonic wave of applied carrier frequency ω_c that is linearly chirped with a constant chirp parameter C. This input chirped Gaussian wave propagates in the source-free half-space $z \geq 0$ filled with a linear, homogeneous, isotropic temporally dispersive, non-hysteretic medium whose refractive index is described by the more realistic [1] multiple (m) resonance Lorentz model. The unified approach, which relies on an asymptotic analysis of the unified, exact integral representation of the propagated field, is shown to be valid from the SVEA to the theoretically and experimentally important sub-cycle pulse regimes, and its accuracy is confirmed upon comparison with the respective depicted results of an independent numerical experiment. Moreover, it generalizes previous findings on the appearance and dynamical evolution of the precursor fields associated with ultrashort and/or ultrawideband pulse propagation [1, 3–5]. According to the obtained unified asymptotic description, the propagated field $A(z,t)$ is comprised of pulse components $A_{Ul}(z,t)$ each being due to the asymptotic contribution of a respective relevant saddle point $\omega_{SP_{Ul}}(\theta)$ of the unified phase function $\Phi_U(\omega,\theta)$. This asymptotic description directly relates the propagation characteristics (including, the locus and propagation velocity of the stationary point(s) of the envelope, and the instantaneous angular oscillation frequency) of each $A_{Ul}(z,t)$ with the dynamics of the respective relevant saddle point $\omega_{SP_{Ul}}(\theta)$. Under certain conditions, such a stationary point of a pulse component's envelope occurs when the respective saddle point trajectory intersects the real frequency axis, and it travels with the group velocity at this frequency crossing value; superluminal velocity may then be observed.

The accuracy and insight of the unified asymptotic description may prove useful in applications involving chirped pulses, overcoming the limitations of other theoretical approaches especially in the extremely ultrashort pulse regime.

Block LU Preconditioner for the Electric Field Integral Equation

S. L. Stavtsev
INM RAS, Russian Federation

Abstract— Boundary element discretizations are applied in many scientific and engineering areas, for example, to solve the problem of electromagnetics scattering with electric field integral equation (EFIE). To solve EFIE on the surfaces of arbitrary shape, RWG functions are traditionally used. The matrices, arising from the discretization of integral equations can be approximated well with low-rank matrices using mosaic-skeleton method. But to solver scattered problem with large wave size of object we have to solve large system $n \sim 10^5$–10^6. System of linear equation with matrixes of such order is solved by iterative method (GMRES). For large wave size matrix is ill-condition and we have to use preconditioner. In this paper to decrease a number iteration of GMRES method the block LU preconditioner is built. In the numerical experiments it is showed that the preconditioner permit to solve the problem of electromagnetic scattering on objects with lager wave size.

Permittivity Reconstruction of a Diaphragm in a Rectangular Waveguide: Unique Solvability of Benchmark Inverse Problems

Y. Shestopalov[2], **Y. Smirnov**[1], **and E. Derevyanchuk**[1]

[1]Penza State University, Russia
[2]University of Gävle, Sweden

Abstract— Determination of electromagnetic characteristics of dielectric bodies is an urgent problem for artificial materials: nanomaterials, metamaterials, and nanocomposite materials. As a rule, electromagnetic parameters of modern materials cannot be measured. Therefore for solving this problem, methods of mathematical modeling must be applied. In this work, we consider the inverse problem of permittivity reconstruction of diaphragms loaded in a rectangular waveguide and present theoretical and numerical results. This work is a continuation of the series of papers [1–3] devoted to the investigation of permittivity reconstruction of layered materials in the form of diaphragms (sections) in a single-mode waveguide of rectangular cross section from the transmission coefficient measured at different frequencies. The aim is the development of the mathematical technique for the analysis of the inverse problem for the case of a one- and multi-sectional diaphragms in a rectangular waveguide. We suppose that the diaphragm is made of material with real electromagnetic parameters. For this case, we obtain analytical solution of the inverse problem. Based on the analytical solution we study more complicated mathematical models, consider different cases of filling the diaphragm sections, and present results of numerical simulation. We perform comparison of experimental and numerical results that validate the efficiency of the proposed technique. The obtained solutions can be implemented in practical measurements for the investigation of new artificial materials and media and can be applied in optics, nanotechnology, and design of microwave devices.

The Application of Non-linear Dynamics Methods for Radar Target Identification

F. J. Rachford and T. L. Carroll
US Naval Research Laboratory, USA

Abstract— Currently radar target identification is effected by finding the downrange distribution of scatterers on a platform using high definition radar and referencing this distribution to a look-up table of measured radar returns. This method is difficult due to the rapid scintillation of the radar signal of a flying target at short wavelengths. We investigate a method of target identification in the low definition, relatively long wavelength, limit using techniques derived from the field of non-linear dynamics. In this limit the radar reflection is much less sensitive to the orientation of the target to the radar and scintillation is greatly reduced. Modern detection advances allows the digitization and processing of raw real time non-pulse compressed waveforms. We simulate the raw radar returns from several very similar small (4 to 5 wavelength) objects (i.e., cylinder, cone-cylinder, cone-ogive and double ogive) illuminated with chaotic or random modulated waveforms using a commercial finite difference time domain code. In this aggressive limit we embed the return in two dimensions using the method of delays to form an attractor. The geometric properties of the attractors are analyzed to distinguish between these similar target objects in the low definition limit. One method selects points on a reference attractor (or strands of points) with many Euclidean nearest neighbors and compares these with the nearest neighbor density of points (or strands) with the same time index on an attractor from an "unknown" target. Comparing the density of nearest neighbors at these points on two attractors allows us to calculate probabilities of correct identification. (Is the unknown signal from the reference target or from one of the other targets?) The robustness of our method is probed by the addition of white noise and/or simulated clutter to the signals.

Verification of Computational Model of Transmission Coefficients of Waveguide Filters

P. Tomasek[1] and Y. V. Shestopalov[2]

[1]Tomas Bata University in Zlin, Czech Republic
[2]University of Gävle, Gävle, Sweden

Abstract— Owing to the recent research [1–3] the way of estimating transmission coefficients for a waveguide of rectangular cross-section loaded with multi-layered parallel-plane dielectrics is found. Consequently, the analysis of the transmitted and reflected fields in terms of the scattering matrix formalism can be performed explicitly. These results can be efficiently applied to modeling of waveguide filters. This article is mainly based on the previous research presented in [1], it enhances the theory and contains comparisons between real measured and computed transmission coefficients of a waveguide filter using a technique based on the method set forth in [2, 3]. The computation employs analysis of closed-form solutions and numerical multi-parameter optimization [4, 5]. The presented waveguide filter is formed by multi-sectional diaphragms placed in a waveguide of rectangular cross-section. The filter consists of a specific combination of diaphragms of FR4, plexi and RO4003 with defined permittivities and thicknesses. The resulting permittivity profile that provides significant range of the parameter and output variations has a characteristic almost-periodic stepwise structure which can be improved using the closed-form solution and numerical optimization. Comparison of the computed and measured transmission coefficients demonstrates that the difference is very low, rather marginal and thus the output of the work is considerably promising. The results prove the ideas, approach and the final implementation of the mathematical background used for computation of the transmission coefficients of a waveguide filter.

Computations Related to Nanoparticle Characterization and Nanocomposite Property Estimation

Fernando Vargas-Lara and Jack F. Douglas
Materials Science and Engineering Laboratory, NIST, Gaithersburg, MD 20879, USA

Abstract— Recently, there has been great interest in enhancing the electrical and thermal conductivity and mechanical properties of polymeric materials with carbon nanotube (CNTs) additives. Large changes in properties have been achieved with these additives and applications, especially in relation to enhanced electrical conductivity, have been realized. However, controlling and understanding these property changes has been a difficulty. It is well known that the resulting nanocomposite properties depend strongly on the geometrical properties of the CNTs such as length, diameter, and shape, as well as the dispersion of the CNT. Commercial forms of these fillers, as opposed to the rod-like structures that are the focus of many academic studies, are typically composed of roughly spherical multi-walled CNT domains having a highly ramified internal structure and a size on the order of a micron. Clearly, such structures, which we term "tumbleweeds" because their resemblance to these natural forms, cannot reasonably be modeled as "rods", and we address the properties of these composite materials through a combination of molecular dynamics simulations and path-integral calculations. As a specific illustration of this computational path, we first calculate electromagnetic properties of the tumbleweeds, such as the self-capacitance, electric polarizabilty tensor, and the intrinsic conductivity. Knowing these basic particle properties, one then can estimate electromagnetic properties of nanocomposites made with these complex- shaped "particles", i.e., conductivity, by incorporating this information in a generalized effective medium theory. Based on this model, we find that the conductivity percolation threshold of the tumbleweeds can be quite low, despite their quasi-spherical average shape.

Exponential Regularization of EM Dyadic Green's Functions via Green's Function-induced Dirac δ-functions

A. R. Baghai-Wadji
University of Cape Town, South Africa

Abstract— In a series of recently published contributions it was shown that dyadic Green's functions arising in computational electromagnetics can be utilized to construct problem-specific integral representations of the Dirac delta function. It was also shown that the constructed Dirac delta functions can be employed to regularize originating Green's functions associated with Poisson equation in isotropic and anisotropic dielectrics. This contribution extends previous efforts as follows: (i) The constructed Dirac delta functions are employed to regularize dyadic Green's functions associated with Maxwell's equations in isotropic media. Thereby, all formulae arising in the discussion are expressed in closed-form in spectral domain, a fact which allows intriguing insights into the dynamics of the proposed regularization method itself. (ii) Complex media do not allow the Green's functions to be constructed in closed form. Consequently, the integral representations for the Dirac delta functions cannot be expressed in closed-form either. An algorithm is presented for the numerical construction of Dirac delta functions. It is claimed that the latter result presents a genuine contribution to the computational physics. (iii) The soundness of the derivations are supported by several Lemmas. (iv) Applications in which near field phenomena play a decisive role, e.g., nanoscopic and plasmonic devices will benefit from the results.

Regularization problems arising in theoretical and computational field theory are fascinating and challenging at the same time; numerically, however, they are most undesirable and may lead to catastrophically ill-conditioned results. Singular field problems, requiring regularization, have characteristic footprints in spectral domain. Singularities in static fields are defined by a $1/|k|$ pole-like behavior in the infrared wavenumber region. The same $1/|k|$ functional behavior in the ultraviolet region leads to slow convergent or divergent Fourier-type integrals. In real domain, the infrared $1/|k|$ pole-like singularity is associated with the properties of the fields in the far-field, whereas, the ultraviolet slow-decay, divergent singularity is related to the near-field. Singularities in dynamic fields manifest themselves in poles and branch points in intermediate regions in spectral domain. It can shown that pole- and branch point singularities can be treated fairly conventionally, with one exception, which arises when constructing universal functions (addressed in an accompanying paper). Thus the prime focus becomes regularization of slow decay property of Green's functions in spectral domain (near-field region). To this end the present author has proposed algebraic as well exponential regularization techniques. This paper focuses on the exponential regularization which is facilitated by Dirac delta functions constructed from the Green's functions themselves.

Abstract— One of the most important ways to improve the radar systems based on smart antennas is to improve the accuracy of angle measurements and to increase the angular resolution. In this regard, the problem to be solved is restoring the image of the object with superresolution. This inverse problem is reduced to a Fredholm integral equation

$$U(\alpha) = \int_{\Omega} F(\alpha - \phi, \varphi) I(\phi, \varphi) d\phi d\varphi, \tag{1}$$

where $U(\alpha)$ is the signal received by the scanning, Ω angular region of location of the signal source, $I(\alpha, \varphi)$ desired angular distribution of the reflected signal amplitude, and $F(\alpha, \varphi)$ radiation pattern. The central problem based on the intelligent analysis and digital signal $U(\alpha)$ is to restore the image of the source using superresolution. In contrast to conventional phased array, the signals received by each element of the smart antennas can be recorded digitally. The new signal processing method is based on the extrapolation of the signals received by each element of the smart antennas beyond the aperture and yields synthesized smart antennas with a greater number of emitters and an aperture increased by the same factor. As a result, the accuracy of angular measurements and angular resolution increases. The best results were obtained using the extrapolation with the Berg linear prediction method. The algorithm predicts the values of the signals for the aperture array ten times higher than the original one with a negligible error. Numerical studies have shown that the Rayleigh criterion in this problem is exceeded by 6–7 times. An important characteristic of solutions is a minimal signal/noise ratio (SNR) with which a super-resolution image reconstruction is still possible. Stability of solutions and quality of image reconstruction were examined using a mathematical model. The results of numerical studies show that the angular resolution is increased 4–10 times under SNR 12–13 dB, which is much lower than that achieved by the known methods.

The proposed new method of signal processing based on digital aperture synthesis significantly improves the accuracy of angle measurements and provides a stable restoration of detailed images of the objects with superresolution in the presence of small distortions. The corresponding algorithm can be implemented in the real-time mode.

Analysis of Quasi-circular Polarization in Near Field of Smart Shelf RFID Antenna Radiation

A. S. Andrenko
SYSU-CMU Shunde International Joint Research Institute
No. 9 Eastern Nanguo Road, Shunde, Guangdong 528300, China

Abstract— This paper presents the EM simulation and accurate analysis of quasi-circular polarization (CP) of the so-called smart shelf antenna designed for the UHF RFID retail and item-tagging applications. The smart shelf antenna utilizes the near field communication in a range close to a wavelength between the planar reader/writer antenna and several tagged items being placed on the shelf. To provide reliable detection of the multiple tags which can generally be distributed within a wide interrogation volume over the shelf surface, uniform and strong near E-field radiated be the smart shelf antenna is required.

The design of the proposed antenna is based on the EM coupling between the open-ended or shorted-to-the ground meander microstrip line utilizing the standing wave current-voltage distribution and periodic metal strips printed on the top surface of a dielectric substrate. The required uniform near E-field has been provided by optimizing the layout of the periodic strips forming the smart shelf antenna layout. Series of full-wave EM simulations have been carried out to analyze the E-field distribution calculated at the different distances from the antenna surface, in a range from 5 cm to 40 cm. It has been confirmed that the proposed antenna creates strong near field within the entire volume where multiple RFID tags are placed. Two types of the smart shelf antenna have been designed and optimized. The first is the antenna where the periodic EM coupled elements are straight strips of approximately one wavelength so that the smart shelf antenna radiates predominantly linearly polarized E-field. The second one has been designed for the apparel tagging applications where tagged items are arbitrary oriented in the plane parallel to the antenna surface. Therefore, EM near field of this antenna has to be quasi-CP with quasi here meaning that the E-field is also having z-component (normal to antenna surface). What is the most important in such an application is that the E-field has to have a well balanced x- and y-components at the different distances from antenna and within an entire interrogation volume. The required quasi-CP near field has been numerically optimized in the series of EM simulations by utilizing the three-section layout of the periodic metal strips and changing the angles of strip sections so that it results in both E_x- and E_y-components being produced. Time-domain calculation of 3D E-field vector distribution has also demonstrated how a simple change of the meander line layout produces both quasi-RHCP and LHCP radiation in the near field.

The prototypes with different layouts of the proposed antenna have been produced and their performance in the UHF RFID system has been verified. 100% detection rate and measured read range for the large number of tagged items have confirmed the simulated near field distribution as well as an excellent performance of the proposed smart shelf antenna.

CICT: A Novel Framework for Biomedical and Bioengineering Application

R. A. Fiorini
Department of Electronics, Information and Bioengineering (DEIB)
Politecnico di Milano University, Italy

Abstract— In 2004, University of Michigan physicist Mark Newman, along with biologist Michael Lachmann and computer scientist Cristopher Moore, showed that if electromagnetic radiation is used as a transmission medium, the most information-efficient format for a given 1-D signal is indistinguishable from blackbody radiation. Since many natural and biological processes maximize the Gibbs-Boltzmann entropy, they should give rise to spectra indistinguishable from optimally efficient transmission. In 2013, Politecnico di Milano academic scientist R. A. Fiorini confirmed Newman, Lachmann and Moore's result, generating analogous example for 2-D signal (image), as an application of CICT (computational information conservation theory) to show that even the current, most sophisticated instrumentation system is completely unable to reliably discriminate so called "random noise" (RN) from any combinatorially optimized encoded message, which CICT called "deterministic noise" (DN). For observing and determining single molecule transport characteristics or for detecting a minute change in resistance or capacitance at biostrucuture nanoscale, we need stronger research and computational tools able to overcome the above operative limitation. To grasp a more reliable representation of experimental reality and to get stronger physical and biological system correlates, researchers and scientists need two intelligently articulated hands: both stochastic and combinatorial approaches synergically articulated by natural coupling. CICT approach brings classical and quantum information theory together in a single framework, by considering information not only on the statistical manifold of model states but also from empirical measures of low-level multiplicative noise source generators, related to experimental high-level overall perturbation. This approach is recommended to design reliable experiment and advanced instrumentation system. In various applications to physical problems, a function can be decomposed into physically meaningful eigenfunctions of a differential operator (typically the Laplace operator): this forms the foundation for the spectral study of functions, in reference to the spectrum of the differential operator. A concrete physical application involves the problem of hearing the shape of a drum: given the fundamental modes of vibration that a drumhead is capable of producing, can one infer the shape of the drum itself? The mathematical formulation of this question involves the Dirichlet eigenvalues of the Laplace equation in the plane, that represent the fundamental modes of vibration in direct analogy with the integers that represent the fundamental modes of vibration of the violin string. Spectral theory also underlies certain aspects of the Fourier transform of a function. Whereas Fourier analysis decomposes a function defined on a compact set into the discrete spectrum of the Laplacian (which corresponds to the vibrations of a violin string or drum), the Fourier transform of a function is the decomposition of a function defined on all of Euclidean space into its components in the continuous spectrum of the Laplacian. The Fourier transformation is also geometrical, in a sense made precise by the Plancherel theorem, that asserts that it is an isometry of one Hilbert space (the time domain) with another (the frequency domain). This isometry property of the Fourier transformation is a recurring theme in abstract harmonic analysis, as evidenced for instance by the Plancherel theorem for spherical functions occurring in noncommutative harmonic analysis. For discrete data, the Discrete Fourier Transform (DFT) is used. As an example, CICT number theoretic transform (NTT) is presented to envisage the development of competitive application devoted to automatic tailoring noise compensation countermeasure to real dynamic device characteristics and performance, even in real-time. That feature can get us closer to ideal self-registering and self-linearizing instrumentation able to generate virtually homogeneous and uniform device experimental probing domain, during its whole designed service life-cycle, offering superior reliable final result at least cost. Its adoption becomes a must either to real High Reliability Organization (HRO) or to mission critical project for low technological risk and crisis management system.

Multichannel Filter Banks and Their Implementation Using Computers with a Parallel Structure

D. I. Kaplun, D. M. Klionskiy, A. S. Voznesenskiy, and V. V. Gulvanskiy
Computer Science Department
Saint Petersburg Electrotechnical University "LETI", Saint Petersburg, Russian Federation

Abstract— The paper is devoted to the development and software-hardware implementation of the *weighted overlap-add algorithm* (WOLA-algorithm) for processing *vector signals* in wideband monitoring tasks. The algorithm is intended for functioning together with instruments that are responsible for airwave control in real time. We have performed the comparison of the suggested algorithm with the polyphase implementation of a multichannel digital filter bank. We have also considered the software-hardware implementation of multichannel processing and we have shown the advantages of applying the CUDA (Compute Unified Device Architecture) technology based on computations using graphical processors.

The WOLA-algorithm for processing vector signals can be considered as a generalization of the corresponding algorithm for processing one-dimensional signals. The suggested modification will make it possible to process a vector signal and also to perform software-hardware implementation using high-performance software and hardware tools.

When we have found signals in each channel it is necessary to perform their *sub-band processing* (each channel signal has its own frequency band) including spectral analysis, time-frequency analysis, statistical analysis in the time domain, demodulation, etc..

Digital filter banks perform parallel processing of an input signal and therefore to improve the hardware implementation efficiency it is most reasonable to employ computers with a parallel structure. Such computers include FPGA (field-programmable gate arrays) and processing devices with the use of CUDA.

CUDA is based on using a set of parallel graphical processors (Graphics Processing Unit — GPU) for handling non-graphical tasks. GPU is a specialized device, which is a co-processor to the Central Processing Unit (CPU), has its own memory and can execute a large number of separate data flows (data flows are parts of one program that run in a parallel way). The advantages of CUDA are cross-platform operation, the existence of complete libraries, use of the extended version of C with additional tools for parallel programming and development of multiflow applications. Furthermore, CUDA does not require application of a graphical interface (API), which has a number of restrictions on multiflow computation arrangements.

Hardware resources for digital filter bank implementation are not boundless (the most critical aspect is the total number of multipliers for FPGA). For this reason we need to design computationally efficient FIR-filters (filters with finite impulse response) that will allow us to reduce hardware-software costs and accelerate signal analysis. Such an approach will make it possible to reduce the total number of devices (including the number of FPGA multipliers) and increase the number of processing devices on a chip.

We suggest performing filter bank implementation using FPGA and the distributed arithmetic. The main difference between this approach and direct implementation with MAC-cores (multiply and accumulate cores) is the fact that the distributed arithmetic does not use any multipliers. Thus we can achieve a more efficient digital filter bank implementation.

Regularization of Ill-conditioned Numerical Scheme of an Analytical Formulation: Scattering by Circularly Layered Cylinders

Emrah Sever[1], **Fatih Dikmen**[1], **Farhad Mazlumi**[2], **and Yury A. Tuchkin**[1]

[1]Electronics Engineering Department, Gebze Technical University, Kocaeli, Turkey
[2]Aviation Electronics Department, Civil Aviation Technology College, Tehran, Iran

Abstract— The new regularization of the well-known analytical formulation of the monochromatic electromagnetic wave scattering by a few eccentrically multilayered homogenous circular dielectric [1] and impedance [2] cylinders will be demonstrated. The polarization of the fields are parallel to the longitudinal axes of the cylinders, thus a two dimensional problem for each both polarizations are under consideration. The ways to simulate such a physical or an engineering process are quite various, owing to the present techniques of using the capabilities of modern hardware and software. Therefore nowadays, the numerical stability of an analytically rigorous formulation of an electromagnetic scattering problem may be taken for granted unintentionally by the user of a powerful computer with modern hardware and software. We can meet the concerns about the numerically stable simulation of an analytical model, starting at least five decades ago [3, 4]. The formulation and its regularization in [3] were suggested for two neighboring perfectly conducting circular cylinders. We present herein the novel extension of the approach in [3] to the considered scattering problem. The integral formulation defined in [4], also having met in [5] gives the strong mathematical background of the analysis here. The main theoretical result herein is the mathematically equivalent reducing of the diffraction problem for the eccentrically multilayered dielectric circular cylinders to a linear algebraic equation system of the second kind in the functional space l_2. The numerical results to be presented will forewarn those who trust in the various numerical methods (even the classical ones) without a careful mathematical and numerical investigation of the methods validity.

Colloidal Quantum Dots and Semiconductor Heteronanocrystals: New Luminescent Materials with Tailored Optical Properties

Celso de Mello Donega
Debye Institute for Nanomaterials Science, Utrecht University, The Netherlands

Abstract— Colloidal semiconductor nanocrystals (NCs) are a versatile class of nanomaterials, whose properties are determined by their composition, size, and shape, thus allowing nanoscale excitons to be confined to zero- (quantum dots, QDs), one- (quantum rods, QRs), or two-dimensions. Semiconductor NCs comprising two (or more) different materials joined together by heterointerfaces, i.e., heteronanocrystals (HNCs), offer even more exciting possibilities regarding property control [1]. The spatial localization of charge carriers in HNCs can be manipulated by controlling the offsets between the energy levels of the materials that are combined at the heterointerface [1]. In Type-I HNCs both carriers are confined in the same material. In contrast, in Type-II HNCs a spatially indirect exciton is formed. In Type-I [1, 2] (or *quasi*-Type-II) HNCs one carrier is delocalized over the HNC, while the other is localized in one of the segments. This allows the electron-hole spatial overlap to be tailored, and gives semiconductor HNCs fascinating and unique properties, which are determined by the size, shape, and composition of each segment. Understanding the properties of nanoscale excitons in colloidal NCs and HNCs is of great scientific interest, from both fundamental and applied viewpoints, since these materials are promising for a variety of technologies (LEDs, solar cells, biomedical imaging, luminescent solar concentrators). In our group, we have applied a multistage preparation strategy that allows the combination of a variety of synthesis techniques (hot-injection, seeded growth, cation exchange, oriented attachment) in a sequential manner in order to achieve the targeted synthesis of colloidal NCs and HNCs. This has allowed us to systematically investigate the optical properties of a number of NC (e.g., CdSe, CdTe, PbSe, ZnO QDs) and HNC compositions (e.g., PbSe/CdSe, CdSe/(Cd,Zn)S/ZnS, CdTe/CdSe, ZnSe/CdSe core/shell QDs, CdSe/CdS core/rod shell nanorods, ultranarrow (Zn,Cd)Te/CdSe heteronanowires) [2-8]. In recent years, we also developed methods to synthesize Cd- and Pb-free HNCs, such as ultrathin $Cu_{2-x}S$ nanosheets [9] and $CuInS_2$ QDs [10]. In this contribution, I will discuss a selection of examples, chosen in order to illustrate specific synthesis strategies and combinations thereof, as well as to show that compositional, size, and shape control can be used to tailor nanoscale excitons, and consequently the optical properties of colloidal HNCs.

On the Route to Metal-free Phosphors

Adrian Kremer[1], **Barbara Ventura**[2], **Nicola Armaroli**[2], **Andrea Barbieri**[2], **and Davide Bonifazi**[1]

[1]Department of Chemistry, University of Namur (UNamur)
Rue de Bruxelles 61, Namur 5000, Belgium
[2]Istituto per la Sintesi Organica e la Fotoreattività (ISOF)
Consiglio Nazionaledelle Ricerche (CNR), Via Gobetti 101, Bologna 40129, Italy

Abstract— Phosphorescence is a key phenomenon on which are based devices for solid-state lighting such as Organic Light Emitting Diodes (OLEDs) [1]. Despite an increasing demand for phosphorescent materials, purely organic (i.e., metal-free) compounds have been very rarely explored as emitters in phosphor applications [2]. Indeed, only a few organic molecules are known to exhibit efficient phosphorescence emission at room temperature, as their long-living triplet excited state are extremely sensitive to collisional quenching by O_2 and other impurities. The main advantage of organic phosphorescent materials vs the inorganic analogues stems from the possibility to fabricate flexible devices and large-area displays by low-cost wet processing techniques (e.g., roll-to-roll printing), taking advantage of the fact that organic materials are typically soluble in a variety of common solvents.

To defy the paradigm that organic materials are not suitable as phosphors, we describe here novel design principles to prepare purely organic phosphorescent molecular materials by incorporating calchogenic atoms into their structure [3]. The synthesis, X-Ray crystal structures, ground and excited state UV-V is absorption spectra and luminescence properties of two series of chalcogen-containing organic emitters equipped on both extremities with benzoxa-, benzothia-, benzoselena- and benzotellurazoles moieties are reported. The insertion of four different chalcogen atoms within the same molecular skeleton enables the investigation of the sole internal heavy-atom effect on the photophysical properties of the organic compounds. A progressive quenching of the fluorescence and concomitant onset of phosphorescence features with gradually shorter lifetimes are detected as the atomic number of the chalcogen heteroatom increases, with the Te derivatives exhibiting only phosphorescence emission. Notably, the phosphorescence spectra of the Se and the Te compounds can be recorded even at room temperature in dilute de-aerated solution, a very rare finding for organic emitters.

These results open the route to the systematic exploitation of the internal heavy atom effect in the design of phosphorescent organic emitters, a rapidly expanding area of vast technological interest. This is a highly desirable goal in light of the difficulties still encountered in the preparation of cheap and stable triplet emitters based on transition metal complexes, particularly in the blue spectral region.

Abstract— A two-wavelength emission laser (two-mode laser) can be used to generate millimeter and terahertz waves by irradiating high-speed photodiodes or nonlinear crystals. In recent times, electromagnetic waves at such frequencies have become important for use in high-speed wireless communication and accurate sensing. We have developed an InAs quantum dot (QD) wavelength tunable two-wavelength emission laser with a narrow linewidth and stable emission wavelength. In this study, we investigate the change of mode separation for a two-mode laser consisting of an InP based laser diode chip with InAs QDs as the gain medium and external cavity. The laser structure with InAs QDs was grown on InP(311)B substrates by solid-source molecular-beam epitaxy. After the growth of the QD laser wafer, the ridge waveguide was fabricated. In addition, an external cavity laser system was constructed using the QD gain chip, an optical band-pass filter, and an etalon filter. The single-mode laser emission is obtained in a conventional configuration in which the peak position of transmission by the band-pass filter is set to that of the etalon filter. The emission wavelength range is 1535 nm. Further, the configuration for a two-wavelength emission laser was modified from the conventional one. We observed two-mode lasing with a frequency separation of 90 GHz, 300 GHz, and 1 THz by changing etalon filter with different free spectral range as shown in Fig. 1. Clear beat signal was observed in the interference measurement for each mode separation. Therefore, two-mode lasing can be considered to have occurred simultaneously. Mode hopping and competition were largely suppressed by using QDs as the gain medium because the QDs have a delta-function-like density of states. Therefore, each of them contributed to the laser emission individually, stabilizing the laser emission wavelength.

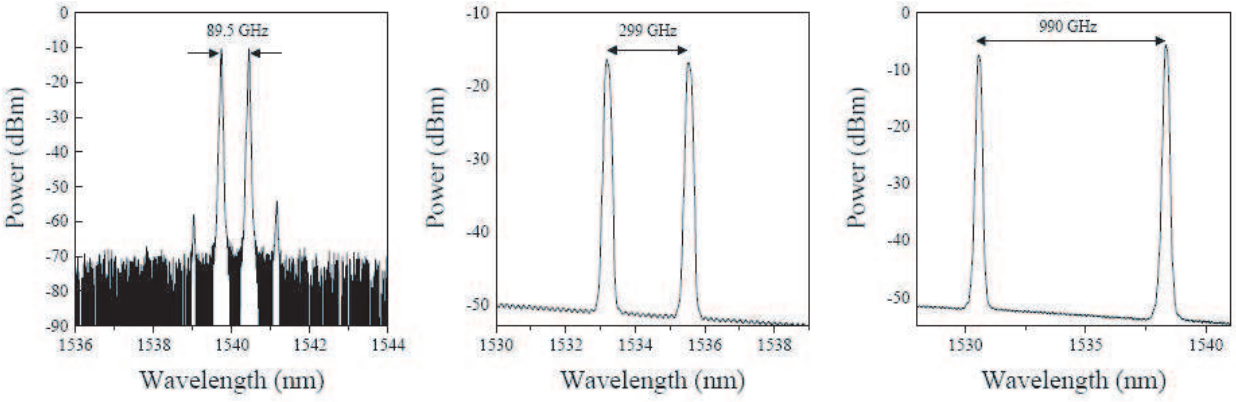

Figure 1: Two-mode lasing spectrum using QD optical gain chip with a frequency separation of (a) 90 GHz, (b) 300 GHz, and (c) 1 THz.

Energy Transfer Processes and Scintillation Performance of Ce^{3+}-doped Multicomponent Garnets

Abstract— Ce^{3+}-doped $Lu_3Al_5O_{12}$ (LuAG) and $Y_3Al_5O_{12}$ (YAG) single crystals are efficient scintillators due to their high density, short decay time and high light yield. However, their scintillating efficiency is degraded by the presence of the electron traps hampering the energy transfer to the dopant ion thus resulting in the appearance of the slow decay component and consequently, decrease of the light yield. Multicomponent garnet single crystals with general formula $(Gd,Lu,Y)_3(Ga,Al)_5O_{12}$ doped with Ce^{3+} recently became very promising candidates due to their greatly improved scintillation characteristics. In the case of optimized Gd^{3+}-Ga^{3+} composition [1, 2], the suppression of shallow electron traps and acceleration of the energy transfer towards Ce^{3+} ions results in a very significant light yield increase and strong reduction of the slow processes in the luminescence decay, see review in [3]. A further understanding of the scintillation mechanism and fine aspects of the energy transfer are of great interest for the ultimate materials optimization. Most recently, positive role of the stable Ce^{4+} centers in scintillation mechanism of Mg^{2+}-codoped garnet scintillators has also been evidenced [4].

In present contribution, the luminescent properties of undoped and Ce^{3+}-doped $(Y_{3-x}Gd_x)Al_{5-y}Ga_yO_{12}$ set of crystals with varying contents of Gd^{3+} and Ga^{3+} are investigated in wide temperature range. In undoped crystals, the Gd^{3+} emission intensity as well as decay time related to ^6P_x-^8S 4f-4f transition is dependent on the Gd^{3+} concentration. A Gd^{3+}-Gd^{3+} nonradiative energy migration was evidenced at room temperature and concentration quenching of Gd^{3+} emission takes place by energy migration to lattice defects. In Ce^{3+}-doped samples, a complex nonradiative Gd^{3+}-Ce^{3+} energy transfer is revealed, influencing the appearance of slow decay processes.

Another set of single crystal samples, Ce^{3+}-doped $(Y_{3-x}Gd_x)Al_5O_{12}$ is used to monitor the role of Gd^{3+}. The dependence of the onset of thermal quenching of Ce^{3+} luminescence on Gd^{3+} content are determined by the temperature dependence of Ce^{3+} decay times related to its 5d-4f emission transition. With the increase of Gd^{3+} content, the maxima of Ce^{3+}-related emission bands are shifted towards lower energy due to the increase in the crystal field splitting of the 5d levels, and as a consequence the onset of thermal quenching moves towards lower temperatures. Further characteristics, e.g., scintillation decay and light yield are also carefully studied.

Finally, for LuAG : Ce and GGAG : Ce samples the effect of Ce^{4+} presence is shown consisting mainly in the acceleration of scintillation response and, in the former case, in the increase of light yield.

Challenges in Materials for Medical Imaging

Cees Ronda[1], **Vashilii Khanin**[1, 2], **Herfried Wieczoreka**[1], **and Piotr Rodnyi**[2]

[1]Philips Group Innovation Research, High Tech Campus 4, 5656 AE Eindhoven, The Netherlands
[2]St. Petersburg State Polytechnic University, Polytekhnicheskaya 29, 195251 St. Petersburg, Russia

Abstract— Current medical imaging equipment relies heavily on optical materials. These materials convert the high energy of γ-rays or X-rays into electron-hole pairs across the band gap. In scintillators, these electron-hole pairs excite luminescent centers (ions or molecular ion groups), leading to the generation of light in a process called scintillation. The light generated is subsequently detected using photo detectors. Alternatively to the scintillation process, the photoconductivity due to free electrons or holes can be measured. The latter scheme is called direct conversion.

The diagnostic value of clinical images is limited by many factors, among others the optical properties of the materials used. After having reviewed the state of the art of scintillating materials, the resulting challenges will be identified. On the basis of the theoretical estimations and experimental data, the optimal conditions for maximum light output, short decay time and low afterglow will be determined.

Correlation of Luminescence Decay and Thermoluminescence of Zinc Oxide Ceramics

Abstract— Bulk scintillating ceramics based on zinc oxide (ZnO) are very promising materials for many applications due to their ultrafast excitonic luminescence. Nowadays there are a lot attempts to create such a scintillator, but slow luminescence decay component that usually appears in ZnO hinders these efforts. Exact origin of slow decay component is still controversial as both excitation and emission mechanisms demonstrate complex properties.

This work is focused on peculiarities of kinetic characteristics of the slow luminescence with the aim to elucidate energy and charge transfer processes which are responsible for the emission.

In this report, temperature evolution of luminescence decay, luminescence spectra, thermoluminescence (TL) glow curves and spectra and in range of 15–300 K of nominally undoped ZnO ceramics are presented and discussed.

The ZnO ceramics were manufactured by the uniaxial hot pressing method in a high vacuum furnace in the form of discs with a diameter of 24 mm.

At room temperature, photoluminescence (PL) spectra of the ceramics consisted of two bands: excitonic luminescence (at 377 nm) and so-called green luminescence (at 495 nm). Green luminescence had a wide band (FWHM 392 meV at 15 K). Additional unresolved emission band arises at low energy side of green luminescence under X-ray excitation.

TL emission spectra with different maximum positions were observed. The spectrum of the most intensive TL peak located at 34 K was centered at 615 nm. In temperature range of 60–160 K, TL had nearly constant intensity without any resolvable peaks. Peaks of TL with relatively small intensity were also observed at 231 K and 291 K. TL in range of 60–160 K and peaks at 231 K and 291 K had the same emission maximum as green luminescence in PL spectra. TL emission peak centered at 720 nm appears at temperature of $\sim$ 170 K. Emission at 720 nm was not detected in emission spectra under X-ray or photoexcitation and appears only in TL.

At temperatures below 20 K, complex green luminescence decay process which includes kinetics of tunneling recombination, exponential component and first order hyperbola was observed. At the temperatures above the most intensive TL peak temperature the exponential component of decay disappears. With rising temperature in range 60–160 K where TL intensity is constant, absolute intensity of hyperbolical component of decay increases. With further rising of temperature, quenching of hyperbolic decay was observed and decay shape evolved into stretched exponential decay.

Processes responsible for the luminescence decay kinetic and defect spectroscopy of the studied ZnO ceramics are presented and discussed.

Enormously Long-wavelength Luminescence of SrS:Ce

[3]Wroclaw Research Centre EIT+, 147 Stablowicka Street, 54-066 Wroclaw, Poland

Abstract— The presentation will show a possibility to generate a new, red Ce^{3+} luminescence in SrS:Ce both in high- and low-concentration compositions. A comprehensive spectral characteristics of the long-wavelength emission will be given together with its relationship to the regular bluish green luminescence.

SrS:Ce is a known luminescent material with an efficient emission appearing in the 450–600 nm region and peaking around 480 nm. Occasionally, a red-shifted emission in SrS:Ce was reported. Yet, its appearance was always connected with high Ce concentrations and consequently with luminescence of Ce^{3+}-Ce^{3+} pairs rather than isolated dopantions.

In this presentation we shall prove that an extremely long-wavelength, abnormal luminescence of SrS:Ce may be generated even in a lightly doped material (0.05%). We shall show that at room temperature its intensity may harmonize with the intensity of the regular emission even if the excitation ($\sim$ 425 nm) goes only to the regular center. Compared to the regular emitting Ce^{3+} ions, the new emitting center has much different excitation spectrum and altogether both luminescent centers absorb the whole UV part of radiation as seen in Fig. 1. We shall also show that the abnormal luminescence has all the characteristics of Ce^{3+} emission its decay time is about 35 ns, while the regular center decays with the time of 27 ns. The long-wavelength luminescence is composed of two components separated by $\sim 2200\,cm^{-1}$, which is the characteristic value of the spin orbit splitting of the $4f^1$ configuration of Ce^{3+}. Spectroscopic data in the 25–450 K range of temperatures will be presented and discussed.

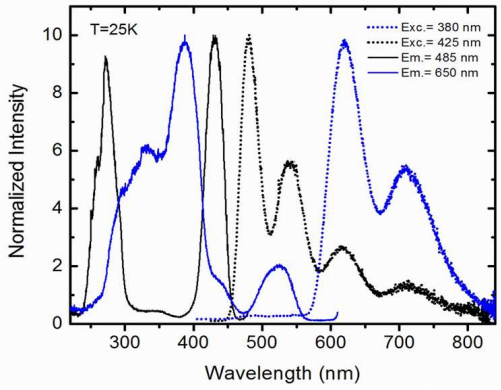

Figure 1: Emission and excitation spectra revealing existence of two different Ce^{3+} luminescence centers in SrS:Ce after a specifically designed processing.

Integrated Spectral Shapers in Silicon Photonics for Generating Chirped Microwave Pulses Based on Optical Spectral Shaping and Wavelength-to-time Mapping

Lawrence R. Chen
Department of Electrical and Computer Engineering
McGill University, Montreal, QC H3A 0E9, Canada

Abstract— Chirped microwave pulses (CMPs) have been used widely in various applications, including spread spectrum communications, microwave remote sensing, and microwave computed tomography. While such waveforms can be generated in the electronic domain, their bandwidths, chirp rate, and central frequencies are limited by the sampling rate of digital electronics. On the other hand, photonic generation of CMPs offer the possibility of achieving central frequencies of tens to hundreds of GHz as well as significant chirp rates, thereby supporting tens of GHz of bandwidth. Photonic approaches also provide increased flexibility, particularly with regards to reconfigurabilty and tunability. The typical system implementation involves some form of optical pulse shaping to synthesize the desired temporal waveform followed by photodetection. To this end, a number of techniques have been employed, such as those based on direct space-to-time pulse shaping, temporal pulse shaping, and optical spectral shaping followed by wavelength-to-time mapping. The latter is straightforward to implement and involves a broadband source, e.g., from a mode-locked fiber laser, a spectral shaper, and a dispersive medium. The spectral shaper modifies the spectrum of the pulsed source, typically in amplitude only, and the shaped spectrum then propagates through the dispersive medium where a wavelength-to-time mapping process takes place, i.e., the shape of the spectrum is mapped to the time domain. The resulting temporal signal corresponds to the microwave waveform which is detected by a photodetector. The key component is the spectral shaper and in this presentation, we review recent progress on developing integrated spectral shapers in silicon photonics. In particular, we describe devices based on cascaded ring resonators as well as those incorporating Bragg grating structures.

Engineered Optical Parametric Processes for Wideband RF Analyzer and Pulse Generation

Camille-Sophie Brès
Ecole Polytechnique Fédérale de Lausanne, Photonic Systems Laboratory (PHOSL), STI-IEL
Station 11, CH-1015 Lausanne, Switzerland

Abstract— Optical parametric processes based on the $\chi^{(3)}$ nonlinear tensor of a waveguide medium have been used successfully for the complex manipulation of optical signals. The advantages of such processes are numerous and noteworthy are the instantaneous response, the efficiency or the large bandwidth. The versatile nature of parametric devices has been exploited for the advent of phase sensitive amplifiers and wideband amplifiers, for the generation of light in distant spectral windows but also for the development of unique processing devices capable of wavelength conversion, multicasting or sampling.

Recently, the development of dispersion engineered parametric fiber links has led to new possibilities in terms of wideband multicasting, analog signal processing and pulse shaping. For example photonic assisted architectures for instantaneous frequency measurements have attracted significant interest, mainly driven by the increasing physical bandwidth used in radar systems. Architectures based on high quality copying of microwave signals by wavelength multicasting in self-seeded mixers and subsequent filtering, trade frequency non-degeneracy of the newly generated copies for ease of filtering. Such scheme also enables compensation for filter fabrication tolerance and dynamic bandwidth/channel spacing reconfiguration by controlled adjustments of copy positioning. Recently filterless wideband channelizer have also been realized based on the similar principle. Another interesting aspect of engineered parametric processes lies in their potential for the generation and shaping of short optical pulses. Indeed it has been shown that the generated pulse shape and pulse duration depend on the signal frequency relative to the pump frequency such that bounding of the phase matching in two-pump parametric amplifiers enables the precise control of the generation process.

In this paper, we review the principle behind parametric wavelength conversion and distortion free wideband multicasting in engineered fiber based devices for applications to parametric channelizers and pulse generators.

The Path towards 100 Gbit/s Wireless Communications

Abstract— Successful operation of wireless communication links with capacities above 100-Gbit/s require sub-THz carrier frequencies, pencil beams, usage of novel modulation techniques and novel photonic-electronic devices. We review a recent 100 Gbit/s wireless link demonstrations and discuss steps to make such systems more viable.

Introduction: Wireless transmission is forecast to grow by a 61% annual compound growth for the next five years [2]. Such growth is only sustainable if fundamental changes in the design of future wireless networks are adopted soon.

A possible path to vastly extend the capacity is to shift the RF carrier to the millimeter waves with frequencies above 100 GHz [3]. As an example, the frequency range between 200 GHz and 300 GHz is characterized by low atmospheric losses where wireless links can be operated even under averse weather conditions [4].

Moving towards higher frequencies will also make it necessary to increase the antenna gain significantly to offset the increased link losses. Thus, narrower beams, or pencil beams will be needed. In return, ultra-fast, continuously tunable true-time delays (TTDs) will be necessary as building blocks in phased array feeder networks to keep such systems flexible and to distribute the information spatially [5].

Additionally, multiple-input multiple-output (MIMO) will become more attractive as it offers another degree for scaling. It will ultimately be needed in order to enhance the capacity of base stations. Fortunately, with an increase in frequency, the constraints due to limited space for the number of antennas that goes along with MIMO will relax. This is particularly important on the user side C where space is scarce [3].

MmWave systems also have to overcome distinct hardware constraints [3]. Major constraints come from the high power consumption of mixed signal components, chiefly the analog-to-digital converters (ADCs) and digital-to-analog converters (DACs). In a conventional approach each antenna would be connected to a single high-rate ADC/DAC system. Equipping every antenna would not only lead to an immense surge in cost but also require large computation powers together with a huge power consumption. MmWave communications is thus unlikely to happen unless there is a huge leap forward in semiconductor technology. However, such constraints can be overcome by a clever hybrid approach based on photonics and microwave communications. Key microwave-photonic elements include true-time delay elements, high-speed photo detectors that can directly translate an optical signal into a microwave signal and microwave-to-photonic receivers.

In this talk we will review some recent approaches on wireless communication links with data rates up to 100 Gbit/s [1]. We will review some of the photonic-electronic hardware implementations.

Broadband Microwave Signal Acquisition by Photonics-assisted Compressive Sampling

Hongwei Chen[1, 2], **Qiang Guo**[1, 2], **Minghua Chen**[1, 2], **and Shizhong Xie**[1, 2]

[1]Tsinghua National Laboratory for Information Science and Technology (TNList), China
[2]Department of Electronic Engineering, Tsinghua University, Beijing, China

Abstract— Microwave signal acquisition plays a key role in radar, electric warfare, communication and other applications. The bandwidth of signal acquisition becomes larger and larger. As the signal bandwidth is beyond to ten GigaHertz, traditional Nyquist Sampling needs ultrafast ADCs used for signal acquisition. Meanwhile, there is a problem of big data but with high redundancy for that signals occupies only several sub bands in so large bandwidth. This means that many data are useless. How to reduce the sampling rate and the redundancy of data attracts researcher's attention. Photonic-assisted compressive sampling supplies a potential candidate to solve this problem. Our work focuses on breaking the limit of photonic CS's bandwidth from PRBS pulse rate and increasing the bandwidth up to tens of GHz. We propose to adopt nonlinear time-delayed PRBS pulses for spectrum compression, which can construct PRBS pulse with higher repetition rate and meanwhile guarantee stable signal recovery in broad band. Based on this, large-bandwidth compressive sampling scheme is proposed, and compressive sampling with 20-GHz bandwidth is successfully realized with four delayed PRBS pulses with 10.16-GHz pulse rate. Also, for the first time, a photonic-assisted CS system is proposed to acquire radar pulse steams. An IQ modulator and a photodetector are utilized to perform the spectral compression of the test pulses. A sliding window-based recovery algorithm is proposed to guarantee the signal sparsity within a time window and realize a continuous signal reconstruction. In the experiment, about 100 radar pulses ranging from 500 MHz to 5 GHz are acquired within 100 μs and exactly recovered with a 520-MHz ADC, experimentally demonstrating the feasibility of the proposed system in spectral estimation for radar pulses.

Abstract— On-chip Stimulated Brillouin scattering (SBS) has recently been exploited for realizing microwave photonic sources and signal processing. On-chip slow-light with a tunable delay of 23 ns and microwave photonic notch filter with ultrahigh selectivity (3 dB bandwidth $\sim$ 30 MHz) and wide frequency (0–30 GHz) and bandwidth tunability ($\sim$ 30–90 MHz) were demonstrated.In this talk, we present recent advances in microwave photonic signal processing exploiting SBS in photonic circuits.

Introduction: Stimulated Brillouin scattering is the strongest optical nonlinearity that results from three-wave interaction among two optical waves and an acoustic wave. Counter-propagating optical waves with frequencies ω_p (pump) and $\omega_s = \omega_p - \Omega_B$, where Ω_B is the frequency of the acoustic wave in the medium, create the acoustic wave (Ω_B) that in turn induces a coupling between the pump and Stokes signal (ω_s) generating a gain resonance at the Stokes frequency. The amplitude and phase response associated with the gain resonance is the key to realize slow-light, dynamic gratings, microwave signal processing and Brillouin lasers [1–3].

On-chip SBS Microwave Photonics: Realization of on-chip SBS requires careful choice of material and device design. A device designed to tightly confineboth optical and acoustic modes(see Fig. 1) and made from a material with large refractive index and elasto-optic coefficient is the key for on-chip SBS [4]. Recently on-chip SBS was realized in a 7 cm long photonic chip and was exploited for slow-light induced tunable delay(see Fig. 1) [5] and realizing a ultra-high selectivity microwave photonic notch filter (~ -55 dB) with wide frequency (0–30 GHz) and bandwidth ($\sim$ 30–90 MHz) tunability using low power of 8 mW (gain $\sim$ 0.8 dB) (see Fig. 2)) [6]. For the SBS slow-light tunable delay of $\sim$ 23 ns was achieved with a gain of 23 dB, which can be used in microwave signal processing tasks such as filters and phased array antenna.

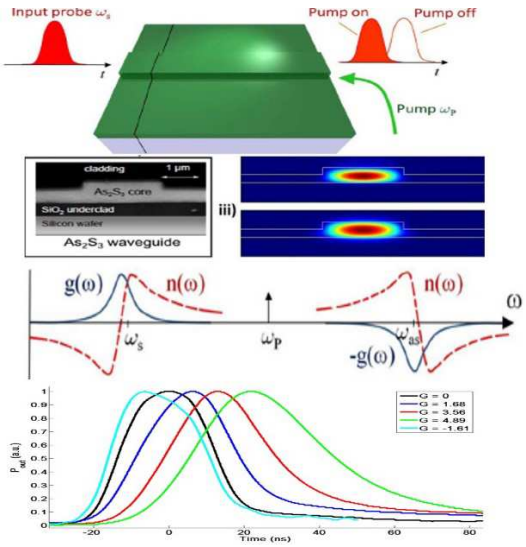

Figure 1: SBS slow-light in a Chalcogenide photonic chip demonstrating fractional delay of nearly one pulse width for a 25 ns long input Gaussian pulse [5].

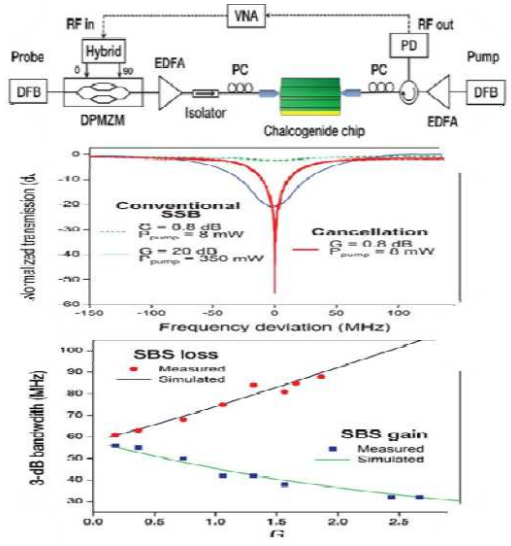

Figure 2: Photonic chip based microwave photonic notch filter with ultrahigh selection and wide tunability using low pump power of 8 mW [6].

On-chip Microwave Signal Processing Platforms Based on Silicon Photonics Technologies

M. Burla and J. Azaña
Institut National de la Recherche Scientifique, Énergie, Matériaux et Télécommunications (INRS-EMT)
800, de la Gauchetière Ouest, Montréal, Québec, H5A 1K6, Canada

Abstract— Microwave photonics (MWP) signal processing by means of photonic integrated circuits has attracted a large amount of attention in recent years, as an enabling technology for a number of functions not attainable by a purely electronic approach. In particular, waveguide Bragg grating (WBG) devices on silicon constitute a particularly attractive solution, thanks to their high compactness and flexibility in producing arbitrarily defined amplitude and phase responses. In this talk a brief overview of recent advances in the field of integrated WBGs applied to microwave photonics will be given, with emphasis on a number of recent demonstrations by our group of the use of WBGs for microwave and ultrafast optical signal processing. Application examples include broadband tunable RF filters, true-time-delay lines and phase shifters with large instantaneous bandwidth, optical pulse shapers operating in the THz regime, and instantaneous frequency measurement systems on-a-chip. A perspective on the exciting possibilities offered by the silicon photonics platform in the field of MWP will be given, potentially enabling integration of highly-complex active and passive functionalities with high yield on a single chip.

Microwave Photonics Techniques Supporting Flexible Wireless Communications Links

Abstract— Wireless data communication links supporting the next generation 5G and beyond mobile networking face a set of engineering challenges related to the mandatory operation at mmw and higher frequency bands, provide capacities above 10 Gb/s, satisfy latency, robustness, flexibility and low complexity constrains. Microwave photonic techniques support a number of key functionalities required to satisfy above-mentioned demands. We will review, in particular, experimental realizations of a number of functionalities such as mmw generation, detection, optical fiber transport and multi-Gigabit data transmission implementation exploiting photonic techniques.

Instantaneous Microwave Frequency Measurement System Using On-chip Nonlinear Optics

David Marpaung
CUDOS, School of Physics, University of Sydney, NSW 2006, Australia

Abstract— Instantaneous frequency measurement (IFM) systems are essential in various defense, electronic warfare, and countermeasure applications. IFM systems are required to rapidly determine a received signal frequency with low error, without actually measuring the frequency. Most of IFM systems code the frequency information to another measureable quantity like power through a function known as amplitude comparison function (ACF). Recently, a number of photonic-assisted IFM systems have been proposed, taking advantage of the wide bandwidth and reconfigurability of photonic system. However, most techniques were based on long and bulky optical fibers. Not only this approach is not attractive in terms of size and weight, but long optical fibers also ad latency to the IFM system. It is thus imperative to integrated IFM systems in compact photonic chips to reduce latency and to achieve advantages in size, weight and power consumption.

In this work, we consider IFM systems that exploit optical nonlinearities in a photonic chip. The use of optical nonlinearities added values such as ultra-low estimation error and simplification of the IFM system. In one demonstration we harness stimulated Brillouin scattering (SBS) in a 7-cm chalcogenide photonic chip to achieve a hybrid IFM system that combines the characteristics of a scanning receiver and an ACF to estimate a wide range of RF frequencies from 7–35 GHz with ultra-low error below 1 MHz. In another demonstration, we report an IFM system based on four-wave mixing (FWM) in a 33 cm thick silicon waveguide. The use of this platform allows us to access higher signal to noise ratio beyond that of a previous demonstration in a length of highly nonlinear fiber. Over 40 GHz frequency range we achieved lower error in the long silicon waveguide compared to that of the fiber system.

Modeling of Coaxial Feed Topologies

Guy A. E. Vandenbosch[1], **Xuezhi Zheng**[1], **and Victor V. Moshchalkov**[2]

[1]Department of Electrical Engineering (ESAT-TELEMIC), KU Leuven, Belgium
[2]Institute for Nanoscale Physics and Chemistry (INPAC), KU Leuven, Belgium

Abstract— In this talk, the basic coaxial feed is revisited. The case under study is a coaxial feed exciting a grounded planar structure of arbitrary layers. This type of feeding structure occurs in a large number of practical microwave devices and antennas. A highly accurate model is given for this widely used topology. The core of the model is to make use of the eigenmodes of a conducting parallel plate system which can be derived analytically to reconstruct the field in the actual configuration. This is based on the physical observation that the differences between the modal fields found in the parallel plate system [1–3] and the ones of the actual configuration are negligible. As a result, we can build a highly accurate equivalent circuit model for the coaxial feed in a general multilayer structure. This circuit model is specifically simplified for two most commonly seen cases: one layer and two-layer structure. Since the model introduces only one unknown for the entire coaxial feeding topology, its numerical complexity is reduced to the same as for the simplest possible model, i.e., the imposed constant probe current model. The way of working opens possibilities for developing full time-domain methods to analyze the susceptibility of microwave electronic circuits based on the natural modes of a multilayer structure to pulsed-field electromagnetic (EM) disturbances [4].

Pulsed EM Field Propagation in Cylindrically Layered Structures

Martin Štumpf[1] and Sven Nordebo[2]

[1]SIX Research Centre, Brno University of Technology
Technická 3082/12, Brno 616 00, The Czech Republic
[2]Department of Physics and Electrical Engineering, Linnnæus University
Hus D 1152, Växjö 351 95, Sweden

Abstract— Power-cable fault localization using time-domain reflectometry requires an efficient computational technique for the evaluation of pulsed electromagnetic fields in cylindrically layered structures. A robust way to handle the problem is to perform a contour complex integration at a number of frequency points and carry out an inverse fast Fourier transformation with respect to time [1]. Alternatively, one may employ a slowness representation along the cable axial direction in combination with a one-sided Laplace time transformation and obtain time-domain results more or less directly. This is exactly the main subject of the present contribution in which it is shown that the pulsed electromagnetic response of a cylindrically layered cable can be constructed with the aid of Cagniard-DeHoop (CdH) technique [2] and a numerical Laplace-transform inversion method in the intermediate step. Specifically, the pulsed electromagnetic wave field in N-layered medium can be then composed of generalized-ray time-domain constituents whose generic slowness-domain representation has the following form

$$\hat{K}(r,z,s) = \frac{s}{2\pi i}\int_{p=-i\infty}^{i\infty} \exp\left\{-s\left[pz + \sum_{K\in\Gamma}\gamma_K(p), \varrho K\right]\right\}\tilde{Q}\,(r,p,s)\,dp \tag{1}$$

where $\Gamma = \{1,\ldots,N\}$, z and r are the axial and radial spatial coordinates, respectively, $\{s \in \mathbb{R};\, s > 0\}$ is the (time) Laplace-transformation parameter, ϱK denotes the radial propagation path traversed in K-th cylindrical shell and $\gamma_K(p)$ is the corresponding propagation coefficient given as $\gamma_K(p) = (1/c_K^2 - p^2)^{1/2}$ with $\mathrm{Re}(\cdot)^{1/2} \geq 0$. It is worth noting that the factor $\tilde{Q}(r,p,s)$ is s-dependent and consists of a combination of the propagation coefficients and the scaled modified Bessel functions. Thanks to this property, the standard CdH procedure has to be supplemented with numerical Laplace transform inversion. As the latter is inherently an ill-conditioned procedure [4, Section 2.1], its evaluation requires a special attention. Finally, once the inversion of (1) is carried out, the resulting wave motion is composed from the corresponding body- and head-wave time-domain constituents that are propagating, reflecting and refracting upon interfaces between cylindrical layers. Sample numerical experiments concerning canonical configurations will be presented at the 36th PIERS.

Wiener-Hopf Analysis of TM Wave Reflection by a Step Discontinuity on the Junction of Two Coaxial Waveguides with Perfectly Conducting and Impedance Walls

G. Çınar[1], S. Akşimşek[2], B. Nilsson[3], S. Nordebo[3], and Ö. Yanaz Çınar[1]

[1]Eskişehir Osmangazi University, Turkey
[2]İstanbul Kültür University, Turkey
[3]Linnæus University, Sweden

Abstract— In this study, the reflection of TM waves by a junction of a perfectly conducting coaxial waveguide with a step discontinuity on its inner wall and an impedance coaxial waveguide is analyzed rigorously by Wiener-Hopf technique (see Fig. 1(a)). The problem represents two main scattering mechanisms which occur in the measurement setup for the experiments performed on a 80 km long High Voltage Direct Current (HVDC) power cable in a factory and on the 250 km long Baltic HVDC power cable [1]. The effect of the step discontinuity alone on the scattered fields has been studied by the authors recently in [2, 3].

In order to determine the reflection coefficient for this problem, one first needs to analyze TM wave propagation along the waveguide junctions shown in Fig. 1(b) and Fig. 1(c). The scattering coefficients obtained by solving these two problems can then be taken into account to apply the generalized scattering matrix method which eventually provide the reflection coefficient related to the original problem.

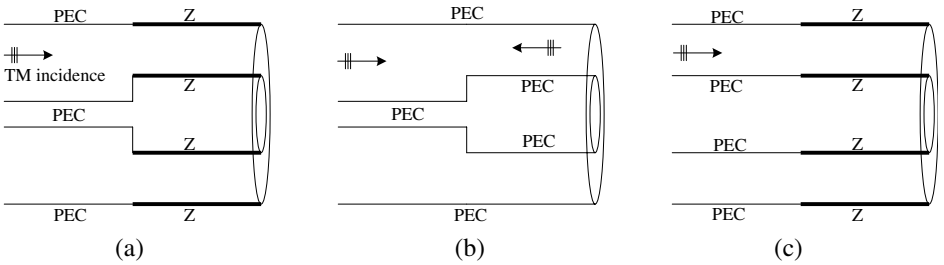

Figure 1.

The scattering coefficients for the problems given in Fig. 1(b) and Fig. 1(c) are obtained simply by extending the formulations described in [3] and [4] (which are done for only TEM modes) to the cases of TM wave incidences. In addition to these, the problem in Fig. 1(b) is also solved when the TM wave is incident from the opposite direction. With the help of these scattering coefficients and the generalized scattering matrix method, the reflection coefficient for the original problem is determined. The numerical results are compared to the ones obtained by applying mode-matching technique directly to the problem shown in Fig. 1(a).

Determination of Normalized Electric Eigenfields in Microwave Cavities with Corners

J. Helsing[1] and A. Karlsson[2]

[1]Centre for Mathematical Sciences, Lund University, Box 118, Lund 221 00, Sweden
[2]Department of Electrical and Information Technology
Lund University, Box 118, Lund 221 00, Sweden

Abstract— We show that high-order convergent Fourier-Nyström schemes for the MFIE can be efficiently implemented when applied to cavities with non-smooth PEC surfaces. Our explicit kernel-split panel-based Fourier-Nyström scheme relies on an underlying 16-point Gauss-Legendre quadrature and a technique called recursively compressed inverse preconditioner (RCIP). It gives a convergence of 16th order and a nearly optimal accuracy that is reached at very few discretization points per wavelength along the generating curve of the cavity. The scheme determines surface current densities and surface charge densities that, via a post-processor, are carried over to normalized electric and magnetic eigenfields at all positions inside the cavity, also close to surfaces where integral equation techniques usually encounter difficulties. At corners with opening angles larger than 180 degrees there are always components of the electric or magnetic fields that are singular. The RCIP technique manages to accurately resolve such singularities down to any desired spatial scale. The post-processor takes advantage of a new surface integral expression for the normalization.

In our collaboration with scientists at the synchrotron light source MAX IV and the European Spallation Source (ESS), both under construction in Lund, Sweden, we have seen a need for improved numerical tools for accurate wakefield evaluations in particle accelerators. This is the motivation for our project. Today, all high energy particle accelerators use microwave cavities for particle acceleration by means of eigenfields, excited by external sources. The cavities consist of one, or several, axially symmetric cells, where in each cell the excited eigenfield corresponds to the TM_{010} mode in a cylindrical cavity. In addition to the eigenfields excited by the external sources, the beam of particles excite wakefields that consist of a large number of higher-order modes (HOM). These wakefields affect the trajectories of the particles and, by that, the quality of the beam. To prevent that harmful wakefields are excited in the accelerator, numerical simulations are used both in its design process and during operation. These simulations need to cover a frequency band up to at least 10 times the frequency of the external source. Our method has been developed in several steps [1–3], to cover more and more applications. It is now at the stage where it can evaluate wakefields in linear accelerators and storage rings with high accuracy and by that become a tool in the design of accelerators.

Abstract— The multipactor effect is an electron discharge that may appear in particle accelerators and microwave devices such as waveguides in satellite on-board equipment under vacuum conditions. This effect has been widely studied, and many investigations have been focused on the prediction of multipactor breakdown in a wide variety of microwave passive components for signals of different frequency and power levels, in order to prevent their damage. Many works [1, 2] take advantage of available susceptibility charts in empty parallel-plate waveguides obtained with analytical models [3], and they are directly used to predict multipactor breakdown in the component under study, which is going to happen in the point of highest field intensity. Thus, they are aimed to determine such highest field intensity region, which is generally the smallest device gap. However, such susceptibility diagrams do not take into account important effects such as the dependence of these diagrams on elastic and inelastic electrons, as well as the 3D character of the motion of the electrons inside the waveguide, or the non-uniform nature of the electromagnetic fields in some particular cases.

In the last years, the authors have developed a 1D model for studying the multipactor effect in partially dielectric-loaded rectangular waveguides [4–6].

In this work it is investigated, in the parallel-plate waveguide case, how the 1D, 2D or 3D motion of the electrons inside the waveguide can affect the generalized susceptibility diagrams, by means of a developed model capable of tracking the exact trajectory of multiple effective electrons which includes effects such as the spreading of the secondary electron departure kinetic energies or the dependence on elastic and inelastic electrons. On the other hand, a comparative study of the susceptibility charts in a parallel-plate and in its equivalent rectangular waveguide with the same height is performed, showing how the inhomogeneity of the electric field inside the waveguide modifies the multipactor region with respect to that predicted by the parallel-plate waveguide case.

The results of this study are going to be extended to a partially dielectric-loaded rectangular waveguide, which is a problem of great interest in the space industry that has not yet been rigorously investigated in the literature.

Power Line Noise Measurements and Statistical Modelling in the Time Domain

A. M. Nyete, **T. J. O. Afullo**, **and I. E. Davidson**
Discipline of Electrical, Electronic and Computer Engineering
University of KwaZulu-Natal, Durban, South Africa

Abstract— The power grid provides a readily available medium for communication purposes. This means that the power grid is the cheapest communication medium since no new cabling is required. However, the power grid was design for the delivery of power and not for communication applications. As such no considerations have been made in the design of power networks to accommodate communication services. However, with the application of current digital signal processing techniques, the power network can be adapted to support communication services. This adaptation requires a full understanding of the power network characteristics, which are noise, distortion and channel effects. These power network characteristics are studied through measurements, modelling and characterization. The results obtained through such studies are then utilized in the redesign of conventional receiver structures and modulation schemes so as to adequately suit them for powerline communication applications. In this paper, we present time domain power line noise measurement results, and then apply a statistical technique for the characterization and modelling of the time domain noise amplitudes in typical indoor power networks. The results obtained are validated through error analysis. The models developed are vital in the optimization of communication applications through the power network.

Analytical Study of Large-scale Current Commutation Processes in Multiply-connected Transmission-line Networks

Dierk Bormann
ABB Corporate Research Väteräs, Sweden

Abstract— In a transmission line network which is multiply connected, like for instance a future DC cable grid, low-frequency or DC currents may temporarily circulate in large loops. Such loop currents can for instance be generated by the intentional disconnection of a current carrying link in the network, or by the unintentional occurrence of a ground fault. If the system has more than one grounding point, or in the case of a ground fault, part of the loop current path may pass through ground. The classical references on the impedance seen by such "ground return currents" are papers by Carson [1] and Pollaczek [2].

Commutation processes between globally different current paths in the system are then expected to be controlled by the effective resistances and inductances seen by corresponding loop currents, the loop inductances being substantially larger than typical differential-mode line inductances. The effects of these loop inductances cannot be accounted for by common system transients simulation programs which receive as input information about the topology of the network only (and not about its geometry).

In this talk, I will study the loop currents by analytical methods. Due to the skin effect in a conducting ground, the loop-current inductances are frequency dependent even at very low frequencies, which leads to surprisingly complex behavior of the current commutation processes. I will present an analytical solution of a slightly idealized model which however captures the essential features of the commutation process. The physical meaning of this solution will be discussed by comparing it with different approximations.

Estimation of Electromagnetic Parameters of Cable Steel

Y. Ivanenko and S. Nordebo
Department of Physics and Electrical Engineering, Linnæus University, Sweden

Abstract— Power losses related to the skin-effect, induced eddy currents and hysteresis losses, are all very important electromagnetic phenomena to consider in the design of high-voltage AC power cables [3]. Due to the complicated structure of these cables, which consist of a variety of material constituents and multiply twisted conductor bundles, it is a non-trivial task to accurately predict the effect of these loss mechanisms. Presently, it is for this purpose that analytical techniques [4] as well as numerical techniques based on Finite Element Modeling [1, 2] and the Method of Moments [5] are being developed.

In this presentation, we will address the problem of accurately estimating the conductivity as well as the magnetic hysteresis of the cable steel armour, as an important input parameter in the above mentioned modeling quest. In particular, we will address the problem of estimating the electromagnetic parameters of the armour with proper account taken to the dimensionality of the test object. A test transformer is built on a single straight wire of magnetic armour steel and wound with very thin copper wires. The transformer is modeled based on the conductivity of the steel and a linearization of the magnetic hysteresis by using a complex valued permeability. The parameters are then determined as an inverse problem based on measurement data and a localy convex optimization. Future work is aiming to validate the accuracy of the estimation based on a numerical simulation of the non-linear hysteresis phenomena.

Periodic Green's Dyadics for Helical Current Distributions

S. Nordebo and Y. Ivanenko
Department of Physics and Electrical Engineering, Linnæus University, Sweden

Abstract— Power losses related to the skin-effect, induced eddy currents and hysteresis losses are all very important electromagnetic phenomena to consider in the design of high-voltage AC power cables [6]. Due to the complicated structure of these cables, which consist of a variety of material constituents and multiply twisted conductor bundles, it is a non-trivial task to accurately predict the effect of these loss mechanisms. Presently, it is for this purpose that analytical techniques [7] as well as numerical techniques based on Finite Element Modeling [2, 3] and the Method of Moments [8, 10] are being developed.

Helical waveguide structures have been treated previously such as, e.g., with helical sheaths [1, 4], and approximations for wire helices [5, 9]. However, to our knowledge there has not been any general presentation regarding the analytical modeling of the electromagnetic fields generated by a helical current distribution. The purpose of this presentation is to provide explicit formulas for the periodic electric and magnetic Green's dyadics [7], and to explain how they can be used to calculate the fields generated by an arbitrary helical current distribution. As an application example, the method is used in an approximate calculation of the induced currents in the metal sheaths and armour of a three-phase power cable.

On Shape Reconstruction in Waveguide Like Structures

M. Norgren and M. Frid Dalarsson
KTH Royal Institute of Technology, Sweden

Abstract— The inverse problem of shape, or boundary, reconstruction has several applications. A potential application may be diagnosing the interior of electrotechnical components, like the winding structure inside a power transformer. For this kind of problem, we will discuss a couple of approaches based on waveguide modelling and theory. The first approach amounts to a full wave modelling of the winding structure, where the interspacing between the conductors is envisaged as a waveguide network. Using propagators and mode-matching, the scattering parameters can be determined and related to the locations of the individual winding conductors, which can be reconstructed by using optimization. This approach, we have verified in principle on generic parallel plate and cylinder geometries. However, a conclusion is that in realistic cases the modelling becomes exceedingly massive and the reconstruction procedure too slow, computationally. The second approach amounts to simplify the model, by in the first step to replace a sheet of winding conductors with an equivalent surface, modelled by a suitable boundary condition. The second step is motivated by that in a power transformer only small deformations of the windings are tolerable, since otherwise the transformer will fail. Hence, we focus on small deformations, which to some extent can be handled by linearizing the problem by means of perturbation theory. This amounts to replace the deformation with equivalent surface currents that radiate the scattered field into the unperturbed waveguide. We will present results for windings modelled as PEC surfaces, inside parallel plate, rectangular and coaxial waveguides, where the deformation varies along the direction of propagation. Our results so far are promising in that the linearized theory can be used for reconstructing unexpectedly large surface deformations, beyond what would be tolerable in a power transformer winding. Ongoing work on reconstructing surfaces deformed in two directions will also be discussed.

An Improved Form of Bessel Functions for Accurately Simulating Higher Order Modes in a Cylindrical Waveguide

M. C. Lin
Department of Electrical and Biomedical Engineering
Hanyang University, Seoul 133-791, Korea

Abstract— A cylindrical waveguide is widely used in electromagnetic (EM) applications for EM wave energy transportation or coupling inside or between systems. To study the wave transport in a cylindrical waveguide, the analytic waveguide theory based on Maxwell's equations is employed in those cases retaining homogeneity and cylindrical symmetry and Bessel functions are obtained for characterizing the guiding modes excited. In general, we use a numerical method such as finite element analysis or finite-difference method to study those non-homogeneous or non-symmetric waveguide systems. We could study a waveguide system either in the frequency domain or in the time domain. The former is good for characterizing stationary behavior and the latter is better for studying transient or time dependent phenomena. For higher order mode excitation in a cylindrical waveguide, a higher order Bessel function is required and numerically an expansion of this function in terms of a series is mostly used. However, the accuracy of mode pattern excited is getting worse when one pushes it to higher and higher order mode with a limited number of expansion series. This inaccuracy usually introduces unwanted or unphysical spurious modes and causes numerical errors in the simulation results. In order to excite a clean higher order mode, we have developed a delicate wave launcher using an improved form of Bessel functions. Since the excitation is located either in the ends (ports) or a cross section somewhere along the waveguide, for a TE or TM mode, the longitudinal magnetic or electric field component respectively is used only for the wave launching source according to the waveguide theory, i.e., all six components of electric and magnetic fields are not independent and all the transverse components can be expressed in terms of the two longitudinal components. This technique has been demonstrated successfully in our finite difference time domain simulations. An introduction of this approach and detailed results will be presented.

The Novel Mixed Spectral Element Method for Waveguide Problems

Na Liu[1] and Qing Huo Liu[2]

[1]Institute of Electromagnetics and Acoustics, Xiamen University, China
[2]Department of Electrical and Computer Engineering, Duke University, USA

Abstract— The increasing complexity of microwave and optical waveguide structures requires highly accurate and efficient simulation methods to calculate waveguide modes and to optimize geometrical and material parameters for waveguide engineering, and so far the most successful one is the finite element method (FEM). By discretizing the waveguide cross section into a number of triangular or quadrilateral elements and applying the variational formulations, the FEM can be used to perform eigenmode analysis of waveguiding structures for their mode dispersion curves and cut-off frequencies. It has been proved by previous researchers that by using the tangential-vector finite element method (TVFEM), the propagation modes in a waveguide can be obtained without the occurrence of nonzero spurious solutions. However, there are still spurious modes confined to the subspace of zero eigenvalues. These spurious modes make it difficult to determine which modes are physical. Furthermore, at a given frequency, these spurious modes will slow down the convergence of desirable modes and cause additional computational complications. In order to suppress the spurious modes with zero eigenvalue, the divergence free condition (i.e., Gauss' law) must be enforced.

In this paper, a novel high-order mixed spectral element method is proposed for the analysis of anisotropic, lossy, and open waveguides. The new variational formulation incorporating Gauss' law into the vectorial wave equation is completely free of spurious modes. It utilizes the edge-based curl-conforming Gauss-Lobatto-Legendre (GLL) polynomials to approximate the tangential vector of the electric field and the nodal-based scalar GLL basis functions to discretize its longitudinal component to obtain the highly accurate simulations. By employing the mass-lumping technique only a smaller generalized eigenvalue problem needs to be solved. The new contributions of this work includes: (a) For the first time the mixed SEM is made free of all spurious modes in a waveguide problem, and the smaller eigenvalue equation speeds up the computation. (b) Both lossy and anisotropic media are made possible in the mixed SEM for a waveguide problem. (c) The perfectly matched layer (PML) has been demonstrated in the mixed SEM for open waveguides. Furthermore, several numerical examples are given to verify that the higher-order spectral element method is free of any spurious eigenmodes and has spectral accuracy with the propagation constant.

Wireless Power Transmission and Harvesting

A High Efficiency WPT System Using Helix Antennas

B. Dubovski and M. Haridim
HIT — Holon Institute Technology, Israel

Abstract— The field of wireless power transmission (WPT) has been growing rapidly in the last few years. WPT allows to remove the need for a wired connection in both short range and long range applications, ranging from laymen, which use it to charge their personal devices or medical devices, to large companies, which take advantage of the technology where they cannot use wired connectivity, furthermore, the use of WPT can help the environment, each year more than 15,000,000,000 non-rechargeable batteries are being thrown away, by using WPT we can reduce these numbers substantially. The gain of the transmitting and receiving antennas is a key measure for achieving a high overall RF-to-DC conversion efficiency.

In this paper, we present a high efficiency WPT system operating at 400 MHz for small to moderate distances. The proposed system is based on incorporating helix antennas in the transmitter and receiver. Use of helix antennas allows to achieve high directivity and high efficiency with a fairly compact antenna size. Various configurations were considered and analyzed with emphasis on compact transmitting and receiving modules. As shown in this paper, the proposed helix antenna can be easily manipulated to obtain small size with good radiation performance. It is shown that the proposed helix antennas operating at 400 MHz, with relatively small dimensions (length of 3.5 cm, and diameter 25 cm) can provide a high gain exceeding 5 dB, with low VSWR. Experimented results are in good agreement with those obtained by numerical electromagnetic simulations using the HFSS tools.

Wireless Transmission of Electromagnetic Energy Based on a Time Reversal Approach for Indoor Applications

R. Ibrahim[1, 2], **B. Allard**[1], **A. Breard**[1], **J. Huillery**[1], **C. Vollaire**[1], **D. Voyer**[1], **and Y. Zaatar**[2]

Abstract— An original approach based on a time reversal technique is proposed in order to realize a wireless transmission of electromagnetic energy for indoor applications. Experiments made in a low-Q cavity of human size with a frequency carrier of 2.45 GHz show that the energy efficiency is greater than for a wireless transmission based on a continuous wave.

Introduction: Most of the recent developments in wireless transmission of electromagnetic energy are concentrated on systems designed to harvest the exceed of electromagnetic energy lost by common wireless systems such as Wi-Fi network. However, the intermittent and unpredictable nature of these ambient sources makes energy harvesting critical for some applications [1]. In scenarii where the energy is transmitted intentionally, systems using continuous waves are not necessary the most efficient. We investigated an alternative approach based on time reversal that is found to be promising for indoor applications. Time reversal with electromagnetic waves was first proved to be feasable in [2]. The implementation needs two stages. In a first step called *learning stage*, a low energy pulse is transmitted through an antenna; at another place in the room, the received antenna records a signal constituted by a succession of many delayed pulses, less or more attenuated, and related to the reflections in the medium. In a second step called *time reversal stage*, a high energy signal built from the time reversal of the recorded signal is transmitted through one of the antennas; it follows that the time reversed waves focus spatially and temporally on the received antenna. These properties are particularly attractive for an energy recovery; moreover, the energy efficiency increases when the medium becomes more and more complex which makes this approach espescially suitable for indoor applications.

Experimental Setup and Results: Two antennas are placed inside a low-Q cavity of human size with two obstacles positionned between them in order to avoid the direct path. In the learning stage, a nanosecond pulse of 2.45 GHz frequency carrier and 5 V amplitude is transmitted; in reception, a complex microsecond signal with a maximum amplitude of 50 mV is recorded using a numerical oscilloscope. The time reversal as well as some filtering operations are made in a Matlab code. Then the reversed signal is transmitted using a wave form generator with a sample frequency of 12 GHz and an amplifier such that the maximum amplitude for the time reversed signal is 5 V ; in reception, one recovers a nanosecond pulse with an amplitude about 10 times a many as during the learning stage. Moreover, the energy efficiency in the reversal stage is about 30 times as many as the efficiency for a transmission of a continuous wave around 2.45 GHz. Note that in this later case, there is a sensivity with respect to the carrier frequency because of the cavity modes; on the contrary, the time reversal technique takes advantage of the complexity of the cavity.

High Efficiency RF Energy Harvesting from Electromagnetic Waves of Digital Terrestrial Television

Jiro Ida, Masanari Mabuchi, Yuta Kunori, Hiroshi Miyagoshi, Keisuke Noguchi, and Kenji Itoh
Division of Electrical Engineering, Kanazawa Institute of Technology
7-1 Ohgigaoka, Nonoichi, Ishikawa 921-8501, Japan

Abstract— Our target of the RF energy harvesting is harvesting from the electromagnetic wave of the Digital Terrestrial Television (DTTV) which frequency is around 470–770 MHz. It is because its covered area and its expected power will become large, compared with others, e.g., the Wi-Fi and the cellular phone. Although the DTTV was chosen, the expected received power is around and below the micro Watts range when the covered area is intended to be enlarged. Therefore, the most important issue of the RF energy harvester is the high efficiency of the rectification on the ultralow input power level.

For this issue, we have proposed the rectenna which is composed of the high impedance antenna and the optimized gate controlled diode (Fig. 1). Although based on the simulations, we have confirmed the efficiency around 40% at the input power level of −15 dBm, and around 10% at −30 dBm, which is the best ever reported value [1].

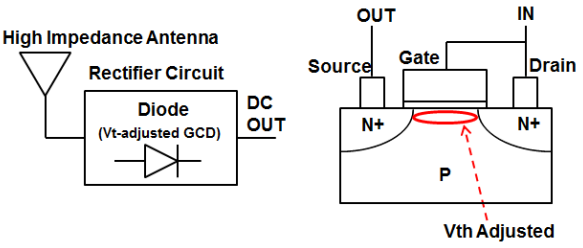

Figure 1: Our concept of the high efficiency RF energy harvesting and the structure of the gate controlled diode.

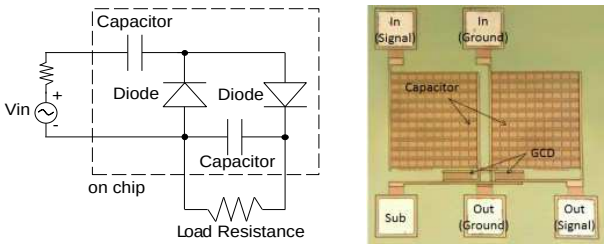

Figure 2: Rectifier circuit and its photograph on the chip.

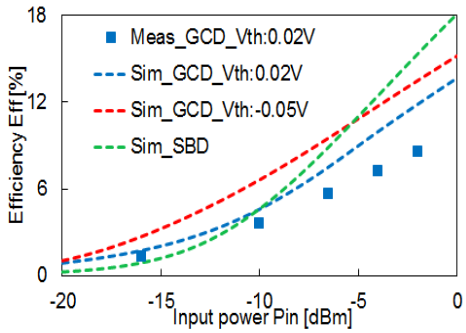

Figure 3: Measured and simulated efficiency of the rectifier on 500 MHz.

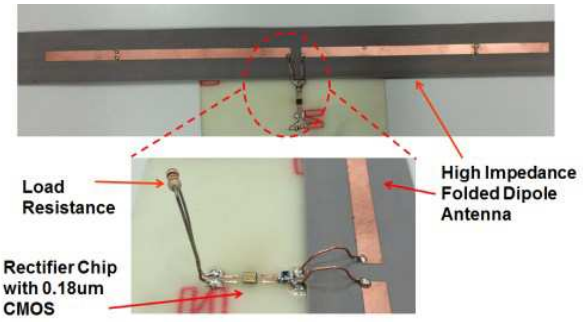

Figure 4: Fabricated rectenna with the high impedance antenna and GCD.

We introduce the status of our study, here. First, we show the results of evaluation on the gate controlled diodes (GCD) and the rectifier circuits fabricated with 0.18 µm CMOS (Fig. 2). It was confirmed that the efficiency of the rectifier with the GCD which has the optimum transistor threshold voltage (V_{th}) overcomes the rectifier using the best Schottky barrier diode for the small signal applications (Fig. 3) [2]. We have already developed the folded dipole antenna with the high impedance of 2 K ohm [3], which is also summarized here. Next, we show the methodology of the optimization with the combination of the high impedance antenna and the optimized GCD for the high efficiency rectification on the ultralow input power level. We have founded out that

the optimum V_{th} shits to the slightly high value and the optimum gate width shifts to the small value with increase of the antenna impedance.

Finally, we will show the fabrication result of the rectenna with the high impedance antenna and the optimized GCD (Fig. 4).

Use Case Analysis of Wiegand-based Energy Harvester in Mechanical Sensing Devices

Ralf Zentgraf and Ulrich Bochtler
Lab for Circuit Design, Aschaffenburg UAS, Germany

Abstract—

Summary: Conventional energy harvester approaches using magnetic-inductive technologies are often realized as mass-spring systems. Due to the small resonance-bandwidth of such systems, bistable magnetic wires can be a sound solution for slow and sporadic movements. On this issue, a pressure sensor system is adapted with a so-called Wiegand-harvester to implement self-sufficient electrical feature functionalities.

The Wiegand-harvester consists of an inductor coil mounted on an amorphous Vicalloy-Core (CoFeV). The large characteristic Barkhausen jump of the alloy is used to generate voltage peaks in the pickup coil in a slow changing magnetic field. Contrary to mass-spring systems or periodical induction, only the value of the coercivity field (ΔH_{ce}) is relevant for generating an energetic voltage pulse to power an electrical circuit.

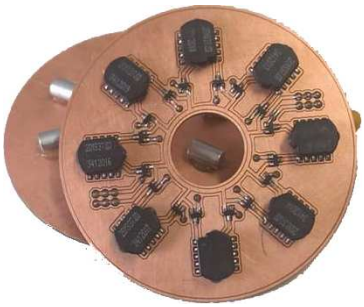

Figure 1: Magnetic harvesting PCB.

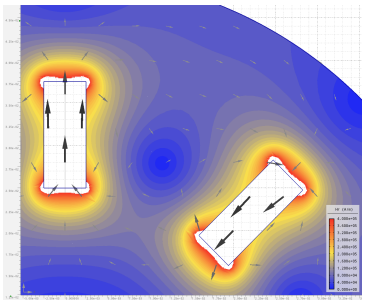

Figure 2: FEM simulation of the neodymium magnets.

This technology can be used in high transient as well as in nearly static environments. A use case analysis for a pressure gauge shows the benefit of Wiegand-based Systems. The powermodule is realized by placing eight harvesters circular on a PCB. Thereby a single rotation of a spindle (360°) is quantized in eight steps. A second disk equipped with eight neodymium permanent magnets is mounted parallel to the PCB. So a twist of 45° delivers a multiplied pulse each of the eight inductor coils [Fig. 1]. A electrical energy output of approx. 13.5 µWs and the twist-hysteresis of $0°2'$ could be achieved and verified using a magnetic FEM simulation [Fig. 2].

Optimal Operating Frequency for Wirelessly Powered Implanted Systems

V. Talla[1], **B. H. Waters**[1], **and J. R. Smith**[1, 2]

[1]Department of Electrical Engineering, University of Washington, USA
[2]Department of Computer Science Engineering, University of Washington, USA

Abstract— Wireless power transfer (WPT) using magnetically coupled resonators is a popular technique to charge/recharge and operate a range of devices such as electric vehicles, consumer electronics and implanted biomedical devices. As a result, numerous WPT systems and multiple standards such as Rezence by A4WP and Qi by WPC operate at different frequency bands (200 KHz, 6.76 MHz, 13.56 MHz to name a few) have been developed in recent years [2–4]. However, there isn't a clear choice of an optimal operating frequency since the system design and behavior is dependent on a variety of factors such as application scenario, size limitations, operating distance and desired power level. In this work, we will focus on choosing an optimal operating frequency for wirelessly powered implanted biomedical devices, while taking account these various system requirements.

One of the key challenges associated with developing WPT systems is to comply with existing regulatory and safety standards. We will focus on two specific applications, which cover the two extremes of the power spectrum of implanted devices. Firstly, we will discuss WPT for left ventricular assist device (LVAD) which require about 10 Ws of power and has a receiver size restrictions of about 10 cm in diameter [1]. Secondly, we will design a WPT for an implanted neural recording device which requires about 100 mWs and the receiver is restricted to 2 cm in diameter and 2 mm in thickness. We will ascertain the optimal operating frequencies for the two applications under the above-mentioned constraints and design the system to satisfy the safety and legal standards and regulations set worth by the Federal Communication Commission (FCC).

The primary goal of a WPT system is to deliver the desired power to the load at maximum efficiency and operating range [6]. An additional, but equally important requirement is to stay within the electromagnetic exposure limits. The electromagnetic exposure limits are set out to ensure that adverse effects associated with electro-stimulation (at lower frequencies 3 KHz–5 MHz) and tissue heating (at higher frequencies 100 KHz–300 GHz) is minimized. As a result there are basic restrictions (BRs) and maximum permission exposure (MPEs) limits, which place an upper bound on, induced fields, induced currents, temperature rise and specific absorption rate (SAR).

Recent work has investigated the choice of optimal frequency for consumer electronic charging applications [8]. Although it assesses RF exposure, it does account for the effect of human hand/body in proximity with the charging system. Herein, we will focus on implanted biomedical systems wherein the receiver will be encapsulated in the biomedical tissue and is of greater risk of electro-stimulation and tissue heating. For our analysis and design of the system, we will undertake the following approach:

- Since the Q-factor of the coils, the power dissipated (i.e., heating) and the WPT effifficiency are all dependent on operating frequency for a given coil size, we will optimize the MCRs for the two applications for different operating frequency bands [7].
- Given this design, we will evaluate the impact of the tissue and biological medium encapsulating the receiver on the efficiency and field distribution for the WPT system [5]. If required, the system will be redesigned to improve efficiency and power delivery.
- Next, we will evaluate and quantify the induced field strengths, induced current and SAR values for different operating frequencies.

Based on the analysis of the systems optimized for different frequency bands, we will ascertain the optimal operating frequency for various wirelessly powered implanted medical devices applications.

Wireless Power Transmission by Enlarging the Near Field Calculation of the Transition from Far to Near Field

Konstantin Meyl
Faculty of Computer and Electrical Engineering, Furtwangen University
1.TZS, Erikaweg 32, D-78048 Villingen-Schwenningen, Germany

Abstract— Continuing the contribution about "wireless power transmission by scalar waves", presented in Moscow 2012, this paper goes deeper, explaining the different types and properties of waves described by the wave equation.

Starting with the wave description of Maxwell an extended version of the Laplace equation is derived, expanding the standard derivations of the near field, showing how to influence the zone, where the longitudinal wave parts occur.

We come to the conclusion that the near field zone is enlarging, if the longitudinal parts of a wave or the antenna voltage are accelerated. This relationship is essential for the wireless transmission of energy. In addition this exciting new result could be tested experimentally.

The simple experiment will be demonstrated at PIERS 2013 in Stockholm. Only by changing the antenna design, it will be shown how both, the speed of propagation and the near field are enlarging proportional to each other.

In all practical applications as discussed in PIERS Proceedings 2012 (pp.664–668), the extended near field is the key of success.

Causal Natural Modes, Retro-causal Natural Modes and Minimum Radiation Modes

Guy A. E. Vandenbosch[1], **Xuezhi Zheng**[1], **and Victor V. Moshchalkov**[2]

[1]Department of Electrical Engineering (ESAT-TELEMIC), KU Leuven, Belgium
[2]Institute for Nanoscale Physics and Chemistry (INPAC), KU Leuven, Belgium

Abstract— In this talk, we discuss three kinds of modes that are crucial to the understanding of a time domain electromagnetic (EM) response. The first targeted mode is called "causal" natural mode. This mode and its corresponding "causal" natural frequency are widely used in the analysis of the transient response of a radiating structure, for example, in the Singularity Expansion Method [1]. They are solutions to the non-standard eigenvalue problem of, e.g., for a microwave antenna, a surface integral equation. In this case, the integral equation only involves the retarded scalar and vector potentials and as a result the electric field at a given time instant t is solely due to an oscillating current in the past. Moreover, since the EM field equations are invariant under time-reversal symmetry, we can reverse the time axis and construct a retro-causal problem for the conventional integral equation. Then, similar to the "causal" natural mode, retro-causal natural modes can be defined when the integral equation is set free of driving force. Last but not the least, we can combine the causal and retro-causal cases to build a new "radiation field" operator. It will be proven that this operator is closely related to the concept of radiated energy [2, 3], and its modes may be defined as "minimum radiation" modes, i.e., where radiated energy and absorbed energy perfectly cancel each other.

Stored Electromagnetic Energy in Bi-isotropic Media

Casimir Ehrenborg and Mats Gustafsson
Department Electrical and Information Technology, Lund University, Box 118, Lund SE-221 00, Sweden

Abstract— Characterizing stored electromagnetic energy is essential in antenna Q calculation [1]. Understanding stored electromagnetic energy as a physical quantity is thus instrumental in characterizing antenna limitations. There exists several expressions for stored electromagnetic energy. In general these expressions give physical results in loss less isotropic media. However, in more complex background materials, such as dispersive or lossy media, these expressions break down, predicting negative energies [2].

This contribution investigates the results of existing stored energy expressions when applied to bi-isotropic media. This is done by implementing the bi-isotropic greens function [3] in the electrical field integral equation in a method of moments code. Stored energy in different types of small antennas will be examined and compared to the stored energy in their equivalent circuit models. The circuit models are generated by Brune synthesis.

On the Properties of Stored Electromagnetic Energy

Miloslav Capek and Lukas Jelinek
Department of Electromagnetic Field, Czech Technical University in Prague, Prague, Czech Republic

Abstract— A consistent definition of stored electromagnetic energy for non-stationary fields is one of the last fundamental and still unsolved problems of classical electrodynamics. One of the key issues is the potentially infinite total energy within a time-harmonic steady state [1]. There is an ill-defined separation of the total energy into radiated energy and stored energy, where it is assumed that the bearer of the infinity is the radiation [2].

The radiation energy is commonly subtracted separately in the region exterior and interior to the radiator, the boundary being defined by the smallest circumscribing sphere. Many methods are known for determining the radiated (stored) energy outside the circumscribing sphere. All these methods yield qualitatively similar results, although quantitative differences can be found. The situation is more severe in the interior region, since only a few methods are able to take effectively into account the actual shape of the radiator [3, 4]. The differences between the predictions of these methods are moreover qualitative [5].

Besides subtraction of the radiated energy, there are also other techniques for estimating the stored energy, the vast majority of which are inspired by circuit theory [6–8]. However, no matter what concept is used, several fundamental principles should always be kept in mind: e.g., the energy must be positively semi-definite, must be coordinate-independent, must be gauge invariant, and it should be possible to define it locally. Clearly, all the concepts of the stored energy for a dynamic field must also be coherent with those for a static field.

In our talk, we will review all the available concepts that have attempted to determine stored energy. It will be pointed out that all these concepts fail in at least one of the "must have" properties mentioned above. Finally, it will be concluded that no fully consistent definition of stored electromagnetic energy is yet known. This of course raises the question whether the very idea of stored (and radiated) energy is well-posed [9].

A Surface Integral Expression for the Electromagnetic Energy in a Microwave Cavity

J. Helsing[1] and A. Karlsson[2]

[1]Centre for Mathematical Sciences, Lund University, Box 118, Lund 221 00, Sweden
[2]Electrical and Information Technology, Lund University, Box 118, Lund 221 00, Sweden

Abstract— Today, all high energy particle accelerators use microwave cavities for particle acceleration by means of eigenfields, excited by external sources. In the design process of such cavities it is important to evaluate these eigenfields and the corresponding resonance frequencies. Numerical accuracy is crucial since even small errors in the evaluations may cause a deterioration of the performance of the accelerator. It is convenient, and sometimes necessary, to use normalized electric eigenfields $\mathbf{E}_n(\mathbf{r})$ such that

$$\int_V |\mathbf{E}_n(\mathbf{r})|^2 \, \mathrm{d}V = 1 \tag{1}$$

In [1] we developed a high-order convergent Fourier-Nyström scheme for the magnetic field integral equation (MFIE) that can determine the eigenfields and their resonance frequencies with very high accuracy. Since MFIE is a surface integral equation it is very costly to evaluate the volume integral in (1). For this reason we derived a surface integral expression for the normalization integral that is less expensive to evaluate. The integral is expressed in terms of the magnetic vector potential and the scalar electric potential. In this contribution we present an efficient numerical method for the numerical evaluation of the expression for some different types of cavities. We also apply the surface integral expression to the exterior problems of radiation from antennas and scattering of waves from perfectly conducting objects and give an interpretation of the energy it then corresponds to.

Estimating Antenna Q-factor from the MoM Impedance Matrix

Doruk Tayli and Mats Gustafsson
Department of Electrical and Information Technology, Lund University, Lund, Sweden

Abstract— The antenna Q-factor is a useful figure of merit that estimates the antennas bandwidth [1, 2]. One difficult part of determining the antenna Q-factor is to calculate the stored energy of an antenna. A method that can be applied to any small antenna is presented in [3–6]. Where the Q-factor is computed using an in-house solver based on a custom method of moments (MoM) implementation. As this requires writing custom code, it is practical to take advantage of the widely available commercial electromagnetic software that have already implemented the MoM and have additional variety of post-processing capabilities.

In this paper the antenna Q-factor is computed from the numerical frequency derivative of the MoM impedance matrix. The impedance matrix is obtained from the commercial software FEKO [7]. Different Q-factor formulations are presented and used to estimate the Q-factor of antennas. These are then compared with the Q-factor calculated from the derivative of the input impedance [8], and the stored energies.

Three-body Momentum and Energy Transfer out of Thermal Equilibrium

Riccardo Messina and Mauro Antezza
Laboratoire Charles Coulomb (L2C), UMR 5221 CNRS and Université Montpellier 2, Montpellier, France

Abstract— A striking consequence of quantum electrodynamics is the existence of an electromagnetic force between any couple of neutral polarizable bodies even in the vacuum state of the electromagnetic field. This effect, known as Casimir effect, was first theoretically predicted in 1948. In 2005 it was shown that the absence of thermal equilibrium deeply modifies this effect, producing quantitative and qualitative differences, such as the appearance of new asymptotic behaviors and the possibility of a repulsive force. The out-of-equilibrium scenario brings to the attention a different closely related effect, the radiative heat transfer.

My talk addresses the combination of the absence of thermal equilibrium with three-body interactions. To this aim I discuss a recently developed general theory describing Casimir force and radiative heat transfer in a system consisting of three arbitrary bodies held at three independent temperatures and immersed in a thermal environment. As an application, I consider the force acting on an atom inside a planar cavity. I show that, differently from the equilibrium configuration, the absence of thermal equilibrium admits one or more positions of minima for the atomic potential, paving the way to a possible trapping scheme for Rydberg atoms.

Near Field Heat Transfer Mediated by External Magnetic Fields

R. Esquivel-Sirvent
Instituto de Fisica, UNAM, Mexico D.F., Mexico

Abstract— We consider two bodies described by a local dielectric function at different temperatures. Tuning of the near field heat transfer (NFHT) at the nanoscale can be achieved by changing the dielectric function. However this means either changing the material or changing the concentration of carriers in the case of semiconductors. Another possibility is using composite materials that combined different materials with specific dielectric function, for example nested nanoparticles.

In this work we given the materials the heat transfer can be modulated by applying external magnetic fields. As a case study we consider the NFHT between a SiO_2 substrate and a plate of a III-V semiconductor such as InSb. When an external magnetic field is applied, the excitation of magneto plasmons introduces an optical anisotropy that will change the reflection coefficients of the InSb plate. This will change the radiative heat flux, depending on the magnitude and direction of the external magnetic field. From a practical point of view, using graphene to control the heat transfer is a better choice since low magnetic fields are needed.

Combining composites and external magnetic fields will provide for more flexibility on the tuning of the heat transfer. The case of a SIO_2 substrate and a superlattice with metal-semiconductor unit cells will also be discussed.

Mesoscopic Transport of Heat in Trapped-ion Crystals

M. Bruderer[1], **A. Bermudez**[2], **and M. B. Plenio**[1]

[1]Institut für Theoretische Physik, Albert-Einstein-Allee 11, Universität Ulm, Ulm 89069, Germany
[2]Instituto de Física Fundamental, IFF-CSIC, Calle Serrano 113b, Madrid E-28006, Spain

Abstract— Measuring and controlling heat flow on the nanoscale poses formidable practical difficulties as elementary devices such as switches and 'ampere meters' for thermal currents are not available. We propose to overcome this problem by realizing heat transport through a chain of trapped ions, where currents of local vibrations (vibrons) are induced by chain edges kept at different temperatures. We show how to efficiently control and measure these currents by coupling vibrons to internal ion states, which in turn can be easily manipulated in experiments. Trapped-ion crystals therefore provide a promising platform for studying heat transport, e.g., through thermal analogues of quantum wires and quantum dots. Specifically, elusive phenomena such as the onset of Fourier's law or bosonic fluctuations of heat currents may be observable in trapped-ion systems.

Controllable van der Waals Interaction in a 1D Waveguide Geometry

Stefan Scheel[1] **and Harald Haakh**[2]

[1]Institute of Physics, University of Rostock
Universitätsplatz 3, D-18055 Rostock, Germany
[2]Max Planck Institute for the Science of Light
Günther-Scharowski-Straße 1/24, D-91058 Erlangen, Germany

Abstract— Dispersion forces such as Casimir, Casimir–Polder and van der Waals forces arise due to fluctuations of the quantised electromagnetic field. Any alteration of the environment in which the (virtual) photons propagate leads invariably to a modification of the respective interaction. Waveguide structures in particular are known to resonantly enhance Casimir-Polder interactions [1]. Here we will focus on the van der Waals interaction between two isolated atoms inside a cylindrical waveguide. Assuming an ideal, perfectly conducting waveguide, we will show how the far-field van der Waals interaction between atoms located on the cylinder axis shows an exponential distance dependence [2, 3], while the near-field potential scales polynomially as in free space. Using dyadic Green function techniques as the basis of phenomenological field quantisation, we are able to go beyond the ideal situation and treat arbitrary dielectric surface materials. In that way, we gain an understanding of the underlying mechanisms and limiting factors for the exponential suppression of the van der Waals interaction in the far field in waveguide structures [3]. The existence of a fundamental mode without cut-off [2] implies a far-field contribution to van der Waals interaction between excited atoms, thereby making it possible to observe the yet elusive retarded dispersion potential between two emitters.

Casimir-Polder Potential of Spheres and Discs and Its Impact on the Poisson Spot

J. Hemmerich, **M. Könne**, **and S. Y. Buhmann**
University of Freiburg, Germany

Abstract— The Casimir-Polder interaction of a ground-state atom or molecule with a dielectric body may be interpreted as a consequence of the vacuum fluctuations of the electromagnetic field. We study this interaction for spheres and discs on the basis of macroscopic QED [1], where it can be given in terms of the atomic polarisability and the Green's tensor of the electromagnetic field. The latter is known for a sphere, while we resort to a Hamaker approach for a disc. We calculate the potentials numerically and give analytical asymptotes for small and large distances and object sizes.

The Casimir-Polder potential plays are crucial role in the interpretation of matter-wave experiments. In particular, scattering at compact objects is known to lead to a bright spot — the Poisson spot — in the classical shadow region due to constructive interference [2]. The Casimir-Polder potential experienced by an atomic matter wave upon passing the scattering object imprints an additional phase and hence alters the Poisson-spot signal. We show how a comparison between theory and experiment can lead to direct evidence for Casimir-Polder interactions from matter-wave scattering.

Abstract— A toolbox for the quantum simulation of attractive and repulsive polarons in ultracold atoms is presented. Motivated by impressing experimental advances in the area of ultracold atomic mixtures, we theoretically study the problem of ultracold atomic impurities immersed in a Bose-Einstein condensate (BEC). The impurity-BEC interaction gives rise to the formation of polarons whose interaction can be effectively tuned using an external laser in a quasi-resonant Raman scheme. Our scheme allows one to change the effective interactions between polarons from positive to negative. This is achieved by simply changing the intensity and the frequency of the two lasers. Such arrangement opens new avenues for the study of strongly correlated condensed matter models in ultracold gases.

Casimir Momentum in Complex Media

Abstract— Casimir energy refers to the electromagnetic energy that quantum mechanics imposes to exist even in a fully empty space at temperature zero. In the presence of polarizable matter it gives rise to many fundamental phenomena in physics such as Lamb shift and Van de Waals forces, and maybe even the cosmological constant. In the conventional picture — either with or without matter — the expectation value of the electromagnetic momentum, $\langle \mathbf{E} \times \mathbf{B} \rangle$, called Casimir momentum vanishes. This may be physically obvious in "simple media", when $\langle \mathbf{E} \times \mathbf{B} \rangle$ is directly proportional to the energy flow $\langle \mathbf{E} \times \mathbf{H} \rangle$ which arguably vanishes unconditionally in thermodynamic equilibrium, but as soon as symmetries are broken (P, and T in particular) the question whether Casimir momentum can exist appears and turns out nontrivial.

The momentum of classical electromagnetic waves has been the subject of a longstanding controversy. In the presence of both an external electric $\mathbf{E}_0$ and magnetic field $\mathbf{B}_0$ the so-called Nelson version (our favorite) predicts a momentum $\alpha(0)\mathbf{E}_0 \times \mathbf{B}_0$ which results in the "Abraham force" $\mathbf{F} = \alpha(0)d/dt(\mathbf{E}_0 \times \mathbf{B}_0)$. We have measured this very tiny force in atomic gases and also searched — in vain — for possible deviations from the (Nelson version of) classical theory. In the QED picture in fact three momenta appear that are all different: kinetic momentum (related to force and thus observable), canonical momentum (conjugate to position operator and subject to gauge fields), and pseudo-momentum (which commutes with Hamiltonian and is thus conserved). We have developed a nonrelativistic QED theory for the electromagnetic momentum for simple objects coupled to the quantum vacuum. It produces the Abraham force *with* a QED correction. For the hydrogen atom the relative correction is equal to $-0.12\alpha^2$, nonzero, yet very small. We speculate that for other (hydrogen-type) atoms the correction scales as $(Z\alpha)^2$. Important to note is that the classical theory diverges in the infrared, and with some cut-off much higher QED corrections are proposed, that would have been within our experimental reach. In the full QED theory, this divergence disappears after mass renormalization.

Does Casimir momentum exist with only a magnetic field? If the matter is optically active, with $\beta(0)$ the static rotatory factor, a momentum $\beta(0)/\alpha(0)e\mathbf{B}_0$ could exist in view of its correct PCT symmetry and its correct dimension. However, such a momentum does not emerge from classical electrodynamics. We have developed a QED theory for a chiral, anisotropic, harmonic oscillator subject to a magnetic field. This theory, free of divergence, predicts a Casimir momentum proportional to $-(\alpha/4\pi)\beta(0)/\alpha(0)e\mathbf{B}_0$. Observation of this momentum is a next challenge. For atypical chiral compound $C_8H_{18}O$ we predict velocities $P/M = 0.5\,\mathrm{nm/sec}$ at 10 Teslas.

Abstract— We consider a quantum field inside a one- or a three-dimensional cavity with a wall which is allowed to move. We assume that the mobile wall is subjected to a harmonic potential, and its mechanical degrees of freedom are treated quantum-mechanically; it is also subjected to the radiation pressure. The wall's position has thus quantum fluctuations around the equilibrium position. The possible motion of the wall makes the cavity length variable, and this gives rise to a wall-field interaction and an effective interaction between the modes of the cavity [1]. Although this system has some analogy with the dynamical Casimir effect, in our case the motion of the wall is not prescribed by an external action but follows the system's internal dynamics.

We consider three different cases: a scalar field in a one-dimensional cavity, the electromagnetic field in a one-dimensional cavity and a scalar field in a three-dimensional cavity. For all these cases we consider the ground state of the interacting wall-field system at zero temperature. We show that the true ground state of the system contains admixtures with states containing excitations in the field and in the mechanical degrees of freedom of the moving wall. We evaluate the consequent change of the field energy densities and field fluctuations inside the cavity with respect to the fixed-wall case [2, 3]. We find that these vacuum energy-density changes are particularly relevant in the proximity of the mobile wall and discuss their dependence from the cutoff frequency, related to the plasma frequency of the conducting wall. The results obtained in the three cases considered (1D scalar, 1D electromagnetic and 3D scalar) are compared with each other. Observability of the new effects obtained through the Casimir-Polder interaction on a polarizable body such as an atom placed inside the cavity is also discussed, and we show that they should be measurable with actual optomechanical techniques. The dependence of the energy-density change and the atom-wall Casimir-Polder interaction on the relevant parameters of the mobile wall, such as its plasma frequency, mass and frequency of the harmonic potential, is discussed in detail.

Abstract— We investigate the effect of a uniform acceleration on resonance interactions and dispersion Casimir-Polder interactions between uniformly accelerated atoms in vacuum. We first consider the Casimir-Polder interaction between two neutral ground-state atoms uniformly accelerated in the same direction and separated by a constant distance, orthogonal to their trajectories. The atoms interact with the electromagnetic field in the vacuum state. We obtain the dispersion energy between the two accelerating atoms as the interaction between the instantaneous atomic dipole moments, which are induced and correlated by the zero-point field fluctuations. We find that the interaction energy is time-dependent; we also find that the dependence of the interatomic Casimir-Polder interaction from the distance is different with respect to the case of atoms at rest. We discuss the physical meaning of these results [1] and their relation with the Unruh effect [2].

We then derive the interatomic scalar Casimir-Polder interaction energy using a different approach; specifically we calculate the interaction between the two atoms separating at the fourth order in perturbation theory the contributions of vacuum fluctuations and radiation reaction. We show that the Casimir-Polder force between the two uniformly accelerated atoms exhibits a transition from the short distance thermal-like behavior predicted by the Unruh effect, to a long distance non-thermal behavior. We identify the characteristic length scale for this crossover with the inverse of the proper acceleration of the two atoms [3].

Finally, we consider the resonance interaction between two uniformly accelerated atoms, one excited and the other in the ground state, and interacting with the quantum electromagnetic field in the vacuum state. We assume the two identical atoms prepared in a maximally entangled state. Separating the contributions of vacuum fluctuations and radiation reaction to the evolution of atomic observables, we show that Unruh thermal fluctuations do not affect the resonant interatomic interaction, which is exclusively modified by radiation reaction corrections. Beyond a characteristic length associated to the breakdown of a local inertial description of our two-particle system, non-thermal effects in the radiation reaction corrections change qualitatively the distance-dependence of the resonance interaction.

Small Self-contained Quantum Thermal Machines

Jonatan Bohr Brask
Département de Physique Théorique, Université de Genève, Switzerland

Abstract— Small autonomous quantum thermal machines function without any external source of coherence or control, but using only incoherent interactions with thermal baths. We discuss the generation of steady-state entanglement in a simple autonomous machine, with possible implementations in superconducting qubits and quantum dots, and we also look into the transient behaviour of a three-qubit quantum referigerator.

Thermodynamics of the Quantum Measurement Process

Philipp Kammerlander[1] **and Janet Anders**[2]

[1]Institute for Theoretical Physics, ETH Zürich, Switzerland
[2]Department for Physics and Astronomy, University of Exeter, UK

Abstract— Thermodynamics is a highly successful macroscopic theory widely used across the natural sciences and for the construction of everyday devices, from car engines and fridges to power plants and solar cells. With thermodynamics predating quantum theory, research now aims to uncover the thermodynamic laws that govern finite size systems which may in addition host quantum effects. Recent theoretical breakthroughs include the characterisation of the efficiency of quantum thermal engines [1–3] and the extension of widely used classical non-equilibrium fluctuation theorems to the quantum regime [4–7]. A new thermodynamic resource theory [8, 9] has led to the discovery of a set of second laws that replaces the standard macroscopic second law for finite size systems [10]. These results have substantially advanced our understanding of nanoscale thermodynamics, however putting a finger on what is genuinely "quantum" in quantum thermodynamics has remained a challenge.

We lay out consequences of seeing measurement, one of the central pillars of quantum theory, not merely as a mathematical projection but as a thermodynamic process. We uncover that measurement, a component of any experimental realisation, is accompanied by work and heat contributions and that these are distinct in classical and quantum thermodynamics. Implications are far-reaching, giving a thermodynamic interpretation to quantum coherence, extending the link between thermodynamics and information theory, and providing key input for the construction of a future quantum thermodynamic framework. Repercussions for existing quantum thermodynamic relations that omitted the role of measurement are discussed, including quantum work fluctuation relations and single-shot approaches.

Information Thermodynamics in a Hybrid Opto-mechanical System

Cyril Elouard, Maxime Richard, and Alexia Auffèves
Institut Néel, CNRS, France

Abstract— Information thermodynamics is a recent field that investigates the links between information and energy. Its most famous "Gedankenexperiments" are Landauer's erasure and Szilard's engine, that allow for the reversible conversion of a single bit of information into an elementary amount of work between a small system and a battery. In the twenty-first century, the validity of such a conversion has been extended to information of quantum nature, i.e., encoded into one or several quantum bits. Along this line, coherence and entanglement have also been shown to have energetical counterparts, leading to stimulating theoretical results about the efficiency of non-local thermal engines, the operational signification of Von Neumann entropy, or the energetical value of entanglement.

In this field, most theoretical proposals rely on the ability to reversibly convert information into energy, namely to experimentally realize Landauer's erasure and Szilard's engine. However so far, direct evidences of such reversible work exchanges have remained elusive: if Landauer's bound has been measured, Szilard's engines protocols are still perturbed by irreversible mechanisms, leading to best information-to-energy conversion rates of typically 30 percents.

In this talk, we investigate potential playgrounds for information thermodynamics. In particular, we show that a hybrid opto-mechanical transducer is a proper platform to monitor these conversions. Such devices consist in an optically active quantum emitter, playing the role of the bit, coupled to a mechanical resonator, playing the role of the battery. Heat is exchanged with the electromagnetic reservoir. Within a mechanical oscillation, we connect the entropy variations of the quantum emitter with the mechanical energy variations, that are identified with work exchanges. These results pave the road towards experimental investigation of quantum information thermodynamics.

Casimir Force within an Inhomogeneous Medium

Fanglin Bao[1, 2] **and Sailing He**[2, 3]

Abstract— As is well-known, the diverging part of Casimir energy can usually be regularized and expressed with the Heat-Kernel coefficients $\tilde{E} \propto V\xi^{-4} + S\xi^{-3} + \ldots + C + X\log\xi$, where $\xi \to 0$ is a cutoff parameter $E = \frac{1}{2}\sum_n \omega_n = \lim_{\xi\to 0} \frac{1}{2}\sum_n \omega_n e^{-\xi\omega_n}$. Coefficients V, S are geometric characteristics, i.e., the Volume and the Surface area of the space where field exists, while prefactor X is unknown of its physical meaning. Many Casimir problems have shown the existence of the logarithmically diverging term, and it is still unresolved how to remove such a logarithmic divergence.

On the other hand, considering Casimir energy or Casimir stress within inhomogeneous media, it is reported that the regular subtraction of the bulk contribution, leaving only the scattering part of the green function which comprises the interaction between molecules, is insufficient to obtain finite results. Additional regularizations must be introduced, however, no one has succeeded.

Here in our paper, we have connected the above two problems. We have shown that the remained infinity in the Casimir stress within inhomogeneous media, contains a logarithmically diverging term and a quadratically diverging term. These two terms, just like the worst diverging term $V\xi^{-4}$, can be compensated by introducing an adjoined cavity. That is, they become constant if we adopt the Casimir piston model rather than the half-space model, then they vanish in the Casimir force. We have also shown that, based on the piston model, for any continuous inhomogeneity we always have cutoff-independent (finite) Casimir force. To illustrate, we have given an explicit example, which should be the benchmark analytical solution for the Casimir force within inhomogeneous media. As for the physical meaning of the logarithmic divergence, we still need further study.

Singular Evanescent Waves in Moving Media

Yu Guo and Zubin Jacob
Department of Electrical and Computer Engineering
University of Alberta, Edmonton AB T6G 2V4, Canada

Abstract— Resonators fold the path of light by reflections leading to a phase balance and thus constructive addition of propagating waves. However, amplitude decrease of these waves due to incomplete reflection or material absorption leads to a finite quality factor of all resonances. Here we report on our discovery that evanescent waves can lead to a perfect phase and amplitude balance causing an ideal Fabry-Perot resonance condition in spite of material absorption and non-ideal reflectivities. This counterintuitive resonance occurs if and only if the metallic Fabry-Perot plates are in relative motion to each other separated by a critical distance. We show that the energy needed to approach the resonance arises from the conversion of the mechanical energy of motion to electromagnetic energy. The phenomenon is similar to lasing where the losses in the cavity resonance are exactly compensated by optical gain media instead of mechanical motion. Nonlinearities and non-localities in material response will inevitably curtail any singularities however we show the giant enhancement in non-equilibrium phenomena due to such resonances in moving media.

The canonical example of a resonator is the Fabry-Perot (FP) system consisting of two reflecting plates separated by a vacuum gap [1, 2]. Light bouncing between them serves as a textbook introduction to the concept of a resonance and is the basis of practical devices from the laser to the interferometer [1, 2]. A simple argument suffices to understand this resonance. The reflection coefficient of propagating waves with frequency ω from the first mirror ($r_1(\omega)$) times that of the second mirror ($r_2(\omega)$) along with the propagation phase accumulated over a round trip ($e^{2ik_z d}$) should reconstruct the wave, capturing it inside, leading to a resonant build-up of intensity. Here, d is the vacuum gap between the mirrors and k_z is the propagation constant perpendicular to the mirrors. We arrive at the Fabry-Perot resonance condition

$$r_1(\omega)r_2(\omega)e^{2ik_z d} = 1, \tag{1}$$

which also follows from a plane wave multiple scattering approach.

It is well known that this above equation cannot be fulfilled by any passive media. Note that the reflection coefficients are complex signifying the change in phase and amplitude of the propagating wave at the mirrors. A closer look reveals that an optimum choice of the gap can possibly lead to a net phase balance ($\arg(r_1(\omega)r_2(\omega)e^{2ik_z d}) = 2n\pi$) for a resonance, but material absorption and non-ideal reflections necessarily require $|r_1(\omega)r_2(\omega)| < 1$. A gain medium is needed to compensate for this loss in amplitude as in a laser. The arguments presented above can be generalized to arbitrary passive structures showing that the bound resonances are signified by the poles of the scattering matrix which always lie in the lower half ($\mathrm{Im}(\omega_{res}) < 0$) of the complex frequency plane [3]. This condition ensures that all resonances decay in time leading to a finite quality factor.

In this paper, we show that the conventional Fabry-Perot condition has fundamental differences in the case of moving media. We explain that evanescent waves bouncing between moving plates can lead to a counterintuitive resonance with perfect amplitude and phase balance. We introduce the concept of a negative Poynting vector flow arising from Doppler shifted negative frequency modes in moving media. The spontaneous emission of negative frequency modes from the moving plate forms the subtle reason for the existence of such a resonance, which in essence is similar to the concept of a laser. The gain is provided by the conversion of the mechanical energy of motion into electromagnetic energy through the negative frequency modes. Finally we show that this resonance can dominate the non-equilibrium heat transfer leading to a singularity for a critical velocity of the moving plate. The singularities will inevitably be curtailed by nonlinearities and non-localities close to the resonance and we discuss in detail the effect of hydrodynamic non-locality on our predicted resonance.

Nanolevitation Phenomena in Real Plane-parallel Systems Mediated by Gravity and Casimir Forces at Thermal Equilibrium

S. Carretero-Palacios, V. Esteso, and H. Míguez
Instituto de Ciencia de Materiales de Sevilla, Consejo Superior de Investigaciones Científicas
Universidad de Sevilla, Sevilla 41092, Spain

Abstract— One of the most exceptional predictions of the generalized Lifshitz's theory is the appearance of repulsive Casimir forces [1–11] when real materials are considered. Additionally, when two interacting objects are under the influence of both Casimir and gravity forces, nanolevitation may take place if the Casimir force equals the gravity force at a certain (equilibrium) distance. Here, we report on the theoretical analysis of equilibrium distances in real plane-parallel systems under the influence of Casimir and gravity forces at thermal equilibrium. Due to the balance between these forces, thin films of teflon, silica (SiO_2), or polystyrene (PS) in a single layer configuration and immersed in glycerol, stand over a silicon substrate at certain stable or unstable positions depending on the material and the slab thickness [12]. Hybrid systems containing SiO_2 and PS, materials which display Casimir forces and equilibrium distances of opposite nature when considered individually, are analyzed in either bilayer arrangements or as composite systems made of a homogeneous matrix with small inclusions inside. We show that the equilibrium distances are modified through the variation of the slab thickness in the single layer configuration, the thickness of the individual components in the bilayer configuration, and the filling fraction of inclusions in the nanocomposites, parameters which have a strong effect in both Casimir and gravity forces. Our results pave the way for novel suspension and nonadhesive strategies at the nanoscale.

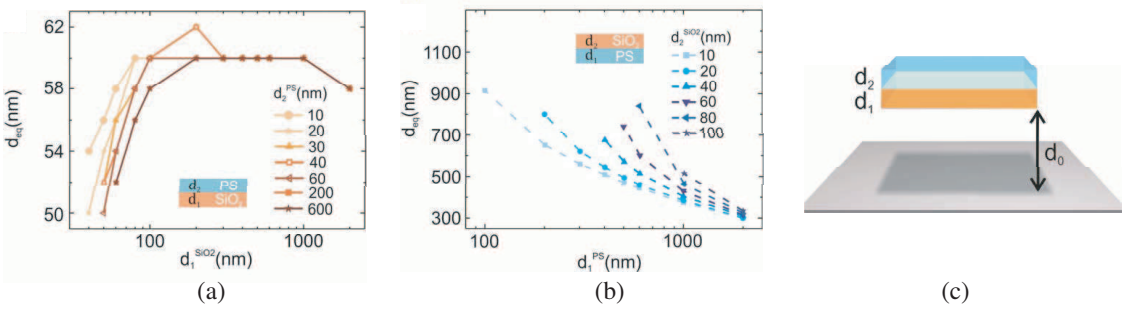

Figure 1: (a), (b) Equilibrium distance (d_{eq}) in a bilayer configuration (containing SiO_2 and PS), immersed in glycerol over a Si substrate, as a function of the slab thickness of the bottom layer (d_1), for different thicknesses of the top layer (d_2), for the configurations represented with the schematics in each panel. (c) Schematics of a bilayer system considered in our studies.

Tunable and Reconfigurable Frequency Rejection Circular Slot Antenna for UWB Communication Applications

Yingsong Li[1] and Raj Mittra[2]

[1]College of Information and Communications Engineering, Harbin Engineering University, Harbin, China
[2]Electromagnetic Communication Lab, Penn State and Central Florida Universities, USA

Abstract— In this paper, a tunable and reconfigurable circular slot antenna with frequency rejection characteristics is proposed for UWB communication applications. The proposed antenna can provide triple-band-notch characteristics by using various stubs for filtering out unwanted narrowband signals shoes frequencies overlapped with those of the UWB band. Center frequencies of these notch bands are tunable, and are realized by adjusting the dimensions of the proposed stubs. Also, the proposed antenna has a reconfigurable frequency rejection function to render the designed antenna suitable for UWB, band-notched UWB, dual band-notched UWB, tri-band-notched UWB or multi-band communication applications. The experimental results show that the proposed can also provide wide tunability, excellent reconfigurable frequency rejection characteristics and good omnidirectional radiation patterns, which make it attractive for indoor UWB communication applications.

A Triple Band-notched UWB Antenna by Using an Arc-shaped Slot and a U-shaped Resonator Techniques

Yuanyuan Kong, Yingsong Li, and Wenhua Yu
College of Information and Communications Engineering
Harbin Engineering University, Harbin 150001, China

Abstract— In this paper, an ultra-wideband (UWB) antenna with triple notch bands is proposed and well designed by etching double arc-shaped slots (DASS) on the fan-shaped radiating parch and integrating a U-shaped resonator (USR) alongside the microstrip feed signal line. The proposed antenna consists of a microstrip feed structure, a trapezoidal ground plane, a fan-shaped radiating patch, which are printed on a substrate with its dielectric constant of 2.65. The three band-notched characteristics are successfully realized by the use of the DASS and USR techniques, while the center frequencies of these notch bands are tunable by adjusting the dimensions of the proposed DASS and USR. By using these techniques, the proposed antenna can filter out unwanted narrowband signals from WiMAX, WLAN and RFID band. The proposed antenna is well designed and extensively investigated. The experimental results are given to verity that the proposed antenna with a wide bandwidth, three designated band-notched functions and good omnidirectional radiation patterns, which is suitable for modern high rate UWB communication applications.

Design of a High Isolation Dual-band MIMO Antenna for WLAN and WIMAX Applications

Lanchao Zhang, Tao Jiang, and Yingsong Li
College of Information and Communications Engineering
Harbin Engineering University, Harbin 150001, China

Abstract— A high isolation dual-band multiple-input multiple-output (MIMO) antenna of two elements is presented for wireless local area networks (WLAN) and worldwide interoperability for microwave access (WIMAX) applications. The MIMO antenna is printed on a FR4-epoxy substrate with the dielectric constant of 4.3 and an overall size of $46 \times 40 \times 1.6\,\mathrm{mm}^3$. Each element consists of two monopole antennas which locate at the top and bottom sides of the substrate respectively. The top one is fed by a $50\,\Omega$ microstrip line directly, and operates in 2.45 GHz band. The bottom is fed by the coupling current and operates in 3.55 GHz band. The two elements are placed perpendicularly to reduce mutual coupling. The neutralization line and the narrow slot are fabricated to improve the isolation characteristic in the high frequency band. The minimum distance between elements is 10.15 mm and superior isolation performance (higher than 20 dB) is achieved in two operation bands (2.4–2.484 and 3.4–3.69 GHz). In addition, good return loss is achieved, above 20 dB in the low frequency band and 14.5 dB in the high frequency band respectively. It is shown that the MIMO antenna presented in this paper is suitable for WLAN and WIMAX applications.

A Compact Dual Band-notched UWB Band-pass Filter by Using a Stub and a Folded Stepped Impedance Resonator

Yanyan Wang, Tao Jiang, and Yingsong Li
College of Information and Communication Engineering
Harbin Engineering University, Harbin 150001, China

Abstract— Mobile communication systems must support multiple users achieving at same time privacy of users contents. Security common solutions are based on encrypted algorithms from higher layers, such as private and public encrypted keys. Other possibility is to implement physical layer security schemes. One advantage of physical layer security relies on their ability to be combined with other security schemes from higher layers.

MIMO (Multiple-input multiple-output) systems can increase throughput in modern wireless networks and reduce interference. Other advantage of MIMO systems is the reduction of the transmitted power. On the other hand, to achieve high spectral efficiency multilevel modulations with high peak-to-average power ratios should be used, which may affect efficiency of power amplification. This problem can be avoided with a transmission scheme, where the constellations are decomposed on several uncorrelated BPSK (Bi Phase Shift Keying), QPSK (Quadri Phase Shift Keying) or OQPSK (Offset QPSK) components, being each component amplified and transmitted independently by an antenna. Combination losses are also avoided since the several signal components are combined at channel level. On the other hand due to the broadcast nature of MIMO systems, security is another critical issue in such systems. However, the constellation shaping on the desired direction introduced by these new transmitters means that we have directivity at the transmitted constellation that can be employed to assure security at physical layer. Privacy is achieved since each user must know the set of coefficients associated to each BPSK component as well as the array configuration, otherwise receives useless data. Therefore, the inherent security lies on the constellation directivity, i.e., the direction in which the constellation is optimized, which can be improved by changes on coefficients' phases or using constellations that are decomposed with a higher number of BPSK components. The several cases analyzed here show effectiveness of the proposed approach to implement a security scheme at physical layer level.

A Compact Ultra-wideband Band-pass Filter Integrated with Dual Tunable Notch Bands

Shumiao Hao, **Tao Jiang**, **Lanchao Zhang**, **and Yingsong Li**
College of Information and Communications Engineering
Harbin Engineering University, Harbin 150001, China

Abstract— A novel ultra-wideband filter integrated with dual tunable notch bands is proposed on the basis of the source-load cross coupling and an L-shaped slot. The dual notch bands are realized by using L-shaped slot and coupled-line sections, which act as inverter circuits in this design. High-low impedance lines are used to form the basic resonators. A folded cross-coupled feeding structure is used to mimic the size and three open stubs are employed to enhance the performance of the band-notched function. The experimental results show that the proposed filter can provide a wide pass-band bandwidth, two designated notch bands and high selectivity, making it promising for UWB applications.

Miniaturized Tag Antennas with Artificial Magnetic Conductor for UHF RFID On-body Applications

Chien-Wen Chiu and Cheng-Yan Yang
Department of Electronic Engineering, National Ilan University, Ilan 260, Taiwan

Abstract— UHF RFID technique is popular in the logistics, inventory management or bioengineering. The performance of an UHF RFID tag antenna is seriously degraded as it is placed close to a human body. The input impedance, radiation pattern, and realized gain of the tag antenna are influenced due to the body-proximity and absorption effects. Recent study finds that reading range of a UHF RFID tag is limited to 3 m [1]. Therefore, the body-proximity effects must be considered when a tag is held or put on the body. Some literatures recommended using artificial magnetic conductors (AMCs) to insulate the effect of the human body for wearable devices.

In this presentation, a two-dimensional square metal patch is initially applied as the unit cell of an artificial magnetic conductor (AMC). The unit cell size of the AMC is $55 \times 55\,\text{mm}^2$ and the gap separation between each unit cell is 1 mm. To miniaturize the AMC size and lower the first resonant frequency, four T-type slots are symmetrically inserted into each side of the metal patch. Each slot is designed with $Lp = 40\,\text{mm}$ and $Wp = 3\,\text{mm}$ so that the operating frequency is reduced to 915 MHz. The periodic square patches are built on a grounded FR4 substrate with height = 3.2 mm, $\varepsilon r = 4.4$ and loss tangent = 0.02. In order to achieve maximum benefit and minimum size, 3×3 T-slot patch-typed AMC unit cells were studied. A miniaturized dipole with T-matching structure was discussed in this presentation. It is placed on the above plane of the AMC in to insulate the influence from the human body. The tag on the AMC substrate is then placed close to a four-layer stratified elliptical cylinder human model to study the performance of the designed tags. Another kind of miniaturized AMC will be presented and discussed in the reference.

The power transmission coefficient and realized gain for the tags with and without AMC were simulated by HFSS. The study finds that the influence due to the body effect is small for the tag with AMC. The maximum realized gain of the designed T-matching dipole without AMC is about 1.9 dBi in the free space. The designed dipole on the T-slot patch-typed AMC raises realized gain up to 3.5 dBi since the AMC has 0^0 reflection phase and it would not cause destructive interference between the direct and reflected waves. When the tag is placed near the human model, the realized gain of the dipole on the AMC is about 2.7 dBi but the realized gain of the tag antenna without AMC is only −10 dBi. The maximum radiation efficiency is up to 38 % for the tag with AMC but only 10% for the tag without AMC. The practical structures were also constructed to measure the input impedance and reading ranges. The measured reading range is about 11 m for the tag with AMC in the free space as the UHF RFID reader has 4W EIRP output power. Considering real body-proximity effects on the tag, the reading range can achieve 9 meters for the tag with AMC but only 2 m for the tag without AMC. However, the size of the AMC is still too large for on-body applications. The design for the miniaturized AMC and tags will be presented in the conference.

A Compact VHF Antenna for Smart Meters

Paul Record and Komsan Kanjanasit
School of Engineering & Physical Sciences, Institute of Sensors, Signals and Systems
Heriot Watt University, Mountbatten Building, Riccarton, Edinburgh EH14 4AS, UK

Abstract— To ease data collection and enable variable energy tariffs the energy companies have demanded two way communications between the consumer energy meter and the company. There are serval bands in use from GSM to short range terminals working at 315, 434 and 868 MHz. In hilly terrains and meters located in basements this frequencies do not propagate well, however frequencies below 200 MHz are much better. This work describes a narrow band antenna derived from a patch antenna with perturbations, working at 169 MHz. Its largest dimension is only 0.06λ at the resonant frequency and it has $ka = 0.18$. A gain of -1.2 dBi and an SII of -20 dB was achieved. The antenna was designed to fit directly to the smart meter so its radiation pattern was optimised to radiate broadside. It incorporates a novel matching element to allow ease of manufacture. From near field studies it can be described as parasitic resonator driven by a single driven electrode matching 50 Ohms. The main method of tuning was by altering the separation of the top fin structures. The antenna was tuned to the require resonant frequency when enclosed a ABS plastic housing.

The Performance Improvement of Printed Inverted-F Antennas Using the Slot Mesh on Ground Plane

Yao-Chiang Kan
Department of Communications Engineering, Yuan Ze University, Taoyuan City 320, Taiwan

Abstract— Most wearable or Band-Aid like sensors employed in mobile health (m-Health) applications is required to integrate a microcontroller, a RF chip, a sensor chip, and a printed antenna onto a small substrate. For the off-body communication, the radiative RF channel is responsible for node-to-gateway data transmission. The performance of the printed antenna is not only affected by the human body, but also the size of the area reserved for the radiator. As shown in Fig. 1, the area reserved for printed antenna is about 20 mm × 5 mm and a mender line monopole or an inverted-F antenna are good candidates for the application. However, the size of the ground plane is significantly sufficient with respect to the frequency at 2.4 GHz, the target frequency of this m-Health application. A slot mesh on the ground plane, located at the second layer in Fig. 2, is employed to improve the antenna performance in this study. The ground plane is first partitioned into a $2^m \times 10$ rectangle mesh. Each element of the mesh could be filled with a rectangle metal or air, the latter is named a slot. The arrangement of the slots in the mesh is decided by the particle swarm optimization (PSO) with the target functions derived from the required antenna parameters. The simulation is implemented using the distributed binary PSO (DBPSO) and run on four computers with HFSS and Matlab installed. A printed IFA with $2^4 \times 10$ slot mesh on the ground plane is found to have bandwidth from 2.4 to 2.5 GHz with efficiency above 80%. Note that the length of radiator, L_r in Fig. 2, is half of that calculated by the empirical formula of printed IFA if the slot mesh is employed. In DBPSO computation, the slot mesh can be replaced by any EBG or AMC element and more general computation algorithm can be developed.

Sierpinski Fractal Monopole Antenna for Wireless Applications

Zachariah C. Alex and K. Shambavi
School of Electronics Engineering, VIT University , Vellore-14, Tamiladu, India

Abstract— Recently the Ultra Wide Band Technology has experienced a rapid growth in wireless communication applications, since federal communication commission (FCC) declared the frequency band (3.1–10.6 GHz) as unlicensed band. The UWB technology is very attractive because of its high data rate transmission and low power consumption, simple hardware configuration and excellent immunity to multipath interference when compared with existing wireless communication systems. Planar antennas reported in literature forUWB systems are large in size compared to our proposed antenna ($19.5 \times 19.5 \times 1\,\mathrm{mm}^3$) that incorporates fractal techniques and multiresonance effect. Fractal planar antennas generally contribute narrow bandwidth, but when realized in monopole configuration it exhibits wideband width and improved radiation efficiency

In this paper we propose Sierpinski fractal monopole antennas for wireless applications. We used Sierpinski fractals to realize antennas for wireless applications. Sierpinski fractal antenna in monopole configuration operates in WLAN/WiMAX frequency range (3.86 GHz to 5.7 GHz), whereas Sierpinski fractal monopole antenna inside a ring structure operates in UWB range (4.24 to 10.25 GHz). The wide bandwidth is due to multiresonance effect of ring and fractal structures. The proposed antennas are designed on FR4 substrate with $\epsilon_{\mathbf{r}} = 4.4$ and thickness 1 mm. Its parametric analysis was carried out using High Frequency Structure Simulator (HFSS v 13). Radiation pattern is omnidirectional in azimuth plane and it is like figure of eight in the elevation plane. Consistent radiation characteristics is observed in both the planes. Since the size of the proposed antenna is very small ($19.5 \times 19.5 \times 1\,\mathrm{mm}^3$) compared to other existing fractal antennas it is well suited for integration with portable UWB devices

It can be observed from the analysis that when the number of iterations of Sierpinski fractal increases, the bandwidth and return loss characteristics are improved with stable radiation pattern. Hence further enhancement in bandwidth and efficiency can be achieved by incorporating more fractal techniques.

A Miniaturized Metamaterial Inspired Hexaband Antenna for GSM, GPS-L1, WLAN and WiMAX Applications

Bharath Raj, **G. S. Kartikeya**, **K. Ullas**,
Sanjji N. Manjunath, **and C. Vindhya**
Antenna Research Laboratory, Department of Electronics and Communication
B.M.S. Institute of Technology and Management, Bengaluru, India

Abstract— This paper illustrates the application of metamaterial inspired unit cells in the patch as well as the ground plane to obtain a compact hexaband antenna. The patch consists of three split ring resonators separated by a distance of 0.5 mm. In addition, each ring has a thickness of 0.5 mm. The splits in the ring helps in reducing the size of the antenna by shifting the resonant frequency towards the lower frequency region. These rings exhibit definite inductive and capacitive characteristics. In addition to the split rings other metamaterial structures like a circular middle portion with interlocking pattern is also utilized. Besides the patch, the ground plane is in the shape of a square spiral, which is also a type of metamaterial structure. FR4 epoxy of thickness 1.6 mm is used as the substrate in the design. The excitation was provided by normal 50 Ohm linefeed. Distinct bands were obtained at various frequencies for LTE (900 MHz), GPS-L1 (1.575 GHz), GSM (1800/1900 GHz), UMTS (B2/B1), WLAN (2.4 and 5.5 GHz) and WiMAX (2.5 and 3.5 GHz). The radiation pattern obtained for the specified frequencies displays an Omni-directional pattern. Furthermore, the radiation pattern also possesses a wide beam width. These two properties are very useful when the purpose of the antenna is wireless communication. These results were obtained while maintaining the antenna dimensions to be limited to $30 \times 30\,\text{mm}^2$.

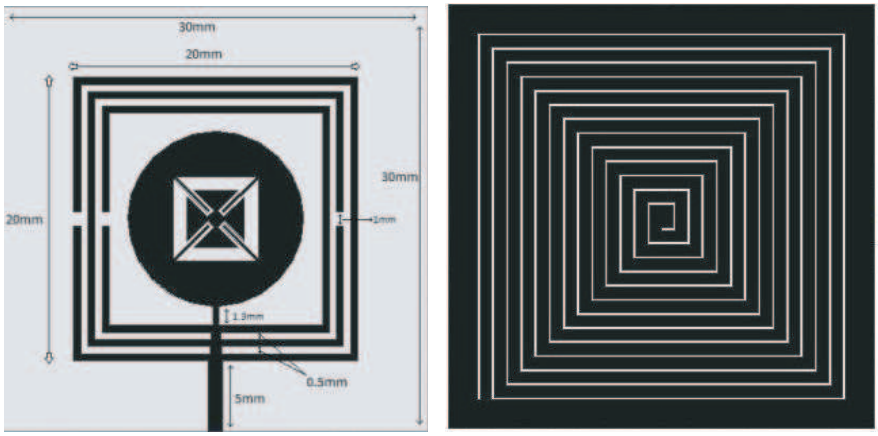

Figure 1: The proposed antenna.

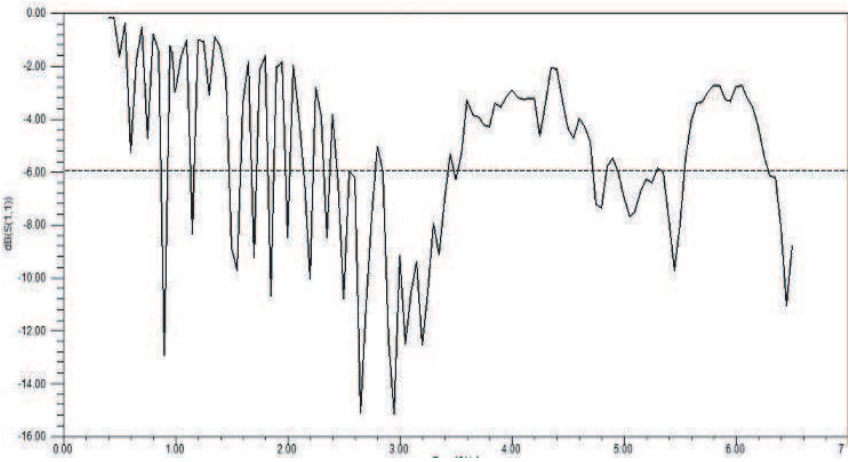

Figure 2: S_{11} of the proposed antenna.

The size of the patch for resonating at 900 MHz is theoretically calculated to be $79.4 \times 79.4\,\mathrm{mm}^2$. It was concluded that the proposed antenna has decreased the size of the antenna resulting in a miniaturization of over 62% and increased the number of bands at which it is resonating. Therefore, by utilizing metamaterial structures the size is reduced by a factor of $0.09\lambda_0$ and the number of bands covered by the antenna were improved.

Antenna Design: The unit cell consists of three split rings in addition to the central circular pattern with the interlocking design. The split rings have a thickness of 0.5 mm and is separated from each other by the same amount. The circular pattern has a radius of 6.2 mm. The complete unit cell occupies an area of $20 \times 20\,\mathrm{mm}^2$ and is positioned on top of the FR4 substrate of dimensions $30 \times 30 \times 1.6\,\mathrm{mm}^3$. The ground plane has the shape of a square spiral etched out.

Results and Discussion: The S_{11} of the proposed antenna is given in Fig. 2.

The S_{11} of the antenna shows resonance at several frequencies in the range from 900 MHz to 6.5 GHz. Among these the widely used ones are LTE (900 MHz), GPS-L1 (1.575 GHz), GSM (1800/1900 GHz), UMTS (B11/B1), WLAN (2.4 and 5.5 GHz). The overall dimension of the antenna is $30 \times 30\,\mathrm{mm}^2$. This accounts for a reduction of over 62% in the size of the antenna. In addition, the radiation patterns of the antenna at these frequencies were Omni-directional and has a wide beam width. Both of these properties are significant in portable wireless communication devices such as smart phones and tablets which are widely popular.

Quad Band Split Koch Snowflake Antenna for LTE/WLAN/WiMAX Applications

K. Ullas, G. S. Karthikeya, Bharath Raj, Sanjji N. Manjunath, and C. Vindhya
Antenna Research Laboratory, BMS Institute of Technology, India

Abstract— Quad Band Split Koch Snowflake antenna is investigated as radiating element. Resonant bands of 0.77–0.82 GHz, 2.3–2.42 GHz, 3.6–3.7 GHz and 5.3–6 GHz with center frequency of 0.8 GHz, 2.35 GHz, 3.65 GHz and 5.5 GHz.These bands very well cover the LTE/WLAN/WiMAX spectrum which are widely used to provide wireless service. The antenna was realized on a FR4 epoxy substrate with dimension $0.08\lambda_o \times 0.08\lambda_o \times 0.0042\lambda_o$ ($30\,\text{mm} \times 30\,\text{mm} \times 1.6\,\text{mm}$). The proposed antenna design is inspired from Koch snowflake fractal of first iteration and split element found in Split Ring Resonator (SRR) which is a metamaterial unit cell. The width of the transmission line in the proposed antenna is tapered gradually for impedance matching. The antenna was excited using a normal line feed technique. For the simulation of the proposed antenna a Finite Element Method solver was used. Antenna was analyzed with normal ground plane and the proposed ground plane, and the results were compared. The contribution of the split element in the Koch snowflake fractal of the proposed antenna was also studied by simulating the proposed antenna with and without the split element and the results were compared. Parametric analysis were carried out on the dimension of various elements of antenna. The radiation pattern of the proposed antenna was obtained at resonant frequencies in both E-plane and H-plane. After an extensive study of the proposed antenna it was found that the multiple Koch snowflake fractal

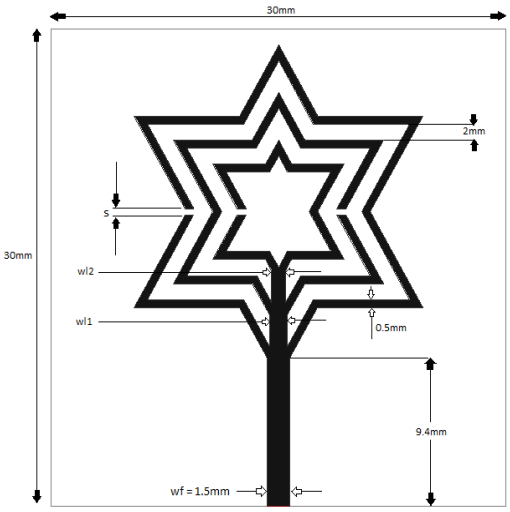

Figure 1: Proposed antenna design.

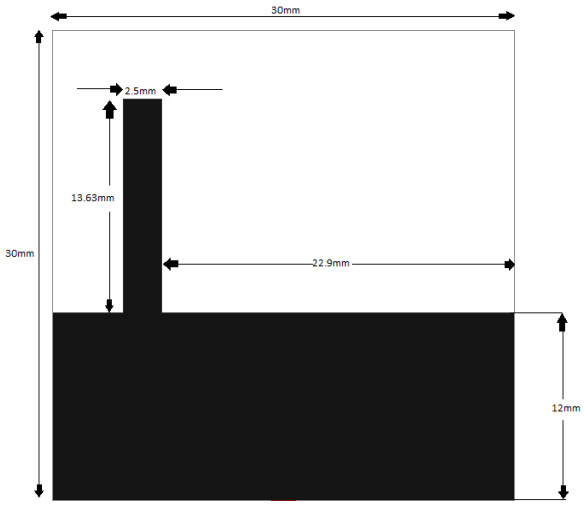

Figure 2: Ground plane of the proposed antenna.

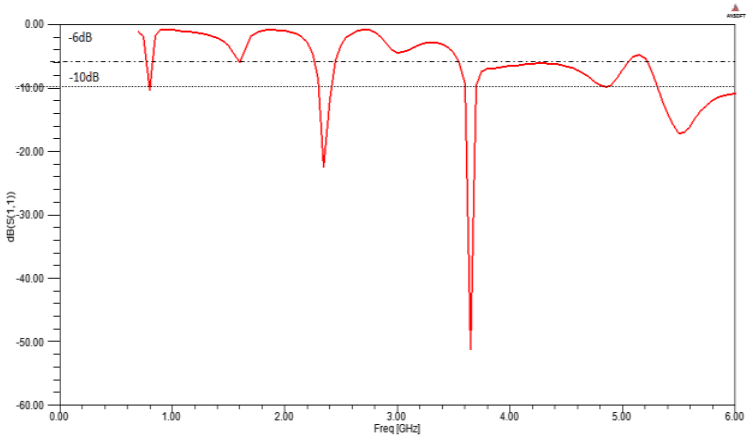

Figure 3: S_{11} of the proposed antenna.

structure was responsible for multiband resonance. The ground plane consisting of a protruding structure was responsible for the antenna to resonate at 5.3 to 6 GHz .The split element in the Koch snowflake fractal enhanced the antenna's ability to resonate at lower frequency of 0.8 GHz.

Miniaturized Multiband Antenna with Modified Split-ring Resonator for WLAN/WiMAX Applications

C. Vindhya, G. S. Karthikeya, Sanjji N. Manjunath, K. Ullas, and Bharath Raj
Antenna Research Laboratory, Department of Electronics and Communication
B.M.S. Institute of Technology and Management, Bengaluru, India

Abstract— In this letter, we propose a novel compact and planar triple band antenna designed using a metamaterial-inspired structure that consists of a slightly modified split-ring resonator (SRR). The ground plane has dielectric slots embedded in it. The proposed design measures $0.156\lambda_0 \times 0.156\lambda_0 \times 0.012\lambda_0$. It resonates at 2.351, 3.635 and 5.121 GHz respectively covering LTE2300, WiMAX and WLAN bands. Radiation pattern along H plane shifts by 90° between 3.8–4 GHz providing beam steering suitable for MIMO LTE (4G) and WiMAX. As a consequence of rapid development in wireless communication, compact multi-band antennas attracted research interest. It is desirable to have a single antenna operating at multiple bands. This enhances compactness which reduces VLSI real estate, cost and volume required in the casing of the device. The proposed design has multiple frequency bands at 2.351, 3.490–3.770 and 5.041–5.256 GHz with reflection co-efficient greater than −6, −10 and −10 dB respectively. It covers LTE2300 (2300–2400 MHz), WiMAX at 3.5 GHz and WLAN at 5.2 GHz. An attempt has been made to improvise on a conventional SRR to scale-down the dimensions while retaining multifrequency functionality. The radiating face of the antenna consists of a remodeled SRR. Resonant frequencies are created by fine tuning the gaps and embedding dielectric slots in the ground plane whose size and position were both realized through a parametric study. In addition to triple band operation, the antenna exhibits frequency beam-scanning ability inherent in a leaky wave antenna. Beam steering up to 90° can be achieved between 3.8–4 GHz. One of the LTE bands is centered

at 3.5 GHz which is also applicable for WiMAX. This feature is similar to the property of a smart antenna used in MIMO system. The geometry of the proposed antenna is shown in Fig. 1. It is fabricated on FR4 epoxy substrate of dimension 20 mm × 20 mm × 1.6 mm with dielectric constant 4.4 and loss tangent of 0.02. The patch consists of a metamaterial structure comprising a rectangular split-ring configuration with two non-opposite slits in each ring which are repositioned. Out of a total of four gaps/splits, three have a width equal to the thickness of the ring and the fourth is slightly smaller. The design uses a novel ground plane configuration. The size of ground plane is half the overall size, i.e., 20 mm × 10 mm. It is slotted with a wide gap at the centre and narrower gap on either side. Gap between slots on either sides of the centre remains constant. It is fed by a microstrip line which can be connected by an SMA. Ansys HFSS software is used to evaluate the antenna performance. The other optimal parameters are $W = 20$ mm, $d = 2$ mm, $d1 = 1.5$ mm, $d2 = 7$ mm, $d3 = 9.75$ mm, $t = 1$ mm, $g = 1$ mm, $g2 = 10$ mm. Frequency bands at 2.351, 3.635 and 5.121 GHz with reflection co-efficient −6.467, −13.494, −15.201 dB respectively are presented in Fig. 2(a). Bandwidths for resonances with S_{11} better than −10 dB at 3.635 GHz is 140 MHz and at 5.121 GHz is 96 MHz. Addition of a new set of gaps/split resulted in multiple bizarre resonances. The position and width of each gap/split were tweaked to get the final result through parametric analysis. It can also be observed that the radiation pattern changes with frequency variation in the range 3.5–4 GHz which is a characteristic of leaky-wave antennas. A change from 3.8–4 GHz returns a 90° shift in radiation along H plane. This is depicted in Fig. 2(b).

Research on Dual Bandpass of Wide Stopband Filter with Tunable Center Frequency

Zhao-Qing Sun, **Yong-Sheng Zhao**, **Han-Lin Duan**, **and Tao Jiang**
College of Information and Communication Engineering
Harbin Engineering University, Harbin 150001, China

Abstract— A dual passband of wide stopband varactor tuned filter using stepped impedance resonators (SIRs) is proposed in this paper. A varactor is loaded on the middle of the E-shaped resonators, through changing the value of the bias voltage across the varactor, the center frequency of the second passband can be tuned from 1.56 GHz to 2.25 GHz, however, the center frequency of the first passband is fixed and maintained at 1.02 GHz. In fact, it is fixed during the whole process. The relative bandwidth of the first passband is 14.7%, the return loss of is 19 dB and the insertion loss is 0.2 dB. The second passband can tuning from 1.56 GHz to 2.25 GHz with the tuning range of 36.2%. The relative bandwidth almost keep unchanged. The return loss change from 16 dB to 30 dB and the insertion loss change from 0.2 dB to 0.8 dB. This filter proposed in this paper has a great characteristic of harmonic suppression, −20 dB up to 3.5 GHz. There are two advantages of the optimization process. The first is that a filter network is added in the input and output coupling line to depress stopband. The second is that spurlines are added at the input and output coupling line which can add zero between the two passbands, which improved the performance for filter. It is good to improve the selectivity of the filter. The filter proposed in this paper can achieve a compact size, lower insertion loss and wider rang harmonic suppression. Simulations show that the filter proposed is valid and has a good performance.

A Very Small Triangular Shaped Printed Monopole Antenna for Bluetooth/WLAN and UWB Applications

Praveen V. Naidu and Akshay Malhotra
Centre for Radio Science Studies, Symbiosis International University (DU), Pune 412115, India

Abstract— In this paper, a compact ($12 \times 20\,\mathrm{mm}^2$) triangular shaped microstrip antenna with dual band characteristics is presented for Bluetooth/WLAN and ultrawideband (UWB) applications. The proposed structure consist of a simple triangular shaped radiating patch for achieving UWB characteristics and quarter wavelength inverted L shaped strip for achieving 2.45 GHz Bluetooth applications. The first operating band characteristics can be controlled by changing the electrical length of the strip along with coupling gap between the patch and strip. To enhance the impedance bandwidth of second operating band, an equilateral triangular shaped cut has been introduced in the patch. The results demonstrates that the proposed antenna exhibit dual frequency operation from 2.4 to 2.52 GHz and from 3.6 to 10.6 GHz. The antenna has omnidirectional radiation patterns in H-plane, bidirectional patterns in E-plane and acceptable peak gains and radiation efficiencies.

Effect of Slow Wave Structures on Scan Angles in Microstrip Leaky-wave Antennas

Saeid Mohammadpour Jaghargh, **Pejman Rezaei**, **and Javad Soleiman Meiguni**
Faculty of Electrical and Computer Engineering, Semnan University, Semnan, Iran

Abstract— This paper presents two miniaturized slow wave structures in microstrip leaky-wave antennas (MLWAs) which operate about 8 GHz. The effects of these structures on the scan angles have been compared in the paper. The designed interdigital capacitors and folded-back line have been investigated with ADS Momentum software. It has been shown that the interdigital capacitors (IDCs) yield to a broad scan angles from +53 to −74 degree, while the folded-back line inductor scans only the positive angles.

Red-shift between Near- and Far-field Electric Intensity Peaks

Alex J. Yuffa and Gorden Videen
Computational & Information Science Directorate, Army Research Laboratory, Adelphi, MD 20783, USA

Abstract— In classical wave scattering by small particles problems, the quantities of general interest are the far-field quantities such as the scattering cross-section. Recent technological advances have made it possible to control the light at the nanoscale by using nanoparticles and nanostructures. At this scale the quantities of interest are related to the near-field and not the far-field as in the classical scenario. A particular quantity of interest in plasmonics is the near-field electric intensity. It has been recently observed that the resonances in the near-field electric intensity are red-shifted with respect to the far-field electric intensity resonances. With the help of a damped harmonic oscillator model, one can demonstrate that the red-shift is caused by the contribution of the evanescent waves to the near-field electric intensity. This model definitely provides valuable physical insight into the problem but it does not provide a value for the red-shift. Clearly an ability to predict the near-field resonances based on the far-field data would be of great practical value to the community. However, to the best of our knowledge, no such formula has appeared in the literature. In fact, currently one computes the red-shift by first numerically computing for the far-field and the near-field resonances and then, taking their difference, which is clearly very time consuming and cumbersome.

In this presentation, we will derive a simple analytical expression for the red-shift between the near- and the far-field electric intensity resonances. This formula will be derived for a cylinder as well as a sphere by using only the Lorenz-Mie theory. We will also demonstrate that our simple formula computes the red-shift within a relative error of one percent. Furthermore, we will discuss possible generalization of our red-shift formula to other particle shapes.

Scanning Near-field Optical Spectroscopy of Semipolar InGaN/GaN Single Quantum Wells

Mounir Mensi, **Ruslan Ivanov**, **and Saulius Marcinkevičius**
Department of Materials and Nanophysics
KTH Royal Institute of Technology, Stockholm, Sweden

Abstract— Group III-nitride ternary alloy light emitting devices present outstanding electroluminescence efficiency. However, they typically exhibit band potential fluctuations related to spatial variations of the alloy composition, strains, extended defects, and cation clustering. Such fluctuations may have different consequences on nitride device performance. In some cases, e.g., polar InGaN quantum wells (QWs), localization separates carriers from dislocations reducing the rate of the nonradiative recombination [1]. In addition, for emitters of polarized light based on non- and semipolar QWs, carrier localization may reduce degree of the linear polarization [2]. Detailed understanding of potential fluctuations and their relation to properties of material growth and defects is important for the development of efficient light emitting devices. Since fluctuations occur on the nanoscale, near-field optical techniques, allowing a resolution beyond the diffraction limit should be used.

This presentation will focus on near-field scanning optical spectroscopy of semipolar $(20\bar{2}1)$ plane $In_xGa_{1-x}N/GaN$ single QWs [3–6] for $0.11 \leq x \leq 0.36$. During the near-field scans, the photoluminescence spectra were measured at every point, which allowed performing correlations and statistical analysis of these maps. Results include spatial variations of emission spectra, peak emission wavelength, intensity, spectral width, and polarization ratio of the photoluminescence emission. The nanoscale data revealed by the subwavelength near-field measurement not only provide a deeper understanding of phenomena behind the band potential fluctuations, but also pinpoint directions towards improvement of device efficiency and stability.

Generation of 1D High-frequency Interference Patterns of Evanescent Waves Using All-dielectric Photonic Crystals

E. A. Bezus[1, 2], **E. A. Kadomina**[1, 2], **and L. L. Doskolovich**[1, 2]

[1]Image Processing Systems Institute of the Russian Academy of Sciences, Samara 443001, Russia
[2]Technical Cybernetics Department, Samara State Aerospace University, Samara 443001, Russia

Abstract— During the last decade, many works dedicated to the generation of high-frequency interference patterns of evanescent electromagnetic waves were published due to both fundamental interest and potential applications in nanolithography and optical trapping and manipulation systems. Most of the research was centered on plasmonic structures [1, 2]. In a recent paper, the generation of such patterns in multilayer metal-dielectric structures was explained in terms of the excitation of volume plasmonic modes in hyperbolic metamaterials [3].

In the present work, we study theoretically and numerically the generation of high-frequency interference patterns of evanescent electromagnetic waves with essentially subwavelength period using all-dielectric structures containing a diffraction grating and a one-dimensional photonic crystal. It is shown that high-quality interference patterns with subwavelength hot-spots can be obtained due to resonant enhancement of the evanescent diffraction orders associated with one of the two possible mechanisms: the excitation of Bloch surface waves or the Fabry-Perot resonance of a high-k volume Bloch mode of the photonic crystal. Contrast of the generated patterns is close to unity, while the period is by an order-of-magnitude (10–20 times) smaller than the period of the used diffraction grating. The presented approach can be used in photolithography systems for the fabrication of periodic structures with nanoscale features.

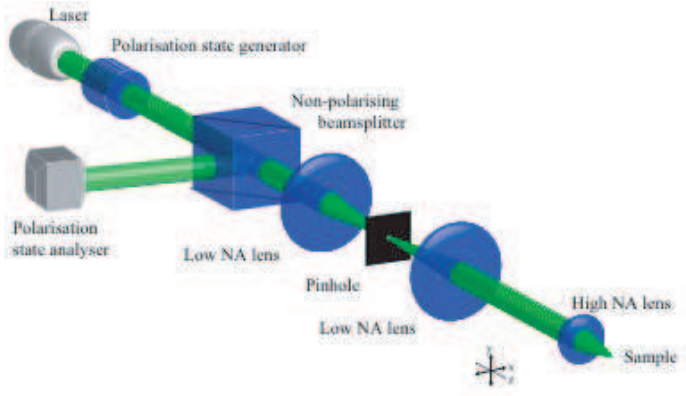
Polarisation Imaging Reveals Near-field Properties of Materials

P. Török, C. A. Macías-Romero, and M. R. Foreman
Department of Physics, Imperial College London, Prince Consort Rd, London SW7 2BW, UK

Abstract—

Introduction: Imaging systems have provided the means to gather information about the physical world throughout history. Recent years have witnessed the development of numerous super-resolution imaging schemes. These techniques however forego the greater information content afforded by polarisation, rather than irradiance, measurements. In this talk we confirm both experimentally and theoretically that far-field polarization imaging allows for continuous nanometric spatial variations in the polarization to be resolved. We present optical measurements of nanostructures resolving spatial polarization changes on the scale of tenths of nanometers. In optical data storage, polarization encoding via nanometric pits is furthermore shown to allow a sevenfold capacity increase.

Optical System: The optical system of a Müller matrix polarimeter microscope is shown in the figure below. The light of the laser is passed through a polarisation state generator that is capable of producing an arbitrary state of polarisation. The rest of the optical path is identical to that of a reciprocal confocal microscope. In the return path light passing through the pinhole is recollimated and split by a non-polarising beam splitter (NPBS). The polarisation state of the light emerging from the NPBS is then analyser by a Stokes polarimeter. By imparting at least four different states of polarisation on the incident light by the polarisation state generator, each one of these producing four intensity measurements in the Stoke polarimeter, it is possible to determine the Müller matrix of a given sample. The possession of this information in turns permits one to determine a wealth of information pertaining to the sample, such as polarisance, diattenuation, etc..



Discussion: It is possible to show using first principle arguments and more conventional optical system analysis that the determination of polarisation state in the far-field is not limited by Abbe's diffraction limit, even though it is emphasised that "breaking the diffraction limit" is not claimed by the present authors. The talk will present experimental images revealing that certain structures can be distinguished by a Müller matrix polarimeter microscope even when their spatial separation does not exceed 50 nm.

Structure-mediated Nano-biophotonics

Abstract— The latest Nobel Prize in chemistry on Nanoscopy has cemented that optics is a key enabling technology for getting a grasp of the micro- and nano-world. By creatively combining a host of complementary approaches one can today realize advanced optical modalities that integrate an increasing number of functionalities and augment not just passive observation but also active access and control over the nanoworld [1, 2]. Using a merger of light and matter sculpting, we have 2PP-fabricated free-floating waveguides that can be optically trapped and "remote-controlled" in a volume; hence coined Wave-guided Optical Waveguides (WOWs). Combining micro-fabrication with optical trapping and manipulation allows us to exploit these WOWs in versatile and dynamically reconfigurable architectures [3]. A plurality of counter-propagating beam-traps relayed to the trapping volume by low-NA microscope objectives on our Biophotonics Worskstation (BWS) [4] control the WOW-structures demonstrating the possibility for a structure-mediated paradigm where micron-sized tools are used to achieve optical near-field tip-size access. However, realizing the full potential of this new structure-mediated approach in challenging microscopic geometries requires a versatile 3D light coupling that can dynamically track a plurality of WOWs to ensure continuous optimal light coupling on the fly.

To maintain high light throughput for the WOWs, we have integrated computer generated holography that can dynamically control the 3D focus position of the coupling beams. Our results show that we can simultaneously maneuver the WOWs in 3D space while dynamically coupling light through them (see Figs. 1(a) and 1(b)) [5]. This structure-mediated approach enables a host of new microscopic functionalities. WOWs with metal-coated tips can exploit plasmonic effects to achieve extreme confinement for localized light excitation and acquisition.

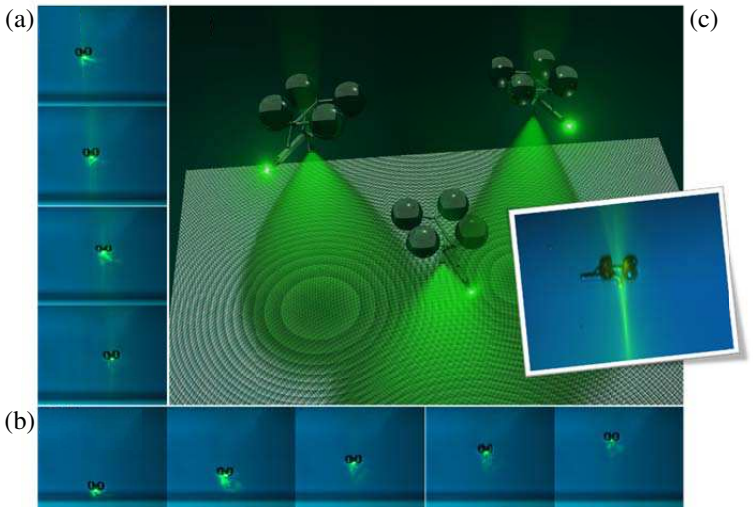

Figure 1: Dynamic coupling of light to 3D-manipulated Wave-guided Optical Waveguides (WOWs). The coupling beams are positioned holographically at the input facets of each WOW making targeted light-delivery at the sub-micron level possible at the WOW-tips. Experimental results show (a) lateral and (b) axial tracking of the coupling beams. (c) A concept art showing the holographically coupled WOWs and snapshot from the experiment.

Nanowires that exhibit particular optical properites can be attached to the WOWs to obtain tunable and fully maneuverable "nano-torches". Another potential application is for advanced Tip-Enhanced Raman Spectroscopy in a full 3D-manuevarable configuration. The micro-to-nano light coupling and the possibility of integrating material transport in the WOW-structures can be a new gate-way for life sciences at the sub-cellular level. The design possibilities offered by 2PP-fabricated WOWs, the augmented holographic light coupling combined with the advanced 3D micromanipulation opens the possibility for performing exciting precision engineered light-matter interaction where it is needed.

Cascaded Field Enhancement in a Multi-scale Nanoparticle-in-cavity Plasmonic Nanoantenna Array Boosted by Fano Resonance

Benfeng Bai and Zhendong Zhu
State Key Laboratory of Precision Measurement Technology and Instruments
Department of Precision Instrument, Tsinghua University, Beijing 100084, China

Abstract— Strong optical near field (i.e., field "hot spots") can be generated in properly designed metallic nanostructures via the coupling and hybridization of localized surface plasmon modes [1], which can greatly enhance the light-matter interaction in the vicinity of the structures. In this work, we propose and realize a nanoparticle-in-cavity (PIC) plasmonic nanoantenna array, in which a 20 nm gold nanoparticle is located at the bottom of a 120 nm truncated gold void in each nanoantenna (see Fig. 1(a)). In this multi-scale system, cascaded field enhancement (CFE) [2] can be realized so that extremely strong and highly confined field hot spots can be generated in nanoscale volumes (Fig. 1(c)). Furthermore, by utilizing and tuning the mode hybridization between the plasmonic dark mode of the gold nanoparticle and a high-order cavity bright mode of the nanovoid, strong Fano resonance can be generated at a target wavelength of 720 nm (Fig. 1(b)), which can significantly boost the CFE. The maximum enhancement factor of the localized field amplitude can reach 10^3. We have developed a cost-effective, efficient and reliable nanofabrication method based on room-temperature nanoimprinting and anisotropic reactive ion etching to fabricate the PIC array (Fig. 1(d)). With this technique, only one gold nanoparticle is guaranteed in each nanovoid and the nanoparticle size can be finely controlled, which are crucial for realizing the CFE effect. To demonstrate the performance of the PIC array, the fabricated PIC samples are employed as active SERS substrates for detecting 4-ATP molecules. The experimentally obtained SERS enhancement factor is as high as 2×10^7, verifying the field enhancement and the potential application of this device.

Abstract— We perform complex investigation of the distribution of electromagnetic fields in the vicinity of an array of silver nanoantennas, which can operate as an efficient light trapping structure in the visible spectral range. In theory, this array should support unusual collective modes (referred to as domino-modes [1]) that possess an advantageous distribution of local electric fields, ensuring both strong field localization beneath nanoantennas and a low level of optical losses inside the metal. To study the distribution of the electromagnetic field near the array we use an aperture-type near-field scanning optical microscope (NSOM) with oblique excitation of the sample. We obtain near-field patterns that show excellent agreement with the NSOM signal which we directly reconstruct from rigorous numerical simulations using an approach based on the electromagnetic reciprocity theorem [2, 3]. This model relates the fields picked up by the near-field probe to the fields that this probe emits when excited by a point (dipole) source placed at the position of the detector. The approach allows us to account both for the non-locality of the NSOM detection process and the shape of the near-field probe. The agreement between theory and experiment allows us to claim the first-time experimental verification of the existence of domino-modes in an array of silver nanoantennas in the visible range.

We also demonstrate that the model of the near-field probe sensitivity based on the reciprocity theorem is very powerful and can be successfully used for the interpretation of the observed NSOM patterns, even in the case of complex geometry with oblique excitation and for structures made of high-index materials, where the probe-sample interaction can be significant. This encourages us to use this model for interpretation of the NSOM signal obtained from the most complex of structures.

On the Effective Volume of Mie Resonators

X. Zambrana-Puyalto and N. Bonod
CNRS, Centrale Marseille, Institut Fresnel UMR 7249, Aix-Marseille Université, Marseille 13013, France

Abstract— We show that the effective volume of spherical resonators depends on ten parameters. We relate each of these parameters to meaningful classical parameters such as the orientation and position of the emitting dipole who gives rise to the effective volumes; Mie-like coefficients; and multipolar decomposition coefficients. As a consequence, we find that given a multipolar order j, the average electric effective volume (for an electric dipolar emitter) is always smaller than the magnetic one. This fact is reversed when a magnetic dipole is coupled to the same resonator.

Introduction: In his seminal letter, Purcell showed that the spontaneous emission of a radio-frequency dipolar emitter in contact with a resonator is enhanced by a factor F [1]. He defined it as $F = 6\pi c^3 Q/\omega^3 V$ where ω is the emission frequency of the dipolar emitter, Q the quality factor of the resonator, and V the effective volume of the resonator. Since then, the Purcell factor has been used in different domains, e.g., optics. It has been known for many years that the Purcell factor gives a good estimation of the enhancement of the decay rates when i) the resonator only supports one mode, ii) when the dipole is oriented along the polarization direction of the mode of the cavity, and iii) when the dipole is located at the modes' maximum [2]. Then, the effective volume is defined as $V = \int_V \epsilon(r)\|\mathbf{E}\|^2 dV$. However, it was seen that F cannot be directly applied in nanophotonics to obtain the enhancement of spontaneous decay rates. In order to do that, very recent works have been done to modify the definition of F [2–4]. The definition of effective volume has been changed to $V_\mu = 1/(\mathbf{p}\cdot\mathbf{E})^2$ where $\mathbf{u_p}$ is the dipolar moment of the emitter, and $\mathbf{E}_\mu$ is a cavity normal mode [3, 4].

Results: Here, we use Mie resonators to give a classical meaning to the effective volume defined by the expression above [5]. It is seen that the effective volume expresses the partial coupling between a dipolar emitter and the normal mode in consideration. Because of that, its expression can be given as a function of the translation-addition coefficients of multipolar theory [5]. As a result, its value can be predicted for some symmetric cases without doing any calculation [5]. Then, using these facts, we compute the average effective volume of an ensemble of uniformly distributed and randomly oriented dipoles for different normal modes of a Si-based resonator. It is observed that the average effective volume is always smaller than the magnetic one [5]. Our calculations can also be applied for magnetic dipoles.

Imaging with Multimode Fibers

Demetri Psaltis
Ecole Polytechnique Federale de Lausanne (EPFL), Switzerland

Abstract— Holography and phase conjugation were proposed in the middle 1960's for correcting the distortions in imaging systems due to aberrating or scattering media. These early methods have been revisited in recent years and successful experimental demonstrations have been reported with digital holographic methods in which the recording and reconstruction of the hologram is done with the help of a digital computer. The digital holographic methods offer a lot more flexibility and control compared to the all-optical methods of the past making holographic imaging much more practical. In addition, adaptive wavefront shaping techniques have been recently developed providing a set of related and synergistic methods for imaging in complex media. In this presentation we will focus primarily on the application of the modern tools of holography to the control of light transmission through multi-mode fibers. The modal dispersion that severely scrambles images propagating through multi-mode fibers can be compensated allowing us to exploit the many degrees of freedom available in the multi-mode fiber for imaging and sensing.

Fiber Lasers and Electro-optic Polymer/Si Waveguide Modulators and Their Applications

N. Peyghambarian
University of Arizona, College of Optical Sciences, USA

Abstract— This talk will be focused on (1) fiber lasers and their bio-medical applications and (2) electro-optic polymer modulators for telecom applications. Phosphate, telluride, and fluoride glasses allow new fiber laser frequencies. Some nonlinear effects including optical parametric oscillators (OPO), SRS and SBS extend the operating wavelengths while others like SBS prevent high power operation. Our recent advances in fiber lasers will be summarized including demonstration of a synchronously pumped fiber optical parametric oscillator (FOPO) operating in the normal dispersion regime. The second part of the talk will focus on the use of EO polymers with r_{33} of = 200–300 pm/V (r_{33} of $LiNbO_3$ = 30 pm/V) in polymer/Si nanowire modulators. Centimeter-length modulators will also be described. Polymers low dielectric constant and low capacitance make them suitable for > 100 G telecom applications.

Spectral Engineering with Tunable Photonic Molecules

Abstract— The ability to control the spectral features of compact photonic devices is a key capability for photonic integration. Diligent device design and active control allow flexible spectral responses that can be tailored to deliver complex optical signal processing functionalities with low power consumption in a reduced footprint.

We present our recent advances using passive and actively controlled silicon photonic molecules for enhanced optical signal processing [1–3]. Based on arrangements of multiple coupled microresonators, these devices overcome the intrinsic interdependence between photonic lifetime, resonance spacing and footprint for single microresonators, introducing a new degree of freedom to perform spectral engineering. Carrier recycling [2], potential for modulation beyond resonance line-width limit, and low-power wavelength multicasting using multiple-split resonances that overcome the trade-off between the cavity free spectral range (FSR) and optical field enhancement [3] are demonstrated in micrometer-scale devices. Using active control, we will demonstrate reconfigurable and continuously tunable mode-splitting in a multi-GHz range with very low resonance shift using an embedded coupled microring device to control the excitation of counter-travelling modes (Figs. 1(a)–(b)). The change in phase response of tunable mode-split resonances is also shown to transit between distinct dispersion regimes, allowing for controllable optical pulse delay/advancement (Fig. 1(c)). These features will be shown to provide great flexibility in designing devices for optical signal processing using very compact structures based on silicon-on-insulator technology.

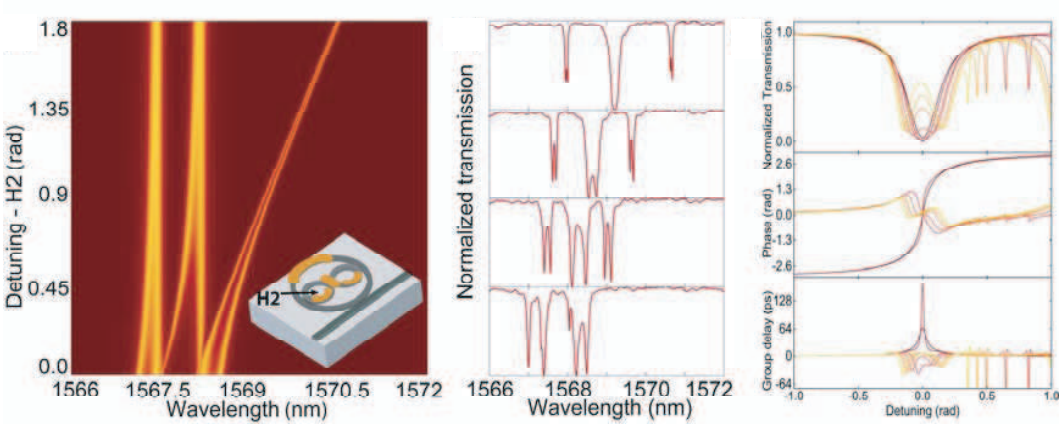

Figure 1: (a), (b) Tunable mode-splitting using embedded coupled microcavities when cavity H2 is detuned. (c) The dispersion regime is changed from normal to anomalous as mode-splitting increases in the central resonance, associated with the outer ring, leading to continuous tuning from light delay to advancement.

Si Photonics for Exascale Computing

Paul S. Davids
Sandia National Laboratories, Albuquerque, NM 87185, USA

Abstract— Optical interconnects have been proposed for more than 25 years as the solution to distance and bandwidth limitations of electrical interconnects. They are currently used in long distance and metro-distance telecommunications and are making extensive inroads in data-center and high performance computing applications. Chip-scale optical interconnects based on Si photonics leverages advanced CMOS process technology but is constrained by the material systems used in standard CMOS processing. Recent advances in low power, small capacitance Si photonic modulators and detectors allows for the realization of compact low power chip-scale transceivers that can provide high bandwidth optical IO for advanced computing applications. In order to achieve the promise of Si photonics in exascale computing, heterogeneous integration of new materials and devices, such as III-V laser sources, and flip chip bonding of high performance electronics with Si photonics are needed to extend the functionality and provides new capability within the Si photonics platform.

In this talk, we will examine advances in the integration and new device architectures that enable low power, high bandwidth communications for exascale computing and also examine extension to quantum Si photonics that could lead to advanced communication networks that promise both algorithmic and physical security.

Photonics as a More-than-Moore Device Technology within Sub-100 nm SOI CMOS

[2]Massachusetts Institute of Technology, USA
[3]University of California Berkeley, USA
[4]IBM T.J. Watson Research Center, USA
[5]National Institute of Standards and Technology, USA

Abstract— I review recent progress of a collaborative effort (by Stojanović, Ram and Popović research groups) to enable the design of photonic devices, and complete on-chip electronic-photonic systems and interfaces, directly in standard microelectronics complementary-metal-oxide-semiconductor (CMOS) processes in a microprocessor foundry, with no in-foundry process modifications. This approach, "zero-change CMOS photonics", allows tight and large-scale mono-lithic integration of silicon photonics with state-of-the-art (sub-100 nm-node) microelectronics, here a 45 nm silicon-on-insulator (SOI) CMOS process. Very large scale integration is enabled by the same manufacturability design methodology that has enabled CMOS microelectronics to yield billions of working transistors on a chip. It enables natural scale-up to manufacturing, and rapid advances in device design due to process repeatability. Our initial driver application is to address the processor-to-memory communication energy bottleneck. In this talk, I will highlight the challenges, and unique opportunities, for photonic device design within an advanced-node scaled CMOS process, using a couple of examples, and their impact through demonstrations of mono-lithically integrated electronic-photonic subsystems on chip. First, I will describe energy-efficient modulators based on an interleaved junction that take advantage of the high resolution of the sub-100 nm (immersion lithography) CMOS process dopant implant masks. They enabled mono-lithically integrated electronic-photonic transmitters on chip (modulator + driver) with record 20 fJ/bit wall plug energy/bit. Second, I will describe array nanoantenna grating couplers that allow efficient and ultra-wideband unidirectional light emission and Gaussian beam forming in unmodified CMOS, and enable 1 dB or better optical coupling from fiber to a 45 nm-node CMOS chip. Last, I will briefly review other unique device technologies that provide a complete photonics platform, and will show results demonstrating the same photonics infrastructure smoothly transitioned one node down in the same CMOS technology strand, into the 32 nm node. These are encouraging developments for the prospects of monolithic electronics-photonics integration. Beyond processor-to-memory interconnects, approaching photonics as a "More-than-Moore" technology inside advanced CMOS promises to enable VLSI electronic-photonic chip platforms tailored to a vast array of emerging applications, from optical and acoustic sensing, high-speed signal processing, RF and optical metrology and clocks, through to analog computation and quantum technology.

Developing a Poly Silicon Photonic Platform on Bulk CMOS

Abstract— Bulk CMOS processes make up for the majority of manufactured electronics for applications as diverse as microprocessors, FPGAs, foundry ASICs and DRAM. Integration of photonics in bulk CMOS has the potential to provide low-power, low-latency interconnects for all of these applications. The main challenge for achieving this goal has been the focus on thick silicon-on-insulator substrates for photonics whereas the majority of CMOS transistors are fabricated directly on bulk Silicon. This fact has driven two-chip hybrid solutions that are not able to leverage the savings in energy, packaging, and manufacturing costs enabled by monolithic electronics and photonics.

In this work, we present a photonics platform in the same polysilicon that is used as the transistor gate in bulk CMOS processes. Through materials and process optimization low-loss polysilicon waveguides using the gate polysilicon have been demonstrated. Waveguides formed from high temperature columnar deposited polysilicon with chemical mechanical polishing (CMP) for improving the top surface roughness; and low temperature amorphous-deposited polysilicon with high temperature anneals without the need for CMP have been demonstrated. These waveguides can be embedded with appropriately doped diode junctions to realize both depletion modulators [1] and all-silicon photodetectors [2] at 1280–1550 nm. The process modules required to realize integrated photonics are inserted without requiring any modification to the performance of electronics.

Recently, passive and active photonic devices have been monolithically integrated with CMOS electronics used for driver and control electric circuits to implement monolithic optical receivers and transmitters that have enabled the successful demonstration of 5 Gbps optical links between two transceiver chips [3]. This demonstration shows the capabilities of the developed polysilicon material platform for electronic photonic integration for a wide range of applications [4].

Abstract— Hybrid metal/dielectric structures are very promising for the fabrication of compact and efficient optical sources. Beside the development of micro- and nano-lasers based on surface plasmons, other surface modes presenting less damping than conventional plasmons can be used such as Tamm plasmons. These surface modes appear at the boundary between a distributed Bragg reflector (DBR) and a metallic layer [1], and present both the advantages of surface plasmons and of microcavities photonic modes. In particular, the losses are reduced compared to a conventional plasmon. We will describe some features of semiconductor quantum wells coupled to extended Tamm modes, like strong coupling with the excitons and lasing [2, 3].

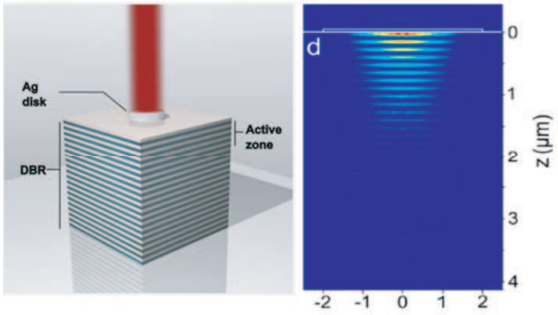

Figure 1: (a) Confined Tamm structure and (b) electric field associated with the Tamm mode.

The main advantage of the Tamm modes lies in the easy confinement of the mode which can be obtained by structuring the metallic part of the structure [4]. The reduction of the mode volume leads to an efficient control of the spontaneous emission (increased beta factor), making Tamm confined structures well suited for single photon emitters and lasers. We will show that confined Tamm plasmon modes can be advantageously exploited for the realization of new kind of metal/semiconductor lasers. Laser emission is studied for Tamm structures with various diameters of the metallic disks which provide the confinement. A reduction of the threshold with the size is observed.

The easy control of the mode properties offered by the patterning of the metallic layer can be applied to the control of the polarization of the emission. Polarization effects in asymmetrical Tamm structures will be discussed. Laser emission with a degree of linear polarization of more than 90% is demonstrated. The polarization can be controlled by tuning the gain of the quantum wells with the Tamm resonance.

Metal-coated Patch Nanolaser Resonators Coupled with a Waveguide

Qian Ding, **Amit Mizrahi**, **Yehaiahu Fainman**, **and Vitaliy Lomakin**
University of California, San Diego, USA

Abstract— An important component to enable miniaturized and integrated photonic circuits is small lasers, which can be required to be smaller than the wavelength of light. In this work, we present electromagnetic design and modeling of nanoscale laser resonators that are smaller than the wavelength of light in all dimensions, including the modal volume extent. The resonators are based on using a low-index dielectric shield layers surrounding a high index core, both placed between two metallic patches. The combination of the high- and low-index dielectric material as well as the metal patches allows significantly reducing both metal and radiation losses. The presented structures are suitable for both optical and electrical pumping, and are smaller than the vacuum wavelength in all three dimensions. The are shown to have a low threshold gain for lasing at room-temperature. Further, it is shown that shifting the gain (high-index) core enables controlled coupling of the resonator electromagnetic modes into a waveguide, opening opportunities for chip-scale integration. It also provides control of the radiation pattern of the resonator. The work includes a analytical analysis of the resonant frequencies and estimates of the threshold gain of the standalone resonators and numerical modeling supporting the analytical findings. The work also includes the analysis of the resonator radiation patterns as well as the resonator coupling to the guided modes of a dielectric waveguide.

Nanoscale Engineering Optical Nonlinearities and Nanoemitters

Y. Fainman
Department of Electrical and Computer Engineering, University of California, San Diego
9500 Gilman Drive, La Jolla, California 92093-0407, USA

Abstract— This paper discusses nanoscale engineered second order nonlinearities in silicon and a 3-D confined metal-dielectric-semiconductor resonant gain geometries used to create a new type of nanolasers for chip-scale integration of photonic information systems. The integration of a photonic information system onto a single chip requires great research effort toward miniaturization of the optical components, similar to the effort that has led to the extensive miniaturization of electronic components. For applications involving a photonics layer between different components on the same chip, the photonic components must be comparable in size to the electronic components, and minimally interfer with each other when densely packed. Such future systems, further require the discovery of new technologies that can operate not only at ultrafast rates ($< 1\,\mathrm{ps}$), but also at extremely low energies, and with low levels of insertion loss. Additionally, future technologies will need to be highly compact, as well as resilient to temperature change. Moreover, the device designs should provide scalability with respect to the operating wavelength, and the optical carrier should be allowed to range in a broad spectral range to support the necessary aggregate information bandwidth. Our most recent work emphasizes the construction of optical subsystems directly on-chip, with the same lithographic tools as the surrounding electronics.

As specific example of our most recent work towards these goals, we present nanoscale engineered second order nonlinearities in silicon. Strained silicon's nonlinear properties were demonstrated, but despite recent accomplishments, the physical mechanisms behind strained silicon's characteristics remain poorly understood. Therefore, the calculations of scaling coefficients which relate the nonlinearity to the local strain gradient are critical to the design of future devices implementing strained silicon. We theoretically analyzed the breaking of symmetry which occurs in silicon as a result of asymmetric strain. We also established phenomenological relationships between two of strained silicons nonlinear components, $\chi^{(2)}_{xxy}$ and $\chi^{(2)}_{yyy}$, and the local strain gradient. To verify our prediction of these nonzero tensor components, we fabricated Fabry-Perot resonators from silicon on insulator (SOI) waveguides strained by silicon nitride. By applying a positive and negative voltage of 25 volts vertically across the waveguides, we induced and measured shifts in the resonances exhibited by the transmission spectra. These shifts correspond to nonlinearities of $\chi^{(2)}_{xxy,eff} = 29.6\,\mathrm{pm/V}$ and $\chi^{(2)}_{yyy,eff} = 44.5\,\mathrm{pm/V}$. By combining our experimentally obtained optical nonlinearities with finite element model simulations, we defined and calculated two scaling coefficients which linearly translated the local strain gradient to the local nonlinearity. We obtained $C_{xxy} = \chi^{(2)}_{xxy}/(de_{xx}/dy) = 2.34(10^{-15})\,\mathrm{m^2/V}$ and $C_{xxy} = \chi^{(2)}_{yyy}/(de_{xx}/dy) = 7.23(10^{-15})\,\mathrm{m^2/V}$. Using these values, we were able to map local nonlinearities exhibited by our waveguides.

For construction of compact nanolasers and light emitters we incorporate metals to reduce the size of the resonator in all 3-D. The modes in such 3-D cavities can be grouped into two main categories: (i) surface bound (that is, surface plasmon polariton (SPP)) resonant modes and (ii) conventional resonant modes within the metal cavity. Although highly confined, the plasmonic modes are lossy and the lasing gain threshold for such cavities can be very large. However, the negative permittivity of metals enables them to act as efficient mirrors, leading to the second class of metallo-dielectric cavity modes, which can be viewed as lossy approximations of the modes in a perfectly conducting metal resonator. In this type of cavity it is possible to achieve higher Q factors and lower lasing gain thresholds, albeit at the expense of reduced mode confinement. Specifically, we describe two types of metal-dielectric 3-D resonators: (a) a composite metal-dielectric-semiconductor cavity where the low index dielectric acts as a shield to reduce the loss into the metal and (b) a coaxial resonator that supports a TEM-like mode which has no cut-off and the physical size of the cavity can be infinitely scaled down in lateral dimensions.

Real Time Single Nano-particle Detection and Sizing thru Whispering Gallery Micro-global Positioning

David Keng[1, 2] **and Stephen Arnold**[1]

[1]MicroParticlePhotoPhysics Lab
NYU Polytechnic School of Engineering, Brooklyn, NY 11201, USA
[2]MP3Laser, Inc., USA

Abstract— Over the past decade, Whispering Gallery Mode (WGM) based optical sensors have demonstrated the ultimate goal of real-time single nano-particle sensing in an aqueous environment; and this achievement has led to the detection of individual virions and single protein molecules from WGM frequency shifts that are proportional both to the volume of the particle and relative intensity at the biding location. However, stochastic random walk of nano-particles in aqueous environment leads to random binding locations on the WGM's sensor surface, causing large variations in the WGM frequency shift, and thereby making real-time sizing problematic. This has made researchers rely on a statistical sizing approach in which the largest signal from an ensemble is associated with equatorial binding, where particle size is extracted from the frequency shift signal. Here we have devised a simple method for determining the size of a nanoparticle in just one binding event by locating its latitudinal position using the shifts of two polar modes of a slightly eccentric WGM spheroidal resonator [1].

Due to the eccentricity of almost all fiber taper driven "micro-spherical" resonators, the $2l + 1$ degeneracy of WGM modes ($-l < m < l$) is lifted and the modes having different m values for a given l are individually accessible. The equatorial mode ($l - |m| = 0$) is concentrated near the equator and has the highest sensitivity. In contrast, the higher latitude modes ($l - |m| > 0$) cover a wider sensing surface area but have lower sensitivity. The ratio of WGM shifts of the equatorial mode to the next higher latitude mode ($l - |m| = 1$) locates the absolute latitude angle at which a nano-particle binds. This ratio has only binding latitude location dependency and is unaffected by the intrinsic properties of the nano-particle (i.e., size, refractive index). Using this binding location, the size of the nanoparticle is calculated using the *Reactive Sensing Principle*. In addition to single particle size and location determination, this sensing scheme also enlarges the effective sensor surface since non-equatorial higher latitude modes also convey the same particle size information. We have experimentally demonstrated this sensing scheme by detecting particle sizes of a colloidal bimodal mixture.

Although our latitude-only micro-global positioning scheme is applied to nanoparticle sizing using slightly eccentric spheroids in aqueous solution, this approach can also be applied to WGM micro-resonators having a variety of shapes and in non-aqueous surroundings (i.e., air, vacuum) as well.

Spectral Correlation in Coupled Random Lasers

Antonio Consoli and Cefe López
Instituto de Ciencia de Materiales de Madrid-ICMM (CSIC)
Sor Juana Inés de la Cruz 3, Madrid 28049, Spain

Abstract— Two coupled random lasers show spectral emissions with strong correlation, with the same mode frequencies activated in both resonators. Experimental evidence of strong mode coupling between adjacent resonators is reported.

In random lasers (RLs), the feedback is given by multiple scattering. A typical feature of RL is an emission with narrow peaks, where the spectral position of the modes arises from the randomness of the cavity. So far, experiments and theoretical work have been oriented to the study of a single random resonator where the cavity is defined either by the pump extension, in large sample, or by the confined region where scatterers are distributed, in micron sized samples. Indirect pumping has been demonstrated as a way of tailoring RL emission [1]. The transverse beam of the pump is properly shaped with the aim of changing the pumping conditions on the considered random resonator. This experimental configuration is particularly interesting for studying interactions between adjacent resonators. We designed our samples in order to have large (hundreds of μm to few millimetres) scatterers aggregates placed at distances of few millimetres (TiO_2 in a bath of dye). We performed experi-ments on a single resonator, by pumping a small region (150 μm) of the TiO_2 with stripe shaped beams of varying length. Selecting two adjacent clusters, placed at 4.0 mm separation, simultaneous pumping with a stripe shaped beam activates the same frequencies in both clusters. Experiments, varying the geometry of the shaped beam show mode competition and strong coupling [2]. These results open the way to a new field of application as networks of mutually coupled RLs.

Abstract— When two resonant modes in a system with gain or loss coalesce in both their resonance position and their width, a so-called exceptional point occurs, which acts as a source of non- trivial physics in a diverse range of systems [1]. Lasers provide a natural setting to study such non-Hermitian degeneracies, as they feature resonant modes and a gain material as their basic constituents. In my talk I will demonstrate that exceptional points can be conveniently induced in a photonic molecule laser by a suitable variation of the applied pump [2] — a concept that was meanwhile also successfully implemented experimentally. In a first realization [3] we used a pair of coupled microdisk quantum cascade lasers, which were shown to produce a characteristic reversal of their pump dependence in the vicinity of these exceptional points. A particularly counter-intuitive aspect we demonstrated here explicitly was a strongly decreasing intensity of the emitted laser light for increasing pump power. In a second realization [4] based on two coupled silica micro-resonators, this phenomenon could directly be linked to the movement of resonance eigenvalues in the complex plane, which follow an avoided eigenvalue crossing near the position of the exceptional point. One of the curious results of this non-trivial behavior is that close to an exceptional point, lasing is inducible solely by adding loss to a resonator. Through this demonstration of "loss-induced lasing" we provide a counter-intuitive extension of the conventional rule that loss needs to be avoided for the laser to reach its lasing threshold.

Abstract— Internet boom can be slowed down by power hungry data centers. Silicon photonics is the technology to face this. A new twist to silicon photonics is provided by microresonators which enable complex functions and devices. The large refractive index difference between silicon and silicon oxide allows a tight confinement in silicon waveguides with small bend radius. Therefore, very small silicon microrings with high quality factors are possible. Microrings show different properties that can be integrated into functional silicon photonic devices. Single, coupled or cascaded microring geometries can be used to achieve complex functions. Still many aspects of the physics of photon confinement in small optical cavities have to be investigated. Therefore silicon microresonators are ideal devices for looking at new phenomena and new physics. Here we review and summarize few of these.

Fiberized Novel Wavelength-scale Planar Waveguides

Xian Feng, **Jindan Shi**, **Peter Horak**, **and Francesco Poletti**
Optoelectronics Research Centre, University of Southampton, Southampton SO17 1BJ, UK

Abstract— The modern glass optical fiber, starting from the simplest circularly symmetric waveguide geometry, has been widely inspired by the geometrical structure and functionalities of glass or non-glass based planar channel waveguides. For instance, the currently well-developed microstructured optical fiber [1] has been inspired by works on planar photonic crystal waveguides [2]. On the other hand, planar channel waveguides, such as slab waveguides, ridge waveguides and slot waveguides, are typically fabricated by various processing approaches, e.g., deposition, sputtering, etching, lithography and so on, at relatively low temperatures. Compact microstructured planar waveguide devices play important roles in various technical areas including telecoms application, sensing, and biomedical diagnostics and imaging. In comparison with planar waveguides, optical fibers have numerous advantages, e.g., long length, low cost per unit length due to high yield and low propagation loss. Fiberization of planar waveguides is a simple and neat idea to combine the advantages of both planar and fiber waveguides for realizing economic and compact photonic devices.

In this work we presented our first fiberized ridge waveguide. A long, narrow raised strip waveguide was constructed on top of a thin, flat substrate, which has a refractive index lower than the ridge. The ridge waveguide with the supporting substrate was built inside a glass jacket, similar to the format of holey fiber. The fiber was fabricated using a sheet-stacking method [3]. Three types of commercial glasses were employed in constructing the fiber. The outer jacket glass has significant lower viscosity than the core glass during the fiber drawing. Because of this large thermal mismatch between the cladding glass and the core glass, the ridge geometry was maintained with acceptable distortion, even when the dimension of the ridge waveguide was reduced to 1 μm. The loss of was measured to be 0.039 dB/cm at 1.55 μm in the fiberized ridge waveguide with ~ 1 μm dimensions, showing a low loss comparable with reported low-loss planar waveguides. A high birefringence of 9.5×10^{-3} was measured in a fabricated fiber ridge waveguide at 1.55 μm. This is close to the highest reported birefringence (1.1×10^{-2}) in optical fibers. Because the ridge waveguide is surrounded by air on three sides, this kind of geometry allows a strong overlap of the optical evanescent field with the surrounding medium. Hence, it provides a highly sensitive structure for chemical sensing. In addition, the ridged geometry also provides a convenient platform for adding heterostructures composed of other materials such as polymer, glass, metal, and semiconductor onto the top of the ridge. Extra optical functionalities can thus be added onto the waveguides. Therefore, we believe that this fiberized waveguide can be a powerful platform to complement the lab-on-fiber technique for chemical sensing.

In addition, the fabrication and characterization of other types of fiberized planar waveguides, e.g., of a slot waveguide [4] which consists of two parallel rails of a high-index glass separated by a subwavelength (~ 100 nm) air-slot, are currently ongoing.

Coupling between Photonic Microcavity and Plasmonic Nanocavity

Keiji Sasaki
Research Institute for Electronic Science
Hokkaido University, Sapporo 001-0020, Japan

Abstract— We present highly efficient coupling between whispering-gallery-mode photonic microcavity and multipolar-mode plasmonic nanocavity. The first topic concerns complete coupling between propagating light (PL) and a single localized-surface-plasmon (LSP) nanostructure. We proposed a tapered-fiber-coupled microspherical cavity system combining an Au-coated probe tip [1]. This system possesses the unique characteristic of precise adjustability for the fiber-cavity coupling rate and the cavity-plasmon coupling rate, which is indispensable for achieving the critical coupling conditions. We successfully demonstrated the 93% PL coupling into the LSP antenna with an effective area of 58-nm circle, exceeding the diffraction limit. In other words, the cross-section of a single plasmonic nanostructure can be effectively enlarged to a size comparable to a mode area of a waveguide, thereby bridging the three-order-of-magnitude difference in size. The well-designed combination of the microcavity enhancement and the LSP localization can realize light focusing into a single-nanometer area with perfect efficiency. The second topic is related to plasmonic nanovortex field. The Laguerre-Gaussian (LG) beam, called as the optical vortex, that possesses helical wave-front and doughnut beam profile has recently attracted significant attention because of the unique characteristics of carrying the orbital angular momentum [2–4]. We proposed a novel approach to forming the single-nanometer-scale localized fields of optical vortex, which works as optical nanocavity. We theoretically demonstrated that a tailored plasmonic multimer surrounding a nano-sized gap makes it possible to localize the LG-mode field into the gap space with conserving the high-order orbital and spin angular momenta. This plasmonic nanovortex field can be expected to fit with the shape of the molecular electron orbital and spin having the corresponding angular momenta. In the presentation, the relation between the degrees of freedom in the metal multimer structure and the transferable angular momenta is also discussed.

Bioinspired Soft Photonics

Melik Demirel
212 EES Bldg, Pennsylvania State University, University Park, PA 16802, USA

Abstract— This talk will focus on soft photonic devices with non-linear optical properties that are manufactured as fibers, waveguides, and resonators. Specifically, we will talk about soft photonic devices that have unique mechanical and optical properties. A broad body of literature has been published in the last decade on optical and photonics biomimetic structures. Recent developments in optical technologies have revealed the strong need for developing soft photonic devices and photonic structures with novel functionalities that cannot be attained with current optical materials. This, in turn, requires utilizing unconventional materials with physical properties different or superior to those presently implemented. Moreover, greener photonics products with less chemical processing and energy consumption are in high demand due to growing environmental concerns. The interplay between the molecular architecture, morphology, and composition of biological photonic systems can provide inspiration for bioinspired soft photonics. Particularly, soft photonics provide molecular level programmability that provides tunability to enable novel functionalities such as Raman enhanced lasing.

Optofluidic Lasers Based on Biological Gain Media Suspended in Liquid Droplet Microcavities

Abstract— Surface tension shapes liquid droplets of sub-millimeter size into virtually perfect spheres with atomically smooth surfaces. Such spherical droplets represent spontaneously formed optical microcavities capable of sustaining high-quality whispering gallery modes (WGMs). Strong spatial confinement of the WGM resonant light circulating near the droplet internal surface then results in very high optical intensity that can couple strongly to the molecules or small particles contained within the droplet liquid. Consequently, lasing emission from a suitable gain medium suspended in the droplets can be observed with pump thresholds that are significantly lower than those required for bulk liquid samples.

Naturally produced fluorescent proteins and their genetically engineered variants with adjustable spectral properties have become a tool of choice for quantitative, selective visualization of localization and mutual interactions of molecular constituents of live cells. In a typical experiment, the intensity of spontaneous light emission from optically pumped fluorescent proteins is detected and evaluated. However, the resulting optical signal is often too low to collect a sufficient number of photons before the chromophore photobleaches. In addition, detection of weak fluorescence signals is frequently hampered by the presence of non-specific background. Incorporation of fluorescent proteins into an optical cavity can lead to the significant increase of fluorescence signal levels due to stimulated emission and light amplification in the cavity, effectively forming a laser with biological active medium. Lasing emission from fluorescent biological molecules can then greatly enhance the performance of fluorescence-based biosensors benefiting from the high sensitivity of non-linear lasing processes to small perturbations in the cavity and the active medium.

We report on experimental characterization of miniature optofluidic biolasers utilizing liquid optical microcavities formed by aqueous droplets deposited on superhydrophobic surfaces. We exploit purified yellow fluorescent protein or a suspension of live *E. coli* bacterial cells expressing the fluorescent protein as the active medium of the studied optofluidic lasers. We characterize the dynamics of lasing emission from these biological materials and show that a single fluorescent bacterial cell of micrometer size confined in a droplet-based cavity is sufficient to serve as a laser gain medium. The lasing bacteria suspended in an aqueous droplet can be provided with all nutrients required for unimpeded growth, which may allow for extension of the operation time of this biologically controlled source of laser light by active regeneration of the gain medium. Using bacterial strains expressing two different fluorescent proteins that form a Förster resonance energy transfer (FRET) donor-acceptor pair, a non-radiative energy-transfer mechanism can be used for laser pumping which would further improve lasing efficiency and open up the possibility for emission wavelength tuning. Furthermore, FRET lasing in connection with self-recognition and self-assembly of biological molecules attached to the fluorescent proteins can be exploited to program and modulate the laser characteristics, thus paving the way to new routes of live-cell bio-sensing.

Whispering-gallery Mode Resonators Based on Liquid Droplets

Gianluca Gagliardi
Consiglio Nazionale delle Ricerche, Istituto Nazionale di Ottica (INO)
Comprensorio A. Olivetti, via Campi Flegrei 34, Pozzuoli, NA 80078, Italy

Abstract— Over the last decade, optical whispering-gallery modes (WGMs) have been observed in solid micro-cavities of various geometries. WGMs supported by dielectric microspheres and toroids exhibit and optical field that is confined near to the surface. Using highly-transparent glasses, light that is coupled into a WGM can circulate around the resonator for a long time before being scattered or absorbed. Q factors $> 10^9$ can be achieved using silica material. Silica resonators proved ultra-sensitive bio-chemical probes but were also studied as miniature systems to observe coupling and interaction phenomena between light and matter. The peculiarity of WGMs is that light travels along closed paths at the interface between the surface of the resonator and the surrounding environment. Unfortunately, most of the light circulates inside the resonator and only the evanescent wave tail may interact with the external medium, i.e., only a small fraction of light is actually used for sensing, thereby reducing the effective cavity enhancement. Here, we propose to use liquid droplets as micro-resonators for sensing applications. The droplet itself serves as the sensor and the sample at the same time, where the internal optical field is directly used to probe dissolved analytes or particles. We demonstrate free-space excitation and laser frequency locking on whispering-gallery modes in vertically-suspended mm-size liquid droplets. Photon lifetime measurements are performed by cavity ring-down techniques recording Q-factors ranging from $5 \cdot 10^5$ to 10^7 in the near-infrared and visible spectral regions. Lifetime changes are measured in mixtures made from different liquids as a proof-of-concept of chemical sensing. Effects of metallic nanoparticles dissolved in the droplets were studied in view of possible plasmon-assisted detection of rare analytes. Appealing applications for spectroscopy, biosensing, material characterization and non-linear optics are envisaged.

Design, Fabrication, and Evaluation of a Polymer Mach-Zehnder Electro-optic Modulator

Xinjie Song, **Rainer Leonhardt**, **and Stuart Gerald Murdoch**
Department of Physics, The University of Auckland, New Zealand

Abstract— We have designed and fabricated a novel polymer M-Z EO modulator for the use at the 1550 nm telecommunication wavelength. Our waveguide structures are cut with µm-resolution by laser ablation. The core layer of the device is made of Polycarbonate/Disperse Red1 (PC/DR1) polymer system. For proper operation, the waveguides of the modulator have to be single mode. A numerical simulation program MODE has been used and shows that typical configuration for a single mode ridge waveguide is $7 \times 4 \times 2.5$ µm (width × height × slab thickness). To achieve the necessary µm-resolution for our waveguides, a 248 nm KrF excimer laser machining system (running at 500 Hz with 5 ns pulse duration) is used to ablate the waveguide structures. Ablation rates for PC at different laser fluences have been characterized, and used for the waveguide machining. ESEM pictures have shown very good surface quality (Fig. 1). In order to measure the propagation loss, we proposed a new method, where waveguides of different lengths are fabricated on one substrate so that the attenuation can be characterized by plotting the output power of these waveguides as a function of length. For our waveguides, the loss was measured to be ∼2 dB/cm. MCL (a moisture-curing polyurethane coating product), UV15 (an epoxy based UV curable coating system) are our choice for the cladding materials, taking into consideration laser machining performance, curing process, refractive indices, resistivity, solubility, glass transition temperature and other properties. An Au-electrode is precisely deposited to cover one arm of the M-Z structure with a metal evaporator. The poling process takes place at 105°C with an applied field of 140 V/µm. A sinusoidal electrical signal (1 kHz) is applied to test the set-up, and the modulated output intensity is measured to determine the effective r_{33} EO coefficient (Fig. 2). Up-to-now, values of 2.5 pm/V have been achieved for r_{33}.

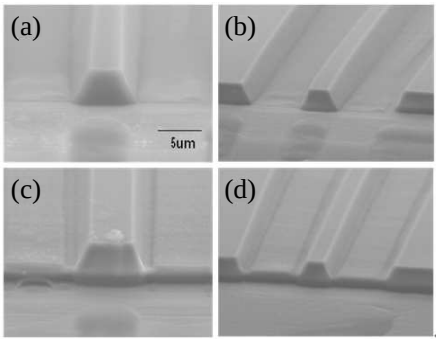

Figure 1: ESEM pictures for single-mode PC waveguides on glass substrate: (a), (b) rectangular waveguides (with material totally removed on both sides); (c), (d) ridge waveguides (with material partially removed on both sides).

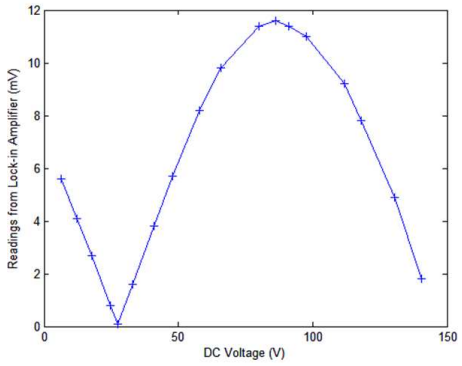

Figure 2: Modulated output amplitude as a function of the DC voltage for a polymer M-Z modulator. The corresponding r_{33} value was estimated to be ∼2.5 pm/V.

Simple Waveguide-QED-based Photonic Quantum Gates

Yuuki Tokunaga[1] and Kazuki Koshino[2]

[1]NTT Secure Platform Laboratories, 3-9-11, Midoricho, Musashinoshi, Tokyo 180-8585, Japan
[2]College of Liberal Arts and Sciences

Abstract— Photonic systems are promising for realizing quantum information processing because of their long coherence times. However, due to the weak interaction between photons, implementation of photon-photon gates has been difficult. One way to overcome this problem is to exchange the photonic and atomic qubits and to enhance the interaction using the cavity-QED or waveguide-QED systems [1–3], where the spatial modes of the input photon and the radiation from the atom match in a one-dimensional field and strongly interfere with each other. Recently, Zheng, et al. proposed a waveguide-QED based photon-photon gate [3], which has advantages compared to Ref. [1] such that it has a cavity-free setting and that single-qubit rotation of the atom is unnecessary. However, in their scheme, three atomic systems are required: a four-level atom is used for the interactions and also two five-level atoms are used for assisting the interaction. Those three atomic systems should be located separately and be kept coherent, which is highly demanding in practice.

In this work, we propose a simple scheme for a waveguide-QED based photonic quantum gate, using only a single six-level atom coupled to a waveguide. The M-shape five levels in the atom are used as a quantum memory like as Refs. [4, 5] for trapping the first incoming photon. The rest one level in the atom is used for performing the controlled-phase gate between the trapped photon and the second incoming photon. The second photon is reflected by the atom or the end of the waveguide without being trapped by the atom. After that, the first photon is retrieved by sending an ancillary photon. The scheme retains the advantages of Ref. [3] such as cavity-free setting and no single-qubit rotation on the atom. This system would be a simple building block for on-chip quantum computation using such as superconducting circuits or photonic crystal waveguides, which recently have dramatic progress [6–9].

Abstract— Optical microdisk laser provide a promising alternative to the well-known Fabry-Perot lasers as well as to VCSELs as the size of optical devices is further reduced to the scale of few micrometers. Whereas high Q-modes are available through whispering-gallery (and similar) resonances that are trapped by total internal reflection inside the resonator, it remains a challenge to achieve directional emission by suitably breaking the rotational symmetry of the devices. In a previous work [1] we have shown that the so-called Limaçon-shape is provides a robust possibility to combine directional far-field emission with high Q-factors. In detail, the far-field characteristic is determined by the unstable manifold of the cavity, a quantity well-known in the field of dynamical systems and quantum chaos. It implies that ray-based calculations, wave-simulations and experiments yield practically the same result. In particular, the easy-to-implement ray-optics methods are an appropriate tool to predict the far-field of microdisk lasers.

We complement our results by discussing various other resonator geometries and alternative schemes to achieve directional light output from microoptics devices. Furthermore, we discuss how boundary imperfections may affect the far-field pattern. To this end we study the effect of sharp and rounded cusps reaching into the resonator or to the outside on the reflection of an incoming test ray.

Finally, we will briefly discuss the polarizations dependence of the emission characteristics as well as semiclassical corrections to the ray picture that occur in the form of beam-shift effects that may become important in the far-field pattern prediction of very small optical microdisk lasers.

Abstract— We will discuss several applications of the coating of silica microspheres. Silica microspheres fall in the group of so called whispering gallery mode (WGM) resonators. They are known to have a very high Q-factor and a low modal volume. Therefore they are suitable for a number of different applications such as lasing, frequency comb generation or sensing. In this paper we will discuss three different applications. Firstly we will discuss the sensing properties of the coated microsphere. We have found that a high refractive index coating can greatly improve the sensing properties of a silica microresonator, improving the theoretical sensing sensitivity from 5 nm/RIU for a blank silica sphere to a maximum of 145 nm/RIU for an amorphous silicon coating. We will also discuss some experimental results dealing with the coating of silica microspheres with a LPCVD a:Si coating. Second application which we will discuss is lasing and optical amplification. By coating the microsphere using an optically active material, microsized lasers can be produced. We have coated a silica microsphere using an erbium doped glass ($70SiO_2$-$30HfO_2$) and have shown that such a system exhibits both lasing and wavelength selective amplification. Finally we will discuss the possibility to tailor the modal dispersion of the resonator by applying a high refractive index coating on top of the microsphere. This can be a crucial step for improving the applicability of the microsphere in non-linear optics applications, such as for four-wave mixing. We used erbium doped silica hafnia glass as a probe to study the influence of the coating on the modal dispersion inside the microresonator and have found that the coating can be used to tailor the modal dispersion in a very wide range in both the normal and anomalous regime.

Wave-inspired Corrections for an Efficient Ray-optical Description of Micro-optics Devices

P. Stockschläder, J. Kreismann, and M. Hentschel
Institute for Physics, Technische Universität Ilmenau, Ilmenau, Germany

Abstract— Ray optics is a versatile tool to describe microscale optical systems like microlasers and their far-field emission. It is successful even in the regime where a wave-dynamical description would be expected to be appropriate. Indeed, when considering structures at length scales of a few light wavelengths, wave-inspired adjustments have to be taken into account to ensure the accuracy of ray-based predictions. These corrections to ray optics are known as the Goos-Hänchen shift, a lateral shift along the interface, and the Fresnel filtering effect, an angular shift, violating Snell's law and the principle of ray-path reversibility.

In a previous work, we have shown that these beam shifts at curved interfaces, characteristic of optical microcavities and microlasers, deviate strongly from the results anticipated for planar interfaces [1]. Especially, the Fresnel filtering effect grows considerably with increasing curvature. This is crucial for the precise prediction of far-field emission characteristics. In this contribution, we study in detail the influences of different factors on the exact size of the corrections paying special attention to the interplay between beam parameters and interface geometry. We obtain our results from analytical calculations using an expectation value approach to the beam shifts. These findings are supported by FDTD simulations.

Knowing the influences of the different parameters, we are able to incorporate well adjusted correction terms in the ray-optical calculations for a large class of micro-optics devices with curved and planar boundaries. Thus, we can make predictions for these devices exploiting the simplicity and efficiency of geometrical optics while keeping the accuracy of wave calculations.

Abstract— Nanolasers are currently at the focus of much research due to their potential as highly integrable, low-consumption and sub-microscopic footprint devices. Given the ultrahigh modulation speed which are projected for some of the most promising devices, modeling is being actively pursued to predict the modulation bandwidth achievable with these devices.

Sophisticated modeling has been conducted up until now on the basis of greatly enhanced rate equations which take into account the physical characteristics of the semiconducting structure both for nanolasers [1, 2] and for nanoLEDs [2]. However, the device's sensitivity to the intrinsic noise cannot be easily tested with these numerical approaches.

Using a recently developed alternative modeling technique [3], based on a Stochastic Simulator (SS) which reproduces the physical processes taking place in a laser, we investigate the potentials for direct modulation (and therefore bandwith response) of nanolasers. Since the SS intrinsically reproduces the stochastic nature of the events which take place in the pumping and in the emission processes, we focus our attention on the effect of noise on the fidelity with which a modulation signal can be transferred onto the optical carrier. Different regimes are considered, from the point of view of biasing, modulation amplitude and cavity quality factor.

Abstract— Previously, Lorentzian lineshape optical resonances have been observed in silicon spherical optical microcavities. Here, we present Fano lineshape whispering gallery mode (WGM) resonances in the 90° elastic scattering obtained from a silicon microsphere. The Fano lineshape optical resonances arise from the constructive interference between a coherent DC background and the WGM resonances, where the Fano lineshape depend on the relative phase between the DC background and the WGM resonances. For the experimental part, an optical fiber half coupler (OFHC) is used to excite the WGMs of the silicon microsphere. A distributed feedback (DFB) laser is used as a tunable light source. The analysis of the experimental spectra shows that the polar angular mode spacing of 0.23 nm correlates well with the calculated mode spacing of the WGM resonances. The measured effective quality factor (Q) of the Fano resonance is on the order of 10^5, which can be further improved with an appropriate choice of experimental setup parameters.

Study on Magnetic Shielding Effect versus Metal Thickness and Aperture Size of Metal Case

S. Yahagi, **R. Suga**, **T. Uwano**, **and O. Hashimoto**
Aoyama Gakuin University, Japan

Abstract— A power control unit for electric and hybrid electric vehicles contains inverter circuits and their switching noise interferes with AM radio. A shielding technique using metal case is widely used for avoiding the interferences, and lightweight case is desirable considering the fuel consumption of the vehicles. Usually, the case has apertures to connect wire cables and exhaust heat and the interferences due to the switching noise through the apertures are concerned. In this paper, the magnetic shielding effect versus metal thickness and aperture size of copper case is discussed.

Figure 1 shows a measurement system of the magnetic shielding effect of a copper case. The shielding effect versus metal thickness t of the case is measured using the system. A 10-turn loop coil with a diameter of 100 mm is located at the center of the case as a virtual noise source. Figure 2 shows the simulation model where W shows a square aperture size of the case. The simulated results with W of 0 mm are compared with measured ones. Here, the shielding effect is evaluated on the basis of the received power with W of 300 mm. Figure 3 shows the measured and simulated results of shielding effect versus t with W of 0 mm. The measured results agree well with the simulated ones and the usability of the simulation is shown. Figure 4 shows simulated results of the shielding effect versus W with t of 105 µm. The shielding effect more than 30 dB is obtained with W of 50 mm. It is shown that the shielding effect is constant by the aperture size below 30 mm.

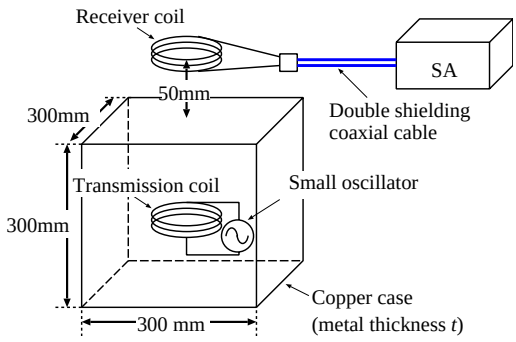

Figure 1: Measurement system of shielding effect.

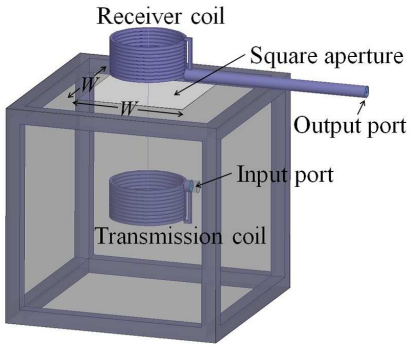

Figure 2: Simulation model of shielding effect.

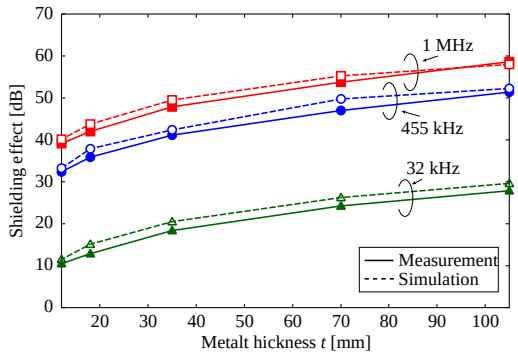

Figure 3: Shielding effect versus the metal thickness ($W = 0$ mm).

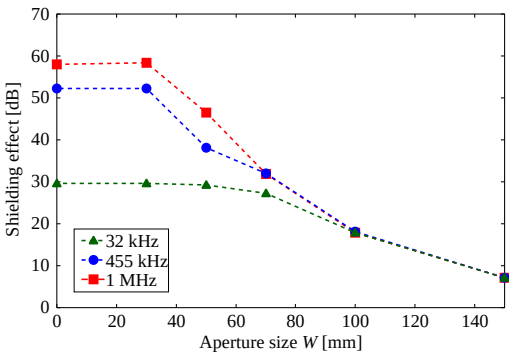

Figure 4: Simulated shielding effect versus aperture size ($t = 105$ µm).

Development of Radar Sensor for Intelligent Building Energy Systems

School of Integrated Technology, Yonsei Institute Convergence Technology
Yonsei University, Seoul, Korea

Abstract— Energy consuming has recently become an important research topic in the world. Buildings are one of the fastest growing energy consuming sectors. The identification of major factors of building energy consumption, together with a thorough understanding of the impacts of the identified on energy consumption patterns, could assist in achieving the goal of improving building energy efficiency and reducing greenhouse gas emissions due to the building energy consumption. One of main building energy consumption factors is Heating, Ventilation and Air-Conditioning (HVAC) energy efficiency. HVAC energy efficiency is closely related to sensors installed in building. Sensors determine that HVAC systems turn on/off. And those control temperature as well as a Wind direction and wind speed. IR-based sensors are one of main sensors that are currently used in building. IR-based sensors have a good performance to detect human. However, those performance are limited to just detection. Microwave-based sensors can to detect human as well as to estimate humans location. Location is an important factor in intelligent building energy systems because that has a strong in uence on HVAC energy efficiency. Radar is extensively used for disaster application. There are some areas in the disaster application field that use radar for detecting human and estimating humans location. This paper analyses the development of radar sensor for intelligent building energy systems. The paper focuses on a technique to detect human and to estimate a location of occupants. In the end, the experimental results show that the proposed radar sensor and algorithm is simple and feasible.

Abstract— In recent years, as many kinds of electronic devices are present, EM (electromagnetic) fields generated from these electronic devices may not only cause problems in the human body, but also affect the electronic devices to induce a malfunction and failure. Therefore, the EMC (electromagnetic compatibility) studies are actively ongoing so that radiation of undesired EM fields can be suppressed below a regulation value and a normal operation can be done in an EM field environment with a constant regulation value.

Standard EM field generators such as transverse electromagnetic (TEM) cell and Gigahertz Transverse Electromagnetic (GTEM) cell are widely used in these EMC field, but have a difficulty in reducing unwanted field components. That is, because the unwanted field components may occur highly in a direction corresponding to the traveling direction of the EM field, there is a problem when generating a near field mode as well as the TEM mode.

In this paper, we proposes a method of reducing the unwanted EM field component in the 4-port TEM cell with two internal septa, which is used for EMC test. Adopting slit structure in the internal septa, 4-port TEM cell provide the improved standard EM field distribution inside the usable test volume.

Abstract— Magnetic resonance wireless power transmission (WPT) have been used as charging systems without power cables such as mobile phones, laptop, etc. [1–3]. However, using WPT systems, unintentional high power interference in a near-field region gradually has become an important issue in practical fields of EMC test [4]. Recently, CISPR published unintentional radiation less than 30 MHz in this point [5]. In this paper, we measured of electromagnetic emission for WPT system as shown in Figure 1. The measurement is carried out in a semi-anechoic chamber using implemented E-bicycle wireless charging system and the measurement distance between the center of the antenna and the EUT (WPT system) is 3 m. In addition, we also analyzed noise source of WPT system.

Study on Evaluation of Composite Electromagnetic Wave Absorber Made of Sendust Particles Dispersed in Polystyrene Resin

Takumi Kubota[1], **Kenji Sakai**[2], **Yuuki Sato**[1], **and Shinzo Yoshikado**[1]

[1]Doshisha University, Japan
[2]Okayama University, Japan

Abstract— Development of an electromagnetic wave absorber suitable for frequencies above 10 GHz is required because of the increasing use of wireless telecommunication systems. For example, it has been proposed to utilize electromagnetic wave of approximately 76 GHz and 90 GHz to the Intelligent Transport System (ITS). In the previous study, Composite electromagnetic wave absorber made of sendust dispersed in resin is low-cost and contains no rare metal. The frequency dependences of the relative complex permeability μ_r^*, the relative complex permittivity ε_r^* and the absorption characteristics for composite electromagnetic wave absorbers made of sendust particles dispersed in polystyrene resin were investigated in the frequency range from 100 MHz to 20 GHz. The composite made of spherical sendust particles with 5 μm were dispersed in polystyrene resin containing 20.0 vol% have approximately 27% normalized −20 dB bandwidth. In this study, to clarify the absorption characteristic in the high frequency range, which has not been evaluated in previous studies, the composites made of sendust particle dispersed in polystyrene resin with the volume ratio of 12.7–28.0 vol% were evaluated return loss in the frequency range of 12.4–110 GHz by free space method. Moreover, it was compared between the measurement values of the absorption characteristics and calculated values of the absorption characteristics obtained from the value of relative complex permeability μ_r^* and relative complex permittivity ε_r^*. As a result, the composites made of sendust particle dispersed in polystyrene resin ware obtain 1.4–3.0% normalized −20 dB bandwidth at frequency range of 12.4–110 GHz.

Thus, the composites made of sendust particle dispersed in polystyrene resin can be used as an electromagnetic wave absorber up to 90 GHz.

Nonlinear Plasmonic Converters for Solar Cell Applications

Abstract— Development of alternative sources of energy is extremely important. Solar energy is one the most promising source of alternative energy and plasmonics can be an important tool to obtain a highly effective solar cells.

Most common material used to produce a solar cell is Silicon because of its availability and low price However, one of a serious limitation of the silicon based solar cells is related with the fact that Silicon does not absorb energies less than 1 eV significantly and there is a substantial amount of solar energy in this region [1]. Optical up-conversion properties of plasmonic structures can be used to efficiently convert unused portion of energy into the useful range. The main focus of our study is to investigate the nonlinear optical up-conversion properties of the plasmonic structures.

Two types of plasmonic interaction appear to be promising and will be investigated in this manner: (a) Localized surface plasmons (LSP) observed on metal nanoparticles. In order to obtain strong nonlinear responses we will decorate dielectric surfaces with periodic or random nano-patterned asymmetric structures which serve as optical antennae leading to strong interaction of solar radiation with LSP at these structures. This kind of design can couple the signal from individual LSP into combined nonlinear response. (b) Lang range surface plasmon-polaritons (LRSPP) observed on multilayer metal-dielectric structures. When the long range surface plasmon polaritons obtain required phase matching condition; effective conversion to higher harmonics is possible [2, 3]. We will create controllable metal-dielectric periodic modulations with holography to generate LRSPPs.

Simulations of Metamaterial Structures for Enhancement of Radiation Absorption in Long Infrared

Mihai Kusko[1], **Cristian Kusko**[1], **and Costin Onofrei**[2]

[1]National Institute for Research and Development in Microtechnologies IMT-Bucharest, Romania
[2] "Politehnica" University from Bucharest, Romania

Abstract— A promising option for the enhancement of radiation absorption for thermal detectors as YBCO based superconducting Transition Edge Sensors is the use of configured layers which manifest resonant absorption. Essentially, a resonant system surrounded by a medium with a small extinction coefficient may present high losses due the thermal dissipation appearing at resonance. The most used resonant system is the split ring resonator (SRR) which is an RLC oscillator having its resonance frequency determined by its geometrical parameters. The SRR is considered to be composed of a YBCO/YSZ/Au thin layer systems on YSZ substrate with the gold and YSZ upper layers to be patterned.

The absorption induced by SRR configurations has been evaluated with simulations performed with OptiFDTD software based on the Finite Difference Time Domain method — FDTD. The dependence with wavelength of power transmission and reflection has been calculated with a Gaussian Pulse which propagates through two observation planes situated after structure and before the radiation input plane, respectively. The obtained results have been used to evaluate the absorption dependence with wavelength. Since the entire system would function at transition temperature from the superconduction to normal state, the YBCO optical complex conductivity was described by using a two fluid model.

From numerical analysis a very sharp peak of absorption has been observed around 8 microns for a SRR with 1.6 micron ring radius. The maximum absorption value is 0.75. The absorption maximum position varies with the SRR ring value so it is possible to design detectors with great absorption at certain wavelengths which opens a way for more efficient thermal detectors.

A Short Note on the Optimization of Halbach Arrays Used as Magnetic Springs

D. Månsson
Royal Institute of Technology KTH, Sweden

Abstract— Neodymium magnets are today widely used for a wide variety of purposes and some commercial types have an adhesive capability of approximately 100 kg even though the dimensions are only $5 * 5 * 2.5$ cm. Therefore the idea of using permanent magnets as springs or bearings isn't uncommon. The simplest form of a linear magnetic spring constitutes of two permanent magnets, with opposing individual magnetizations (e.g., $\bar{M} = \pm M_0 \hat{z}$), this however is not the best choice.

If several small individual magnets are used according to a specific magnetization scheme often described as a "Halbach array" [1], i.e., $\bar{M} = M_0$ $(\hat{x} \sin kx \pm \hat{y} \cos kx)$, a structure that (ideally) have a one sided flux is formed [2]. I.e., the magnetic field is concentrated to the "enhancing side" and the field strength is (ideally) zero on the opposing, "cancellation side" of the structure. (This constitutes however not a magnetic monopole.) If two such Halbach arrays, with opposing magnetization schemes, are employed opposite each other, the total magnetic field is primarily concentrated in the gap between the two structures and an improved, linear, magnetic spring is formed.

Here, both analytical methods using Maxwell's stress tensor (MST) and numerical simulations using *FEMM* [3] are applied to calculate the vertical force on the lower structure (if this is considered to be fixed in space). The characteristics of the vertical force between the two Halbach arrays are very dependent upon the dimensions and the wavelength of the magnetization in the material (through $k = 2\pi/\lambda$). Thus, it should be clear (see Fig. 1) that varying λ will greatly affect the characteristics of the magnetic spring and different applications will require different dimensions and magnetization wavelengths.

In addition, increasing the discretization of the individual elements that are used to form a Halbach array quickly improves the formed magnetic field towards that which is created by a continuous magnetization. Thus, instead of looking at the number of elements per wavelength, the actual wavelength is a more important variable for optimization.

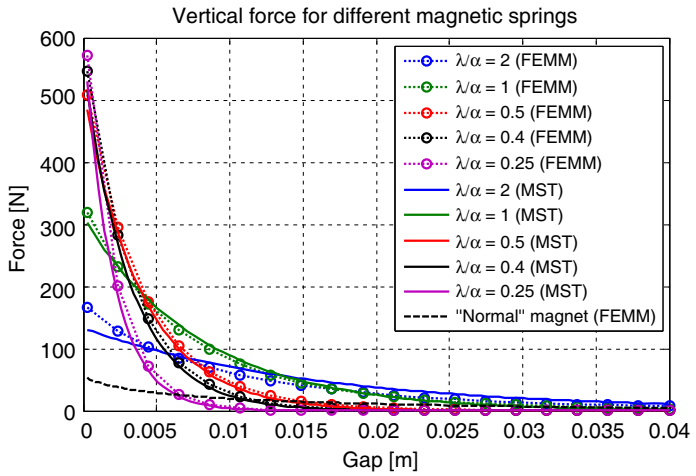

Figure 1: The vertical force created in different magnetic springs using two opposing Halbach arrays with different wavelengths, λ (in relation to the width, α, of the Halbach array). The dimensions here ($\alpha = 5$ cm, $\beta = 1$ cm, $\gamma = 1$ cm) are in the ($\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, $\hat{\mathbf{z}}$) direction respectively. The results are acquired both using numerical simulations (FEMM) and Maxwell's stress tensor (MST). Both methods agree very well. Notice the much lower force (i.e., at most a factor of 10) created between two "normal" magnets of the same dimensions and maximum magnetization (M_0). The small differences, between the MST and FEMM results, in some cases are due to approximations made in order to acquire a simple analytical expression. (In the case where $\lambda/\alpha = 2$, the magnetic structure can't really be considered a Halbach array anymore.).

Also, important aspects such as internal stresses, horizontal forces and spring stiffness are discussed.

Abstract— The boundary value problem in chirowaveguides with translational symmetry is formulated in this paper and used to study the rectangular case. By applying the Green's second identity to a metallic guide filled with chiral material and using the propagation modes in unbound chiral media, i.e., right (RCP) and left (LCP) circularly polarized waves, the electromagnetic field components in the waveguide can be retrieved. To do that, the boundary conditions were formulated in terms of the propagation modes and the integral equations discretized into a matrix equations. The application of the compatibility condition to the system of linear equations provides the propagation constant and, therefore, the dispersion diagram.

The model has been applied to study several chiral materials. The diagram dispersions and transversal cross secton of the propagation modes will be presented for a wide range of the chirality parameter, including a comparison with the achiral guide.

As an example the figure shows the transversal cross section of the longitudinal component of the RCP field for the first propagation mode as a function of the relative chirality parameter: $\kappa_r = 0.1$ (a), $\kappa_r = 0.3$ (b), and $\kappa_r = 0.5$ (c). It can be observed that the reflection symmetry of the typical TE_{10} mode for dielectric waveguide is broken and the fields still keep a rotacion symmetry.

Propagation of EM Fields through a Rotating Circular Hollow Dielectric Cylinder: Numerical Simulation in 2Ds

Mingtsu Ho, **Hui-Hung Lin**, **and Tsaoan Chang**
Graduate School of Opto-Mechatronics and Materials, WuFeng University, Taiwan

Abstract— The propagation of electromagnetic (EM) fields through a rotating circular hollow lossless dielectric cylinder has been numerically simulated in two dimensions using the method of characteristics (MOC) and the numerical results were presented in this paper. The passing center swing back grids (PCSBG) technique was devised and introduced in collaboration of MOC in a modified O-type grid system to resolve the distortion of grid cell caused by the rotational movement. There are two cylinders under the illumination of EM pulse, made of dielectric and impedance matching materials, were used in this work. The computational results, presented in a side-by-side manner for clear comparisons, include the EM field distribution over the whole numerical domain and the EM fields sampled at the center of cylinder.

A Computational Model of Heat Spreader Sheet for Electromagnetic Shielding and Heat Spread

Jin-Sup Kim and Jong-Kyu Kim
Convergence Communication Components Research Center
Korea Electronics Technology Institute, Republic of Korea

Abstract— In this paper, we have designed a computational model of heat spreader sheet using smart device. Modeling heat transfer in a thin graphite sheet, this paper simulates how to use the heat transfer interface's out-of-plane heat transfer feature. Because the spreader sheet thickness is only 35 µm, it is appropriate to simulate the process using a 2-D approximation where the temperature is assumed to be constant along the thickness. Comparison of the temperature from both the 2-D and 3-D model. The simulation graphs coincide to a very high degree, making it difficult to tell them apart. In this paper, we used carbon sheet. The thermal conductivity is 1350 W/m·K (x-y axis) and electrical conductivity is 15000 S/cm. Fig. 1 shows the temperature profile in the 3-D case.

Rapid High-accuracy Modeling Simulation Method for Full Trajectory of the Ballistic Missile

Jianhua Wu, **Gang Li**, **Jian Chen**, **Shiyou Xu**, **and Zengping Chen**
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha, China

Abstract— Ballistic missile trajectory modeling is one of the key technologies in the missile echo simulation and recognition system. However, to the best of our knowledge, all the existing modeling methods simply ignore the characteristics of different flight phase, the effect of the earth's rotation and the low speed of the ballistic generation. In order to overcome these problems, a simulation modeling method with six degree of freedom for the full ballistic trajectory is proposed. The method needs the latitude and the longitude of ballistic missile's launch point and impact point to be known. The first procedure of this method employs an improved inverse solution of Bessel's geodetic algorithm to calculate the trajectory's flight range and azimuth angles of missile's launch point and impact point. The main advantage of this improved algorithm is that it could be suitable for missiles with different trajectory ranges and obtain the results with higher accuracy. Then, based on the ellipse trajectory theory and the minimal energy trajectory theory, we put forward an optimized ballistic iterative method,during which performance parameters (including velocity, optimum ballistic angle and coordinates at the missile burnout point) were estimated. It turns out that the method can markedly decrease the iterations, speed up ballistic generation and improve the accuracy of the result. Moreover, the error of the missile's impact point also can be constrained in a permissible range. We have applied the modeling method into a system of target echo simulation and recognition; the results have shown that the modeling method is rather effective.

Electromagnetic Forces in the Complex-octonion Curved Space

Zi-Hua Weng
School of Physics and Mechanical & Electrical Engineering
Xiamen University, Xiamen 361005, China

Abstract— J. C. Maxwell was the first to research the electromagnetic field with the algebra of quaternions. This method encourages scholars to study the electromagnetic and gravitational theories with the complex quaternion and octonion. In the paper, the complex octonion can be separated into the complex quaternion and S-quaternion. And the curved complex octonion space is separated into two subspaces, the curved complex quaternion and S-quaternion spaces.

The curved complex quaternion space can be used to depict the gravitational field, while the curved complex S-quaternion space is able to describe the electromagnetic field. From the integrating function of field potential, the paper is able to study the field potential, field strength, and field source, in the curved complex octonion space. From the field source, it is capable of researching the linear momentum, angular momentum, torque, force and so forth in the curved complex octonion space.

The paper discusses the influence of curved complex octonion space on the motion of object in the electromagnetic and gravitational fields. It reveals that the field source and curved octonion space both will impact the object's motion in the two fields. By means of the coefficient and curvature in the curved complex octonion space, the field potential (or angular momentum, or the integrating function of field potential) has an extra influence on the field source (or force, or field strength).

Electromagnetic Force on Charged Objects with the Angular Velocity

Zi-Hua Weng
School of Physics and Mechanical & Electrical Engineering
Xiamen University, Xiamen 361005, China

Abstract— The quaternion was first used to study the electromagnetic theory by J. C. Maxwell. Nowadays the complex quaternion is applied to describe the electromagnetic and gravitational theories. Further the complex octonion is capable of studying the electromagnetic and gravitational fields simultaneously, including the field potential, field strength, field source, linear momentum, angular momentum, torque, force and so forth.

The complex octonion radius vector can be combined with the integrating function of complex octonion field potential to become one compounding radius vector, in the compounding complex octonion space. Meanwhile the compounding complex octonion space is able to be separated into two components, the compounding complex quaternion space, and the compounding complex S-quaternion space.

The compounding complex quaternion space is fit for describing the object's movement with the angular velocity in the gravitational field. While the compounding complex S-quaternion space is suitable to depict the charged object's movement with the angular velocity in the electromagnetic field. In other words, in the compounding complex octonion space, it is able to investigate the force in the presence of the velocity curl, acceleration, jerk, and jounce.

The compounding force includes the gravity, inertial force, and Lorentz force and so on. When the compounding force and torque are equal to zero respectively, it is able to deduce some equilibrium states. When the field source does not equal zero, the compounding force and torque may deviate from zero. That is, the rotating charged object will not stay on the equilibrium state. It causes the field to exchange the angular momentum and so on with the rotating charged object.

Power Spectrum Method for the Processing of the DNA in the Genome Sequencing

M. Valla, **E. Gescheidtova**, **and P. Fiala**
Department of Theoretical and Experimental Electrical Engineering, DTEEE, FEKT
Brno University of Technology, Brno, Czech Republic

Abstract— The fractal systems are broadly found throughout the nature, generally in any scale. For each dimension (1D, 2D...) in any structures and in any mathematical algorithms or in any object (sequence, line, square) its dimension can be calculated. These dimensions are specific parameters for description of the DNA sequence characters ACGT strings. Generally a first step consists in the converting of a one-dimensional sequence into the image. In the second step, the method for calculating the dimensions for all scales is selected. For the calculations of the above mentioned dimensions the Power Spectrum (PS) method has been proposed and examined. The Power Spectrum method provides universal calculation of dimension and it allows to obtain the resulting multifractal coefficient. The multifractal coefficient represents the means rate of approximation to ideal power spectrum. It has to be emphasized that the multifractal coefficient is independent of any scale to be chosen. Moreover, the multifractal coefficient serves as an advanced parameter for mathematical description of analyzed specific sequence of the deoxyribonucleic acid (DNA) or the whole genome. The conversion of the sequence into the image as the first step of the pre-processing can be used also for the alternative imaging and the description of sequence and it is possible to choose another method for the processing and analysing a fractal image (for example Box Counting method).

In the paper, the method for the processing of the DNA in the genome sequencing, the Power Spectrum method, will be introduced. The results of the Power Spectrum methods will be presented also.

Electrically Tunable Spin Polarization in Silicene

Son-Hsien Chen
Department of Applied Physics and Chemistry, University of Taipei, Taiwan

Abstract— It was shown recently that charge currents can be highly spin-polarized during transport through silicene in the phase of marginal valley-polarized metal (MVPM). In this paper, by employing the spin-density matrix formalism capable of dealing with spin-flip processes such as in the case of Rashba spin-orbit (SO) interaction, we show that the spin polarization can be tuned via amenable electrical means. Considering the setup consisting of metallic source (injector) and drain (detector) in contract of a MVPM silicene nanoribbon (SN), where two opposite out-of-plane electric fields are applied to the left and right portions, respectively, we find that the outgoing polarization can be adjusted by varying the position of the internal boundary of the two electric fields for injected spins that are in x direction, in y direction, or unpolarized. In the case of two opposite fields applied to top and bottom portions, the polarization oscillates rapidly with the position of the internal boundary. This suggests that the polarization is more controllable by left-right than top-bottom internal boundary. The polarization grows linearly with the Fermi energy in the linear band regime near zero energy. As the length of the SN becomes larger, polarization first oscillates, and starts to increase when the ribbon length is comparable to the width. For incoming spins polarized in arbitrary directions, the out-going polarizations all approach one-hundred percent in the limit of long SN (length much greater than width), which even holds when injecting currents are unpolarized. In the case of weak Rashba SO interaction (weaker than intrinsic SO coupling), if the injected spins are in z direction, then the detected spins are almost fully polarized because z direction is approximately the spin quantization axis. In fact, irrespective of the injected spin directions, the presence of the Rashba SO interaction suppresses polarization because of the entanglement of the spin and orbit degrees of freedom. Contrarily, the disorder effectively closes conducting channels and thus reduces the entanglement, giving larger polarization. The enhancement of the polarization due to similar diminishing of the entanglement is also found by increasing the applied electric field uniformly applied to the SN so that the SN reaches the phase of band insulator in which field-dependent bulking potential is greater than some value characterized by the intrinsic SO interaction. This again implies that the spin polarizations are electrically tunable.

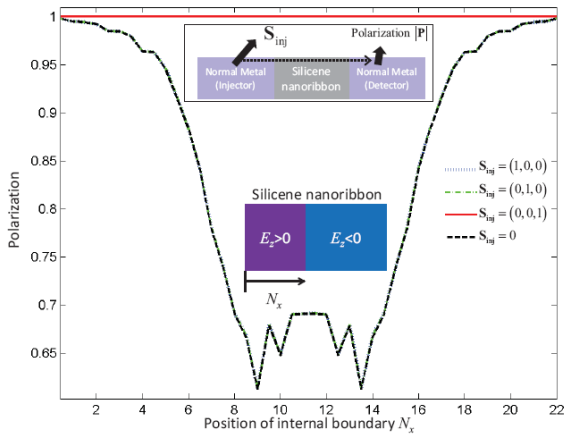

Figure 1: Detected outgoing spin polarization as a function of position of the internal boundary N_x with different directions S_{inj} of injecting spins. Here $S_{inj} = 0$ denotes the case of injecting unpolarized currents. The inset shows the studied setup, while the schematics indicates the direction of the applied electric fields E_z.

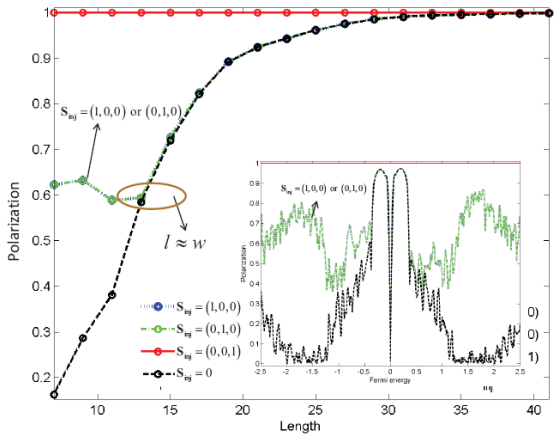

Figure 2: Detected outgoing spin polarization as a function of the length of silicene nanoribbon. The inset shows polarization as a function of Fermi energy.

Lorentz-like Transformations for the Velocity and Acceleration

Zi-Hua Weng
School of Physics and Mechanical & Electrical Engineering
Xiamen University, Xiamen 361005, China

Abstract— Analyzing the existing studies relevant to the Lorentz transformation reveals that all of these existing theories started off with some invariants (space-time interval, or speed of light), to deduce the Lorentz transformation and so forth. However the paper is able to direct deduce some invariants and the Lorentz transformation and so forth in the complex quaternion coordinate system, without the help of introducing the basic postulate.

In the complex quaternion space, when the coordinate system transforms orthogonally from one to the other, the scalar part or norm of one complex quaternion physical quantity remains invariable. The coordinate transformation between two threedimensional coordinate systems with the time, in the presence of relative movement, is equivalent to the orthogonal transformation between two complex quaternion coordinate systems.

Obviously it is able to direct deduce the invariants and Lorentz transformation and so forth, for the three-dimensional coordinate systems in the presence of relative movement, from the orthogonal transformation of complex quaternion coordinate systems. Especially it is not necessary to introduce additionally the invariant or basic postulate into the complex quaternion space, to deduce the coordinate transformations in the Special Theory of Relativity.

Furthermore, making use of the orthogonal transformation in the complex quaternion coordinate system relevant to the radius vector and velocity, it is able to deduce directly the invariants and some other coordinate transformations, besides the Galilean and Lorentz transformations. Similarly one can derive the Galilean-like and Lorentz-like transformations for the velocity and acceleration and so forth, from the above equivalency and invariants.

Realization of a Compact High Speed Mass Storage System

Haishan Tian, **Wenge Chang**, **and Xiangyang Li**
College of Electronic Science and Engineering
National University of Defense Technology, Deya Street 109, Changsha 410073, China

Abstract— The ongoing effort of the miniaturization of the airborne synthetic aperture radar (SAR) systems demands for the compact SAR storage components, particularly in the application where the data rate of the SAR is very high. Conventional on-board storage systems are often weighty, large and power consuming, which can't meet the requirement of the miniature carrier platform.

A new data storage system, integrated with SAR signal processor on one board, is presented in this paper. It uses compact flash (CF) card as storage medium and the FPGA as the host of the CF card. However, there are two obstacles for the high speed data storage. The first one is the internal overhead that the operation of the content erasing of the sectors is needed before the write operation of the CF card. Another obstacle is the frequently cluster switching involving the retrieving and updating of the cluster connection information in the file allocation table (FAT) and file information in the file directory table (FDT). The write response time due to above two obstacles is relatively long and can't be predicted precisely.

Two methods are presented in this paper to solve the problems. The first one is that the DDR3 flashes connecting with the DSP are used as the buffer of the SAR data in the irregular write response time. When the CF card start to store the data, the SAR data in the buffer is transferred to the DSP and then to the FPGA through the high speed interface:the SRIO. The flashes with the capacity of 1 GB are large enough as the buffer of the SAR data. In addition, the speeds of the SRIO and DDR3 interface are all so high that it wouldn't influence the speed of the storage. Another method is that all the available clusters are pre-allocated at once when the files are created. Thus the file can be written without further cluster allocation which requires the updating and retrieving in the FAT and FDT. When the data storage ends, the unused clusters and files are released. According to the two methods and the data flow of the signal processor, the hardware circuit and the software design of the data storage are presented respectively. The block diagram of the implementation is shown in Fig. 1, which consists of the data channel, containing data transfer and CF card read/write unit, and their control channel which controls the work of data channel.

To verify our proposal, the prototype data storage system is implemented on a signal processing board and a CF card with the capacity of 128 GB, as shown in Fig. 2. Yellow marked parts are the key devices of data storage system: CF card, FPGA, DDR3 flashes and DSP. The added size for the data storage is about 60 mm × 41 mm × 2 mm and the added weight is no more than 70 grams. Moreover, the data writing rate is over 100 MB/s and the added power consumption is no more than 1.2 W. As a consequence, the system achieves our goal successfully in that the storage system of the miniature SAR is compact, high speed and large capacity.

Development of Intelligent Electronic Fence System

Jin-Sup Kim
Convergence Communication Components Research Center
Korea Electronics Technology Institute, Korea

Abstract— Radar sensors for monitoring the movements have been continuously evolved from the radar sensor module to the integrated circuit form. Such integrated circuits include RF front-end, analog block, and voltage regulator. Intelligent Electronic Fence (IEF) system is one of the important system for avoiding critical accidents in industrial area. In this paper, IEF system based on radar for avoiding accidents is proposed and implemented using 0.13 µm CMOS technology. The block diagram of the proposed one is shown in Figure 1. In this work, we design and fabricate the IEF system with Bi-CMOS transceiver for low power consumption. The detecting range is about 25 m. The output power is 10 dBm at 24.15 GHz. The frequency tuning range is from 24.05 to 24.25 GHz. The supply voltage is 12-V.

Analyzing Five-layer Planar Optical Waveguides with Kerr-type Nonlinear Metamaterial Guiding Films

Yaw-Dong Wu, Ming-Hsiung Cheng, and Tien-Tsorng Shih
Department of Electronic Engineering
National Kaohsiung University of Applied Sciences, Kaohsiung, Taiwan

Abstract— In this paper, we proposed a method to analyze the electric field distributions of the five-layer planar optical waveguide structure with nonlinear metamaterial guiding films. The proposed nonlinear metamaterial planar optical waveguide is composed of two different kinds of media. One is the Kerr-type nonlinear metamaterial in the guiding films, and the other is the linear double-positive medium (DPS) in the interaction layer, the cladding and the substrate. We have derived the transcendental equations of the proposed five-layer planar optical nonlinear metamaterial waveguide structure. The propagation characteristics of the transverse electric (TE) waves were investigated analytically and numerically in the this structure. The analytical and numerical results show excellent agreement. The simulation results are helpful to figure out the propagation situation of the TE polarized waves in the five-layer nonlinear metamaterial waveguide structure. The transverse magnetic (TM) polarized waves can also be predicted by the similar process. It can also be very useful for designing a planar nonlinear metamaterial waveguide devices.

Z-scan Determination of the Nonlinear Optical Properties of Assembled Gold-nanoparticle Films

Tsong-Ru Tsai[1], **Ming-Chan Shieh**[1], **I-Chi Ni**[2], **and Shien-Der Tzeng**[2]

[1]Institute of Optoelectronic sciences, National Taiwan Ocean University, Keelung 20224, Taiwan
[2]Department of Physics, National Dong Hwa University, Hualien 974, Taiwan

Abstract— The nonlinear optical properties that were obtained by femtosecond pulsed Z-scan measurements in assembled gold-nanoparticle films were investigated at 720 nm. Very large value of the nonlinear optical absorption coefficient β was estimated to be 10^{-3} cm/W. And the imaginary part of susceptibility $\mathrm{Im}\chi^{(3)} \sim 10^{-7}$ esu was obtained. These experimental results suggest that the assembled gold-nanoparticle films are promising materials for applications in nonlinear optical devices.

Plasmons Generation at a Lossy Interface with Induced Anisotropy

Jaromír Pištora[1], **Tibor Fördös**[1], **Michal Lesňák**[2], **and Marek Kolenčík**[1]

[1]Nanotechnology Centre, VŠB — Technical University of Ostrava
17. listopadu 15, 708 33 Ostrava-Poruba, Czech Republic
[2]Institute of Physics, VŠB — Technical University of Ostrava
17. listopadu 15, 708 33 Ostrava-Poruba, Czech Republic

Abstract— The paper is devoted to the analysis of a plasmon field at a metal-dielectric boundary. The model approach based on matrix algebra is used to describe plasmon polariton solutions at a lossy interface with magnetic ordering. The attention has been focused on specification of exact expressions for normal and longitudinal wave vector components on metal-dielectric boundary with induced anisotropy. The influence of permittivity and wavelength on wave vector components is discussed in detail.

The matrix formalism is an extremely useful form of describing the steady-state solution to Maxwell's equations subject to the boundary conditions imposed by isotropic and anisotropic multilayer stacks. The effects of magnetization on the relative permittivity tensor components are usually small and they can be expanded into series:

$$\varepsilon_{ij} = \varepsilon_{0,ij} + K_{ijk}M_k + G_{ijkl}M_kM_l + \ldots = \varepsilon_{0,ij} + \varepsilon_{1,ij} + \varepsilon_{2,ij} + \ldots$$

where $\varepsilon_{0,ij}$ are the permittivity components without magnetization in the crystal ($M = 0$), K_{ijk} are components of the third rank linear magneto-optical tensor describing linear dependence on the magnetization and G_{ijkl} are components of a fourth rank quadratic magneto-optical tensor characterizing quadratic dependence on the magnetization. Since the quadratic contribution to the relative permittivity is generally small, the modeling has been focused on linear magneto-optical properties. The chosen Cartesian system has the xy plane parallel to the planar system (x-axis is normal to the incidence plane); z-axis is normal to the structure. For an anisotropic case in the transverse geometry, the relatively single elements of characteristic matrices provide a valuable insight into the magnetic and optical behavior of the system. In this special arrangement, the mode conversion is not observed and waves are traveling through the structure without polarization conversion. The analytical formulae for real and imaginary parts of longitudinal (parallel to interface and plane of incidence) and normal wave vector components have been determined as function of tensor permittivity elements. The realized model and analytical results including induced anisotropy have been tested by using Bi:YIG off-diagonal tensor permittivity values. The distribution of real part and imaginary one of normalized (k_y/k_0) tangential component of wave vector (longitudinal orientation) as permittivity function of anisotropic medium has been specified. The graphical results have been completed by the dependence of real k_y/k_0 component in 3D image on permittivity and wavelength. Bottom curves characterize induced anisotropy influence. The modulation of mentioned dependences created by induced anisotropy has been observed. This effect explains on the one hand some incorrections when the approximate results are employed for the analysis of a plasmon field at a metal-dielectric boundary, on the other hand brings new ideas for SPR applications.

Permittivity of Thin Quantum Dot Film with Local Field Effects

M. N. Anokhin, **A. A. Tishchenko**, **and M. N. Strikhanov**
National Research Nuclear University "MEPhI", Moscow, Russia

Abstract— It is known that electronic properties of a quantum dot (QD) depend on its size and shape. Spectrum of emission light of a QD is changed by tuning their core diameter. For example, the cadmium selenite (CdSe) QDs emit blue light when the diameter of the core is 2 nm and emit red light when it is 7 nm [1]. Because of it QDs have a good potential for using in different light emitting devices including organic light emitting diodes (OLEDs). For example, QDs gives a good opportunity for design white OLEDs etc..

In this work we study a natural variation of dielectric properties of a very thin film consisting of QDs, with thickness in some QD diameters. For such thin film usually used macroelectrodinamical approach does not work, which needs improving of existing techniques. We manage to obtain the generalized Clausius-Mossotti relation for dielectric permittivity of thin film from the first principles with help of the local field theory [2–4]. The distinctive feature of the local field theory is that it permits to take into account interaction between the QDs, and to express the results through the properties of single QD and radial function of distribution, characterizing their mutual disposition. In article [4] such method was developed for an amorphous substance occupying a half-space. Here we develop this technique for the case of very thin layer using dipole approximation assuming that a QD diameter is considerably smaller than the wave-length of light. We obtain the conditions when resonance lines for system of interacting QDs are shifted in comparison with the resonance lines of a single QD, which is defined by local field effects.

Dielectric Properties and Solvothermal Synthesis of Nanocrystalline TiO_2 in Toluene with Surfactant

Jong-Ho Park
Department of Science Education, Chinju National University of Education, Jinju 660-756, Korea

Abstract— Nowadays as the concerns with global environmental issue increase, the application of TiO_2 to the treatment of polluted air and wastewater has become more and more widespread because of its promising photocatalytic performance. Solvothermal treatment is useful because it can control the grain size, the particle morphology, the crystalline phases, and the surface chemistry by regulating the sol composition, the reaction temperature, pressures, solvents, additives, and aging time. In this article, we report the synthesis of TiO_2 nanoparticles with a solvothermal method and their characteristics in anhydrous toluene solutions. Since toluene has a relatively lower vapor pressure than other organic solvents, the synthesis of TiO_2 nanoparticles can be achieved safely at a relatively high temperature in a shorter time than usual with a relatively simple process. Therefore, we could control the shapes of the TiO_2 nanoparticles by using the solvothermal method.

Synthesis of narrow-dispersed nanocrystalline TiO_2 was investigated by surfactant-aided solvothermal synthetic method in toluene solutions. Titanium isopropoxide, $Ti[OCH(CH_3)_2]_4$ (TIP) was used as precursor, which was decomposed at high temperature in the surfactant-dissolved solution. After the solution was thermally treated at 250 °C for 20 h in an autoclave, low-dispersed TiO_2 nanocrystalline particles with average size of < 6 nm were synthesized. When a sufficient amount of TIP, was added to the solution, the shapes of TiO_2 nanoparticles changed from spheres to long dumbbell rods.

The aggregated microstructures of the nano-sized TiO_2 in systems of spheres, long dumbbell rods were studied using X-ray, TEM, dielectric spectroscopy. From X-ray experiment, when sufficient amount of TIP or surfactant was added in the solution, long dumbbell-shaped nano-rods were formed, which may be due to the oriented growth of particles along [0 0 1] axis.

The dielectric property in spheres and rod-nano TiO_2 were measured over a temperature range of 30–500 °C at several frequencies. we carried out a data analysis in the frequency space. The rod TiO_2 nano particles present the variation of the imaginary dielectric (e") vs. frequency using a double logarithmic scale for several temperatures. The relaxational peak frequency of e" moves to a high-frequency region with increasing temperatures. In the low-frequency region, the other relaxational peak frequency of e" in rod nano TiO_2 particle appeared from room temperature and rose with the increase in temperature. These two different tendencies in temperature dependence suggest that two dispersion mechanisms may be involved.

Optical Properties of Poly-3-hexylthiophene Crystalline Nanofibers Oriented by the Electric Poling Procedure

Gleb Lobov, **Yichen Zhao**, **Alexandrs Marinins**, **Sergei Popov**, **and Muhammet Toprak**
KTH, Sweden

Abstract— Non-linear optics (NLO) had recently made a great contribution to the integration of various photonic devices to the circuit and even chip scale. Organic chromophores with the donor-bridge-acceptor structure are known as good candidates to replace the well-studied non-organic materials. However the area of search for more efficient NLO materials extends beyond the boundaries of azo dyes.

It was recently shown that the conjugated polymer poly-3-hexylthiophene (P3HT) which lacks the classical donor-acceptor structure shows the third-order susceptibility higher than that of Disperse Red 1 [1]. The third-order susceptibility for a 0.1–0.2% wt solution of P3HT was measured to be 1.55×10^{-8} esu, while the maximum value for a 1% wt solution of Disperse red 1 was shown to be 10^{-7} esu [2]. Moreover, it was discovered that the $\chi^{(3)}$ of P3HT is strongly enhanced by the lamellar stacking through a π-orbital overlap [3]. This stacking results in having P3HT in a conformation of separated fibers of controlled thickness and length with a random orientation (Figure 1).

Further on our task was to show that it is possible to achieve other unique optical properties by breaking the centro-symmetry through introducing the spatial ordering of the fibers. The alignment of the fibers was achieved under application of a quasi-static electric field between specially designed electrodes. The results were verified by SEM analysis after poling a very diluted sample at $\approx 1.8\,\mathrm{V/\mu m}$ and are shown on Figure 2.

As seen on the Figure 2, fibers react to electric field and align perpendicular to the gold electrodes. Such induced anisotropy of crystalline polymer conformation is absolutely novel and unstudied in terms of spectroscopic measurements and electro-optical properties. Anisotropic ordering of the fibers also allows 2nd order non-linear effects which had not been studied in this material ever before.

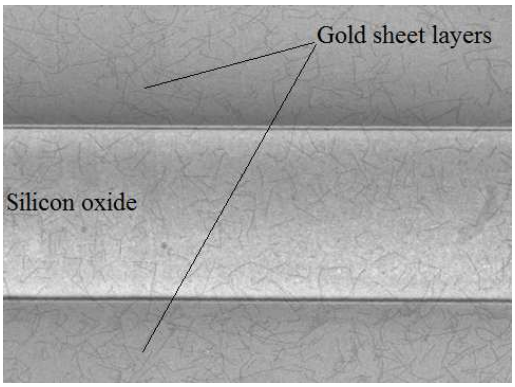

Figure 1: SEM image of unordered P3HT nanofibers.

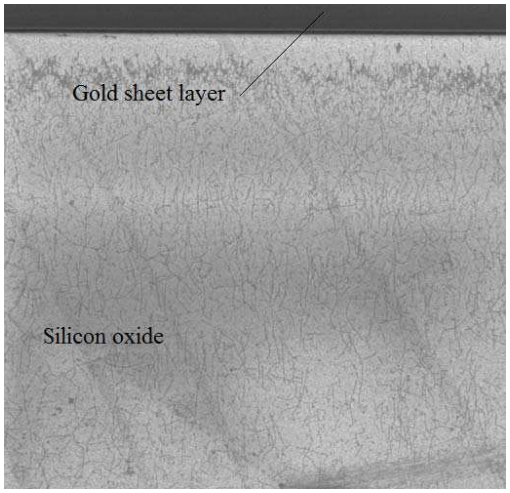

Figure 2: SEM analysis of the ordered P3HT nanofibers.

New Design of All-optical Flip-flop Device Based on Multimode Interference Photonic Crystal Waveguides

Yaw-Dong Wu, Jui-Hong Hsu, Hsiu-Chuan Huang, and Tien-Tsorng Shih
Department of Electronic Engineering
National Kaohsiung University of Applied Sciences, Kaohsiung, Taiwan

Abstract— In this paper, we proposed an all-optical flip-flop device based on the multimode interference (MMI) with photonic crystal (PC) waveguides. The proposed all-optical logic gate was numerically studied by the finite-difference time-domain method (FDTD). In recent years, the photonic crystal is a very popular topic due to photonic band gaps (PBGs) which were known to exist in the periodically modulated dielectric materials. We try to combine the MMI principle and photonic crystal waveguide to design a whole new all-optical RS flip-flop device based on the MMI PC waveguide structures. By introducing a point defect rod both in the control ports, we can make outgoing field propagating in the output waveguide or not. The intensity profiles show snapshots optioned at different times. This numerical results show that the proposed PC waveguide structure could really function as an all-optical RS flip-flop logic gate. Note that if we have an RS flip-flop, we can realize various much complex logic processing based on it.

Ultrashort Pulse Generation in Tapered Photonic Crystal Fiber at 400 nm

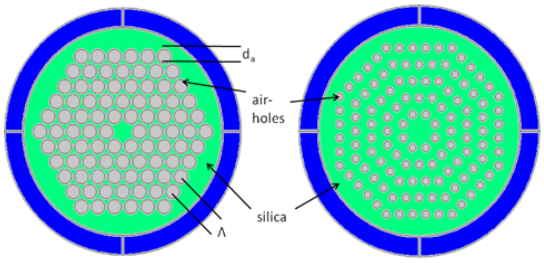
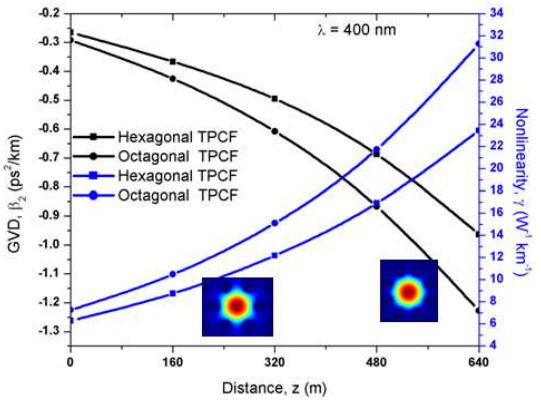
Abstract— The generation of ultrashort pulses at shorter wavelength near 450 nm is especially preferred in satellite sensors, ophthalmology in optical coherence tomography system, optical imaging, etc.. However, it is difficult to produce such a shortest pulse at near visible wavelength even from the best available laser sources. Of late, the generation of desired pulse width of ultrashort pulses is quite possible through pulse compression technique with the advent of photonic crystal fiber (PCF) where the anomalous dispersion can also be obtained at visible regime. Achieving single mode and high dispersion near the visible wavelength are considered to be challenging tasks in the generation of ultrashort pulses in PCF. In general, there are two proven ways to enhance the nonlinearity and dispersion values in PCFs. First, one can modify the design of PCF with large air hole size leading to high nonlinearity and large dispersion. However, the single mode tends to vanish for larger values of air hole size. Second, the nonsilica technology such as SF6, TF10, CS2, nitrobenzene, and so on, enhances the nonlinearity and eventually the required input energy of the pulse can be minimized considerably. Even in the non-silica technology, obtaining a single mode as well as anomalous dispersion at visible regime is very difficult in PCF for large air hole diameter.

In general, the tapering is done by reducing the pitch and diameter. Fiber tapering provides a convenient way to reduce the mode-field diameter of fibers, thereby allowing for a better pulse compression. We, thus, emphasize that the tapered PCFs (TPCFs) are very much suitable for effective pulse compression when compared to conventional PCFs. In this paper, we design hexagonal and octagonal TPCFs wherein dispersion and nonlinearity vary exponentially in line at 400 nm wavelength according to the self-similar analysis. By exploiting these optical properties, we demonstrate the effective pulse compression schemes at 400 nm wavelength.

Geometrical structure and variations of group velocity dispersion (GVD) and nonlinearity along the propagation direction for both hexagonal and octagonal TPCFs at 400 nm wavelength are given by:





Electrical Field Energy Oscillation near the Photonic Structure Faces

Vyacheslav A. Trofimov, Elena S. Komarova, Alexey S. Barykin, and Mikhail V. Fedotov
Lomonosov Moscow State University, Leninskie Gory, Moscow 119992, Russia

Abstract— Using on the 1D Maxwell's equations, we analyze a femtosecond laser pulse interaction with transparent layered structure (1D photonic crystal — PhC). As it is well-known, such structure is wide used in photonics.

Laser pulse falls on a PhC and propagates inthe structure. Because of multi-layers the laser pulse reflects many times from boundaries between the PhC. As a consequence of this, part of a laser pulse localizes in the PhC during certain time interval. Analyzing this process we found out new effect: oscillation of laser pulse energy near the PhC faces but outsides the PhC. More precisely, part of laser pulse, leaving the photonic crystal through its faces, changes its motion direction and returns into the structure. A reason of such electric field energy evolution is wave vector direction change. Therefore, the corresponding part of wave packet moves more towards to the PhC and comes back into the structure.

Amplitude of electric field energy oscillation depends on dielectric permittivity of PhC layers and their lengths. We investigate in details the laser pulse duration influence on the electric field energy oscillation as well as the PhC characteristic influence on this regime of laser radiation interaction with PhC.

Accuracy of Waveguide Mode Solver Based on Boundary Integral Equations

J. Vincent[1,2], **A. Calvez**[3], **R. Perrussel**[1], **and J.-R. Poirier**[1]

Abstract— In this paper, we investigate the accuracy of a waveguide mode solver based on boundary integral equations. The propagation of light in several Photonic Crystal Fibers with different geometries of their cross section is analyzed. The obtained results are compared with those given by the Finite-Element Method.

Introduction: To design Photonic Crystal Fibers (PCF) for various applications, fast and accurate numerical simulations are needed. Recent studies [1, 2] shows the efficiency of a high order waveguide mode solver based on the Boundary Integral Equations (BIE). The aim of this paper is to use this solver with different PCF geometries and to evaluate the accuracy of the results with those given by the Finite-Element Method (FEM) computed with the commercial software COMSOL.

Formulation and Solution of the Problem: The cross section of a PCF consists of a finite number of homogeneous inclusions with refraction index n_i, embedded in a homogeneous background material with refraction index n_e. The problem is to determine the total effective refraction index n_{eff} of the structure. Writing Maxwell equations and the interface conditions on the electromagnetic field, one obtains a system of equations. The use of the single and double layer potentials on all the hole boundaries in the previous system gives rise to a nonlinear eigenvalue problem

$$A(n_{\text{eff}})x = 0, \tag{1}$$

where the vector x gathers the unknown values and the matrix A is an analytic function of n_{eff}. The main advantage of using BIE instead of the FEM is that only the boundary holes are discretized. This matrix problem can be turned into a complex root finding process for the function $f(n_{\text{eff}})$ with two fixed random vectors y and z

$$f(n_{\text{eff}}) = \frac{1}{(y^T A^{-1}(n_{\text{eff}})z)} = 0, \tag{2}$$

where $A^{-1}z$ is computed by solving the system $Ab = z$. Since the operator in the matrix A are hypersingular and the interfaces between the holes and the cladding of the PCFs are smooth, kernel-splitting techniques developed by Kress [3] are used. As in [1, 2], we solve $n_{\text{eff}} \in [n_e; n_i]$ from (2) using Müller's method.

Conclusion: This study shows the accuracy of a waveguide mode solver based on boundary integral equations for different PCFs. The results are compared with those given by the FEM computed with COMSOL.

A Method of ISAR Sequences Quality Assessment for Aerospace Target

Gang Li, **Qingkai Hou**, **Shiyou Xu**, **and Zengping Chen**
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha, China

Abstract— Inverse synthetic aperture radar (ISAR) can generate 2D image for a non-cooperative moving target and be used for military and civilian purpose. In practice, however, the effect of ISAR imaging is affected by many factors, some quality problem is existed in the ISAR image, such as blur, deformation, tailing, ghost copy etc.. So it is necessary to evaluate the image quality by some corresponding parameters. In addition, the research on that how to choose the high quality image from the mass result, has important significance to realize image interpretation and obtain the target information. The techniques for SAR image quality assessment have been developed in recent years, and already formed a commercial product, but the research on ISAR image is still poor.

In the traditional method, image entropy and contrast is adopted to evaluate the image quality, however, this method is only suitable for comparing the image quality from the same measurement data in different processing algorithm. It still has no viable standard on that how to evaluate the ISAR images in different measurement periods.

In this paper, the traditional ISAR image quality evaluation standard and its limitation is analyzed. An ISAR quality evaluation method of aerospace targets is presented, combining with ISAR imaging mechanism and the structural characteristics of aerospace targets, referencing the standard of optical image quality evaluation. Beyond some current commonly used indications, a new indication based on the power spectrum is adopted in this method. The simulation data and real data shows the validity of the algorithm.

Compensation for System Distortion Using Low Signal-to-noise-ratio Echo from Spherical Satellite

Jianzhi Lin, **Weixing Li**, **Weihua Wang**, **Gang Li**, **and Zengping Chen**
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha 410073, China

Abstract— Compensation for amplitude and phase distortion in inverse synthetic aperture radar (ISAR) system is important for the system performance. There are two types of techniques to measure the amplitude and phase distortions in the system: closed loop and the employment of an external test target. The former excludes the antenna and propagation medium, leading to limited results. The latter uses the complete system and is better. The type of the test target may be a corner reflector, a metallic ball towed by a balloon, an active radar calibrator (ARC) on a tower, or a spherical satellite. However, the corner reflector may suffer from high level of clutter. The metallic ball towed by a balloon will be difficult to carry out daily in practice and is costly. The current approach is to use the ARC. But the ARC includes optic transceivers, fibre-optic delay line, and amplifiers, which induces additional distortion. Although it is best to take the spherical satellite as the test target, it is unpractical because the signal-to-noise-ratio (SNR) is too low.

In this paper, we analyze the reason why the low SNR signal received from the spherical satellite fails to compensate for the distortion. Then we utilize pulse compression technique based on matched filtering to find the target region and then take inverse matched filtering on the region to get high SNR signal. Thus we can achieve the distortion coefficients and compensate for the system distortion. Experiments based on real radar data show that the results are better than that by the ARC.

Enhanced Efficiency of Second Harmonic Generation with Twelve-fold Photonic Quasi-crystal Fiber in Telecommunication Band

Abstract— We design an index guided silica core photonic quasi-crystal fiber of twelve-fold symmetry for enhancing the efficiency of second harmonic generation by using the fundamental input wavelength of 1.55 μm in the telecommunication band. We find the quasi periodic arrangement of holes in the cladding does highly influence the modal confinement as well as the intensity distribution of both the fundamental and second harmonic fields inside the core. As a result, the two most important aspects of second harmonic generation, namely, phase mismatch factor and overlap area related to the efficiency of second harmonic generation get highly affected. Moreover, these two quantities must be as minimum as possible for enhancing the efficiency of second harmonic generation. Hence, in this study, we emphasize on minimizing these two factors with proper choice of geometrical parameters of the photonic quasi-crystal fiber. In this analysis, we consider the pitch range of 1–15 μm and relative hole diameter of 0.5. We find that the overlap area increases with increase in pitch but the phase-mismatch factor decreases. Also here we consider the first order quasi phase matching technique for phase matching. In quasi phase matching, the phase mismatch factor is taken care by the quasi phase matching period. Hence, in quasi phase matching, the overlap area takes much significant role in determining the efficiency of second harmonic generation. But a lower value of phase mismatch factor always supports ease of poling by increasing the quasi phase matching period. With the available poling technology, we optimize the pitch of the photonic quasi-crystal fiber at 7 μm and report a relative efficiency of second harmonic generation as 38.22% $W^{-1}cm^{-2}$, when the overlap area is 2.74 μm^2 and phase-mismatch factor is 0.102 μm^{-1}. This value is much higher than that of already reported relative efficiency of second harmonic generation with photonic crystal fiber. This work can be extended for higher harmonic generation and atto-second pulse generation.

Few-cycle Pulse Generation Using Solid-core Photonic Quasi-crystal Fiber

Abstract— In recent years, the generation of few cycle pulses has been of great scientific and technological interest. In this line, the microstructured optical fibers have been playing a vital role since the desired optical properties can easily be engineered by adjusting the geometrical parameters. The recent results reveal that the quasicrystals exhibit several interesting photonic properties over periodic crystals. A solid core photonic quasi-crystal fiber (SC-PQF) is a novel microstructured fiber with quasi periodicity in structure and has a long range order with aperiodic arrangement in its cladding region. The structure of the cladding region consists of air holes of diameter d and pitch, Λ, with five rings of air holes. In the central region, the air hole is removed and the resulting solid silica core acts as a defect and gives rise to the propagation of guided modes.The photonic quasi-crystal fiber provides a very large nonlinearity and sufficiently lowdispersion that could be exploited for generating single cycle pulses.We look for the hitherto mentioned optical properties in the proposed SC-PQF by carefully optimizing the geometrical parameters namely, core diameter and the pitch. Eventually, with the proposed fiber, we study both dispersion and nonlinearity for a range of wavelengths from 300 to 2000 nm and demonstrate sufficiently low dispersion ($-1.9478\,\mathrm{ps}^2/\mathrm{m}$) with zero confinement loss and enhanced nonlinearity ($\gamma = 578\,\mathrm{W}^{-1}\mathrm{m}^{-1}$) for a wavelength of 850 nm. The higher-order soliton effect compression of the femtosecond pulses in the proposed SC-PQF at 850 nm wavelength is numerically studied. An input pulse of 15 fs widthis compressed down to 5 fs nearly 1.8 cycles of pulse generation.Besides, we also calculate the power (211 W) and energy (0.9 pJ) of the compressed few-cycle pulse at 850 nm wavelength.

Overcoming Bandwidth Limitation of LED by Using Multilevel Differential PAM in VLC

S. H. Yang, D. H. Kwon, and S. K. Han
Department of Electrical and Electronic Engineering, Yonsei University
50 Yonsei-ro, Seodaemun-Gu, Seoul, Korea

Abstract— Narrow modulation bandwidth of commercial white LED is limitation of optical wireless visible light communication system. Thus, several studies have been researched to overcome the bandwidth limitation of white LED. First, for the white lighting, most devices use a blue LED which illuminates a layer of yellow phosphor. However, modulation bandwidth is typically lower than several MHz by slow time constant of the yellow phosphor, thus optical blue filtering techniques have been researched to improve the modulation bandwidth. Secondly, to enlarge modulation bandwidth and compensate the channel response, electrical equalizer is adopted. Thirdly, to secure the additional optical channel, WDM based on RGB LED with optical filter at receiver and PDM based on polarizer are researched. Last, high-speed wireless connectivity is implemented using adaptive modulation: QAM with OFDM or DMT. The transmission capacity can be increased significantly, because spectral efficiency is maximized. However, these modulation methods need additional digital signal processing such as FFT and IFFT, thus hardware and computational complexity of transmitter and receiver is increasing. In addition, modulated signals have a high PAPR, thus the linear devices to have large dynamic range is required. As a result, nonlinear characteristics of RF and optical devices are cause of undesired distortions.

In this paper, we propose a novel modulation and de-modulation format to reduce the complexity of transmitter and receiver which is named multilevel differential pulse amplitude modulation (MD-PAM). The proposed modulation scheme transmits different PAM signals with same amplitude and unit time delay using multiple LED chips, respectively. Optical signals from every LED chips are linearly accumulated during through the optical wireless channel and directly detected at the single optical receiver. Received signal is demodulated using received signal power difference which is changed by light intensity. As a result, we experimentally confirmed that 100-Mbit/s transmission was possible using LED which has 25 MHz modulation bandwidth.

Photo-induced Electrical Instability in Transparent Electronics

Jun-Young Jeon and Tae-Jun Ha
Department of Electronic Materials Engineering, Kwangwoon University, Seoul 139-701, Korea

Abstract— Transparent conducting oxides (TCOs) are based on post-transition of metal combined oxides with an outer major quantum number of > 4. Since the s orbital possesses a large spatial size and forms hybridization, oxide can be a good electrical dopant securing high density and stability. Most TCOs exhibit visible-light insensitivity and difficulty attaining charges by light absorption due to the wide band gap. High performance transparent electronics consisting of metal-oxide semiconductors such as zinc-oxide (ZnO), indium-zinc-oxide (IZO) and indium-gallium-zinc-oxide (IGZO) have been extensively investigated to realize the unit pixels for next-generation displays. However, unexpected instability caused by photo-induced electrical bias in amorphous metal-oxide based thin film transistors (oxide-TFTs) retards the development of transparent electronics.

We will present the origin of photo-induced electrical instability in oxide-TFTs based on transparent electronics by applying the photo irradiation with a wave length of $400 \sim 800$ nm by using a monochromator. The combination of photo irradiation and prolonged gate bias stress enhanced the electrical instability in transparent devices. Such results stem from the extended trapped charges possessing the energy absorbed from light-wave at the localized defect states related to oxygen vacancy. We will also demonstrate the chemically clean interface in oxide-TFTs by employing oxygen annealing which reduces the density of trap states, thereby resulting in improved photo-induced stability.

We believe that this study provides significant information on the device physics of optoelectronics, which commonly exhibit photo-induced instability and charge transport, as a results of prolonged exposure to photo irradiation.

Split-step Time-domain Analysis of Optical Code Division Multiple Access En/Decoder Composed of Ring Resonator Waveguides

Youngchul Chung
Department of Communications and Electronics Engineering, Kwangwoon University
20, Gwangun-ro, Nowon-gu, Seoul 139-701, Korea

Abstract— By applying CDMA (Code Division Multiple Access) to optical communication systems, it is possible to use wide bandwidth of optical fiber, to provide passive code decryption, and to protect the optical physical layer. Two-dimensional (2-D) OCDMA (Optical CDMA) en/decoders can be realized in the form of compact photonic integrated circuits by cascading ring resonator waveguide filters as shown in Fig. 1. The 2-D optical en/decoder based on micro-ring resonators can provide wavelength hopping and spectral phase coding patterns which can be simultaneously reconfigured. In this paper, a split-step time-domain modeling (SS-TDM) is adopted to analyze the reconfigurable 2-D OCDMA en/decoders. The SS-TDM is implemented in two-steps. First the optical wave propagation through every divided section of the bus and ring waveguides is calculated with appropriate boundary conditions. Using the calculated electric field values, the bus-ring and ring-ring coupling calculations are performed. In the calculation the stepping time interval should be equal to the section length divided by the group velocity. With this algorithm the pulse propagation characteristics through the ring resonator filters can be efficiently analyzed, thus the encoded and decoded waveform can be readily obtained to assess the applicability of the designed en/decoder devices. The 2-D en/decoder with two wavelengths and two phases are simulated for a demonstration and the results are shown in Fig. 2. The encoded waveform is shown in Fig. 2 and the decoded waveforms are shown in Fig. 3. When the conjugate code is used for decoding, the original optical pulse is found to be recovered.

Dependence of Radio Frequency Magnetron Sputter-deposited ZnO-SnO_2 Thin Films on Substrate Temperature

Ik-Jae Lee, Hoju Kang, and Nark-Eon Sung
Pohang Accelerator Laboratory (PAL), Pohang University of Science and Technology
Pohang 790-784, South Korea

Abstract— ZnO-SnO_2 (ZTO) thin films were deposited by radio frequency sputtering on quartz substrates at various substrate temperatures T_S, and characterized using x-ray diffraction (XRD), selected-area electron diffraction, atomic force microscopy (AFM) and spectrophotometer, four-point probe method and Hall measurement. XRD analysis indicates that the ZTO films can be either amorphous ($T_S \leq 350°C$) or crystalline ($T_S \geq 450°C$). AFM studies of the ZTO films indicate that the surfaces are fairly smooth with root-mean-squared surface roughness of 1.04 to 3.55 nm. The average optical transmittance of the ZTO films was $\geq 85\%$. The optical bandgap, estimated using a Tauc plot, increased as T_S increased. Blue shift was observed in the absorption edge and was attributed to decrease in the oxygen vacancies and dangling bonds. The lowest resistivity was on the order of $10^{-2}\,\Omega$·cm for films deposited at $T_S \geq 650°C$: films deposited at $T_S \leq 450°C$ were weakly conducting. The conductivity of films increased as T_S increased. These results can guide modifications of ZTO for applications that incorporate electrically-conducting, optically-transparent thin films.

Design Procedure for 2D Slotted Waveguide Antenna with Inclined Coupling Slots for Sidelobe Level Control

H. M. El Misilmani[1], **M. Al-Husseini**[2], **and K. Y. Kabalan**[1]

[1]American University of Beirut, Beirut 1107 2020, Lebanon
[2]Lebanese Center for Studies and Research, Beirut 2030 8303, Lebanon

Abstract— Slotted Waveguide Antennas (SWAs) radiate energy through slots cut in a broad or narrow wall of a rectangular waveguide. They offer clear advantages in terms of their design, weight, volume, power handling, directivity, and efficiency. SWAs can be resonant (standing wave) or non-resonant (traveling wave). Resonant SWAs outperform the non-resonant SWAs in terms of efficiency due to its termination with a short circuit, compared to matching load in the case of the latter, but with a narrower bandwidth. For broad-wall SWAs, the slot displacements from the wall centerline determine the antenna's sidelobe level (SLL). In addition, the rotation angle of the coupling slot in a 2D system array of SWAs determines the power fed by each slot into each branchline SWA.

This paper presents an inventive simple procedure for the design of a two-dimensional (2D) SWA array system with desired sidelobe level (SLL). The system consists of multiple branchline waveguides with broadwall radiating shunt slots. A main waveguide is used to feed the branch waveguides through a series of inclined coupling slots with well-defined rotation angles for low SLLs. For a specified number of identical longitudinal slots, the described procedure finds the slots length, width, locations along the length of the waveguide, and displacements from the centerline, for each branch waveguide. Furthermore, for a specified number of branch waveguides, the method finds the rotation angle of each of the coupling slots.

To explain the controllable-sidelobe 2D SWA design procedure, an SWA with 8×8 elliptical slots, designed for an SLL lower than -20 dB, is taken as an example. An 8-element 1D SWA with a desired SLL is designed first. Eight identical such SWAs are then attached side by side. The proper design of the 1D SWAs ensures having the desired SLL in one principal plane. To enforce the same SLL over the whole 3D pattern, special care should be given to the design of the feed SWA, whose slots should power the radiating SWAs according to a correct distribution. For the taken example, the feed SWA should have 8 slots, separated consecutively by a distance related to the radiating SWA aperture width and wall thickness. The power fed by each slot in the feeder and fed to the branchline waveguide is controlled by the inclination angle of the coupling slot.

Figures 1(b) and 1(c) show a comparison of the gain patterns for the following 2 cases: Case 1 where the radiating slots have a uniform displacement and the coupling slots have a uniform rotation angle; and Case 2 where the radiating slots have non-uniform displacements and the coupling slots have non-uniform rotation angles as per the design procedure. As inspected, the SLL decreased from -12.1 dB in case of uniform displacements and rotation angles to less than -20 dB with the non-uniform displacements and inclinations calculated using the presented simple design procedure.

Tripolarization Antenna for DSRC Applications

Sumin Yun and Sangwook Nam
INMC, School of Engineering and Computer Science, Seoul National University, Korea

Abstract— With a development of wireless communications, a DSRC (Dedicated Short Range Communication) applications are proposed for various applications like collision avoidance, traffic control, autonomous driving. Therefore, the reliability of DSRC is essential because the vehicle safety is directly affected by the communication reliability. In this paper, the MIMO (Multiple Input Multiple Output) antenna is proposed for the DSRC applications.

A patch antennas, which has many favorable characteristics like low-profile, planar structure, are widely used in various applications. A patch antenna also can be used in MIMO systems [1], because it has degenerate modes. A horizontal polarization can be easily generated by the patch antenna. However, it is hard to generate perpendicular polarization in same frequency. The monopole like characteristic mode, which generates the vertical polarization, has lower resonance frequency compared to that of the resonant modes generating the horizontal polarization.

In this paper, the parallel plate is placed between a patch and a ground for the monopole mode. By using the parallel plate, the resonance frequency of monopole mode has increased to the resonance frequency of patch modes. Along with the two degenerate patch modes, the excited monopole mode generate tripolarization. As the three ports excite orthogonal characteristic mode, higher than 30 dB isolation is achieved. The simulated result shows that the proposed antenna has −10 dB impedance bandwidth from 5.8 to 6 GHz. The proposed antenna has a dimension of $24 \times 24 \times 3.14\,\text{mm}^3$, which is a size of a conventional patch antenna. The proposed achieved tripolarization without increasing the conventional size of the patch antenna.

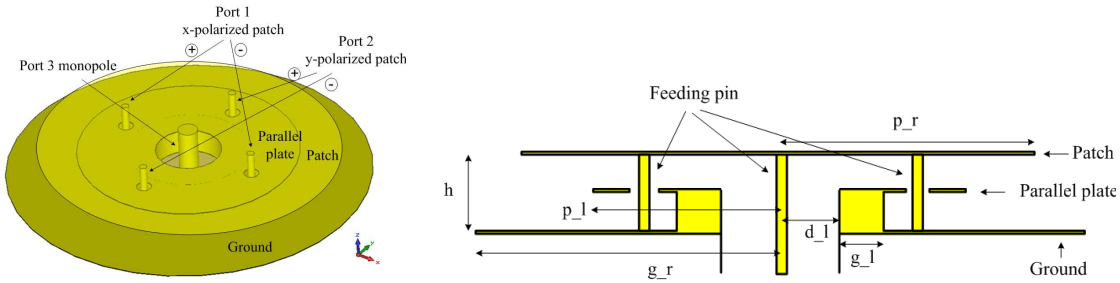

Figure 1: Geometry of the proposed tripolarization antenna (dimensions of the simulated antenna, $h = 3.14$, $p_l = 7.2$, $p_r = 9.4$, $g_r = 12$, $d_l = 2.18$, $g_l = 1.4$, all in the unit of mm.).

Wide Bandwidth Compact Size Meander Antenna for the 800 MHz LTE Band

Sanghoon Park, **Ki-Jin Kim**, **Kwangho Ahn**, **Koon-Tae Kim**, **and Sehwan Choi**
Convergence Communication Components Research Center
Korea Electronics Technology Institute, South Korea (R.O.K.)

Abstract— The machine-to-machine (M2M) connection is the key technology nowadays. Lots of sensors and devices have acquired the communication ability. Then, more and more devices become connected and will constitute a huge network in the future. However, current communication modules or chipsets are mainly focusing on the higher data rate. In order to facilitate the machine connection, an exclusive small and cheap communication module which supports long-term evolution (LTE) is highly desired. One of the most important factors to build the M2M exclusive LTE module is to minimize the antenna size. We chose the meandering with the CPW feeding method for this purpose. The antenna is optimized to use the adaptive particle swam optimization with the ten particles and six design parameters. The FR-4 type PCB showing the permittivity constant of 4.4 has the size of $30 \times 35\,\text{mm}^2$ with height of 1 mm. The measured resonant frequency band ranges from 810 to 915 MHz which is 10 MHz wider than the simulation results, as shown in Fig. 1.

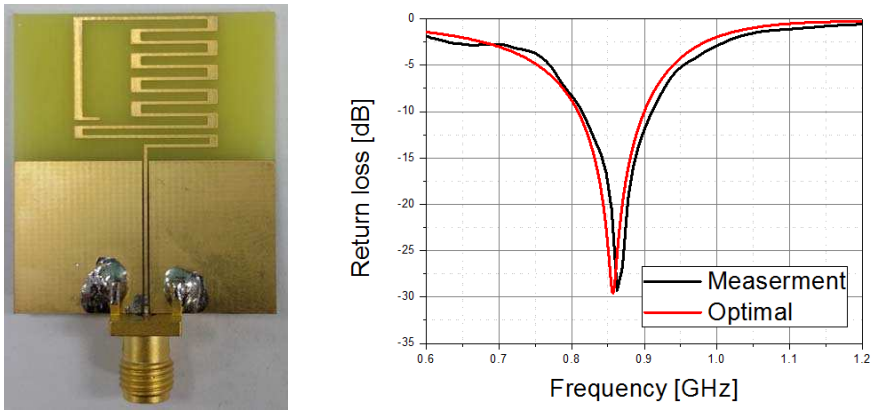

Figure 1: Compact size meander antenna for the 800 MHz LTE band.

Cavity-backed and Shorted Microstrip Patch Antenna for On-body Systems

Sehwan Choi and Hojun Lee
Korea Electronics Technology Institute, Seongnam-si, Gyeonggi-do 463-816, Korea

Abstract— After the introduction of wireless wearable devices, the interest to applications utilizing this technology has increased. These devices have been applied in sports, military and medical area such as monitoring of heart rate and blood pressure. But it has been an obstacle to use them because of the inconvenience caused to be attached to the human body. Antennas must have the characteristics of low profile, small size and high efficiency in order to reduce the inconvenience. Various antennas such as textile and UWB have been researched actively and electro-magnetic band-gap materials are also researched to reduce phenomena such as frequency shift and efficiency decline appears when they are closer to the human body.

This paper proposes the cavity-backed and shorted microstrip patch antenna for antenna miniaturization and insensitivity for surrounding environment. The proposed antenna is fabricated by bonding two substrates that are Rogers RT5880 31 mil. In order to know the changes depending on environment, placing the antenna on air, arm, breast and pig skin, the frequency responses were measured by network analyzer. And the radiation efficiency is measured in anechoic chamber. As a result of the measurement, frequency responses are hardly changed and radiation efficiency reduces from 73.2% in the air to 32.5% on the pig skin.

Frequency Invariant Beamforming under Bandpass Sampling Based on Convex Optimization

Lijie Fan, **Bian Tian**, **Shiyou Xu**, **and Zengping Chen**
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— Beamforming is a spatial filtering technique for receiving signals illuminating an array of sensors from some specific directions, whilst attenuating signals from other directions. As higher frequency and lager bandwidth has been utilized in many real platforms especially in the field of radar and electronic reconnaissance systems, wideband beamforming has been studied extensively in the past decade. For wideband signals, there exists phase difference between sensor outputs cause wideband signals consist different frequency components and usually this phenomenon is called "the array dispersion". For a fixed aperture, the spatial resolution of a beamformer is proportional to frequency. Our purpose is to obtain the nearly identical beam response for wideband signals getting through the array of sensors. Such beamformers are independent of frequency, they are often called frequency independent beamformers or frequency invariant beamformers (FIBs). Many literatures have considered and promoted various methods to solve this problem. Among these methods, the class of optimization method is the main stream. Wideband beamformer is implemented by a group of FIR filters after each sensor and the coefficients of FIR filters are obtained through the optimization process.

A common assumption is made that these algorithms handle the receiving signals by Nyquist sampling, but we are acquainted with that signals are often bandpass sampled getting through the sensors and transformed to the base band through the digital down conversion (DDC) processing in many practical systems. After the DDC processing, the signals are passed to the FIR beamformer. The bandpass sampling and DDC alter the signal expression and make the objective function different compared with signals under Nyquist sampling. The main difference induced by bandpass sampling and DDC is the implementation resource consumption under the identical desired beam pattern, in detail the FIR beamformer cost more taps to achieve the same beam pattern under bandpass sampling. In this paper, the effect caused by bandpass sampling and DDC is addressed and analyzed in detail; through convex optimization toolbox a strategy to deal with this circumstance is proposed; the formulation of such convex optimization problem is presented.

A comparison has been made between two kinds of sampling procession to achieve FIB beamforming. The effect caused by bandpass sampling and DDC is addressed and analyzed in detail for wideband beamforming. Simulation results show that the method proposed in this paper is effective in dealing with FIB problem under bandpass sampling.

A Novel InP Based Planar PIN Diode

Hao Sun, **Lingyun Li**, **Qilian Zhang**, **Huifeng Ding**,

Abstract— A InP based novel planar PIN diode was fabricated for high frequency and high speed circuits applications. This novel structure diode provided new ideas for fabrication high speed and frequency switch circuits.

PIN diode heterostructures were grown on a 2″ SI-InP substrate by V90 GSMBE system using AsH_3 and PH_3 as group V sources and CBr_4 as p-type doping source. The epitaxial layers include a thick (∼3 µm) un-doped $In_{0.53}Ga_{0.47}As$ buffer layer. Followed a 300 nm thick heavily silicon doped $In_{0.53}Ga_{0.47}As$ N layer, a 1 µm thick un-doped $In_{0.53}Ga_{0.47}As$ as I layer and a 200 nm thick heavily carbon doped $In_{0.53}Ga_{0.47}As$ (3×10^{19} cm^{-3}) P layer.

A novel planar air-bridge structure was utilized to form good connection with the anode and cathode of the PIN diode, of which structure can simplify the processing compared to the traditional one. The air-bridges were fabricated using phosphoric acid base wet lateral etching technologies. Etching velocities as well as morphology of the etched $In_{0.53}Ga_{0.47}As$ materials were studied for different rations of phosphoric acid base etchant solutions by the profiler, and scanning electron microscopy (SEM) respectively.

InGaAs/InP PIN diodes with an anode of 4 µm radius were fabricated. The planar air-bridge was of 4 µm wide, 30 µm wide and 4 µm high. A turn on voltage of 0.43 V and breakdown voltage of larger than 7 V were obtained by DC measurement. The equivalent turn-on resistance of 9 ohm and shut-off capacitance of 18 fF can be obtained from the S-parameters measurement. This novel structure diode provided new ideas for fabrication high speed and frequency switch circuits.

Layer	Dopant	Doping (cm^{-3})	Thickness (nm)
P+ InGaAs	C	3×10^{19}	200
I InGaAs	-	-	1000
N+ InGaAs	Si	3×10^{19}	300

Switched Phase Shifter for Load Modulation of QPSK Signal

Sehwan Choi, **Jin-Sup Kim**, **and Jae-Young Lee**
Korea Electronics Technology Institute, Republic of Korea

Abstract— For the demand for high-speed wireless communications, MIMO (Multiple-Input and Multiple-Output) has become mandatory in many modern wireless communication systems. This MIMO technology provides significantly us with a spectral efficiency but increases the number of antennas and RF front-end modules. This finally causes an increasement of current consumption and overall size of the system. In order to solve these problems, researches utilizing a single RF system based on ESPAR (Electronically Steerable Parasitic Antenna Radiators) and LMA (Load Modulated Array) have been actively conducted.

In the case of ESPAR, various orthogonal radiation patterns are generated by impedance loading circuits. Digital signals are modulated by mapping digital signals onto radiation patterns. So, these systems requires many orthogonal radiation patterns and ultra-high speed switches with a few nanoseconds. LMA systems are operated independently by multiple antennas with high isolation. Because each antenna sends the separate stream, these systems have the advantage of improving the system implementation and data-rate. In order to implement LMA system, phase shifter was developed by using high speed switches in this paper. It was successfully sent 4-stream QPSK signal of 2.5 MHz chip-rate at 2.38 GHz using this board.

Compact Waveguide Load with Thin Film Resistor

Manseok Uhm, **Hongyeal Lee**, **Changsoo Kwak**, **Sohyeun Yun**, **and Inbok Yom**
Satellite & Wireless RF Technology Section, Electronics and Telecommunications Research Institute, Korea

Abstract— Due to excellent electrical performance such as low insertion loss, high return loss and high power handling capacity, waveguide components are widely adopted for microwave communication systems in spite of a relatively larger volume than microstrip or coaxial components. Waveguide loads are needed for directional couplers used for test set-up and hybrid waveguide couplers for obtaining high output power from parallel power amplifiers. Especially, a compact waveguide load is required to develop compact SSPA using hybrid couplers (branch coupler or magic-tee combiner) with matched loads.

Since absorbing material in the waveguide attenuates input RF signal, the shape and the place of absorber depend on electrical performances of loads. In general, gradual increase of absorber makes good impedance matching over a wide bandwidth. The absorber is located at the highest electric field intensity.

We proposed a compact rectangular waveguide load using a thin film resistor as an absorber. It works by placing a resistor in the center of the waveguide where the electric field intensity is the greatest. An increase in step width of the resistor will lead to good return loss. The thin film resistor with good temperature coefficient and stable performances is produced on an alumina substrate that shows suitable accuracy of dimension. We designed a compact waveguide load with TaN thin film resistor for Ka band applications. The resistivity is 100 Ω/sq and the height of substrate is 5 mil. The proposed matching termination can be easily attached at an end wall of a waveguide. Thus it can be easily connected to the waveguide flange of a component.

Several samples for WR 28 standard waveguide were fabricated and measured to confirm the reproducibility. The actual size of the alumina substrate is 3.5 mm × 9.0 mm. We confirmed that all the results agreed excellently. The measured results have proved the design results, as shown in Figure 1. Return loss above 20.0 dB has been obtained over 4.0 GHz of bandwidth in the Ka band.

Channel Equilibration in Wideband Digital Array Radar Test-bed

Weixing Li, **Jianzhi Lin**, **Weihua Wang**, **Biao Tian**, **and Zengping Chen**
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha, China

Abstract— Digital array radar (DAR) is remarkable for the characteristics of large instantaneous dynamic range, flexible control, multi-beams simultaneously and superior ability of anti-interference. Most array processing algorithms are based on ideal assumption of both the signals and channels. For actual systems, amplitude and phase errors caused by antennas, amplifiers and ADCs will lead to substantial performance degradation of digital processing such as digital beam-forming (DBF) and direction of arrival (DOA).

Based on a wideband DAR test-bed operating at 0.6∼3.0 GHz with the instantaneous bandwidth of 500 MHz, this paper presents the design and implement of channel equilibration module. In the first part, a wideband waveform generator based on DAC + FPGA architecture is designed with the purpose of generating various analog waveforms for channel equilibration. The waveform generator is a FPGA Mezzanine Card integrated with a 12 bits, 3 Gsps DAC. It is capable of generate desired waveforms from 0 GHz to 6.0 GHz flexibly by direct digital synthesize technology. In order to calibrate the reconstruction errors, a pre-distortion filter is designed to compensate the waveforms generated by DAC. In the second part, a practical algorithm is proposed for wideband channel equilibration in jamming environment. The operating bandwidth of DAR is divided in to two parts: the frequency band without interferences and with interferences. In the first frequency band, the channel responses can be obtained by coupling high quality wideband signals into the receive channels. As for the frequencies that exist in unknown interferences, this paper takes the interferences as calibration signals to evaluate the amplitude and phase errors. After the distortion characteristics of the whole bandwidth are obtained, an improved frequency-domain equilibration algorithm based on overlap-save is studied and realized in FPGA to eliminate the discontinuity of phase. Finally, experiments are carried out using the DAR test-bed. The processing results of measured data demonstrate the feasibility and effectiveness of the channel equilibration module.

An Ultra Low-power and Low-noise VCO Using Transformer Coupled Dual LC Tanks Topology

Tzu-Yun Chou, **Kuan-Hsiu Chien**, **and Hwann-Kaeo Chiou**
Department of Electrical Engineering, National Central University, Jhongli City, Taoyuan, Taiwan

Abstract— A K-band low power voltage-controlled oscillator (VCO) using transformer coupled dual LC tanks is implemented in a tsmc^{TM} commercial 90-nm CMOS process. The use of transformer provides tight coupling factor between two identical LC tanks that improves the phase noise performance by increasing the output signal swing and waveform symmetry of the VCO. The cross-coupled transistors provide an effective negative resistance for the VCO core to compensate the resistive loss in the primary and secondary LC-tanks. The secondary LC tank is DC isolated from the primary one, thus it does not consume DC power from the primary LC tank. Accordingly, compared to the conventional topology, this core power consumption can be significantly reduced. The drain voltage could swing above the supply voltage by using the proposed transformer. Effectively, the oscillation amplitude is enhanced, and the supply voltage can be reduced for the same phase noise with lower power consumption or for better phase noise with the same power consumption. By taking advantage of the tight-coupling transformer, the inductor layout is properly designed to obtain a high Q-factor and a die area comparable to single-inductor VCO. The VCO core dissipates very small DC power of 1.61 mW from a 0.7-V supply due to the benefit of tight-coupled transformer. The measured phase noise is −97.61 dBc/Hz at 1-MHz offset frequency from the oscillation frequency of 24 GHz. The proposed VCO has an excellent FOM of −183.14 dBc/Hz. This novel VCO topology will find wide applications in 24 GHz low power wireless sensor networks.

A Reconfigurable Bandpass to Bandstop Filter Using PIN Diodes Based on the Square Ring Resonator

Salman Arain, **Muhammad Ali Babar Abbassi**, **Symeon Nikolaou**, **and Photos Vryonides**
Department of Electrical Engineering, Frederick University, Cyprus

Abstract— Microwave filters are of primitive importance when dealing with RF communication systems. Modern day development in this technology has led to the requirement of a compact, multipurpose and efficient design. In this context electronically switchable filters are gaining wide interest of both researchers and developers. Microwave filters are designed keeping in mind the compactness and ease in switching ability among different operational modes. Using commercially available PIN diodes, filters can be engineered to switch between different resonating frequencies hence making the structure reconfigurable.

This paper presents a reconfigurable bandpass to bandstop switchable filter based on square ring resonator with two tuning stubs controlling bandpass response. In this work, switching between the bandpass and bandstop filter has been achieved by strategically placing PIN diodes in locations which do not affect the resonating response of the overall design. Skyworks SMP1345-079LF RF PIN diodes are used to switch from bandpass to bandstop filter. Central frequency of the filter is 2.4 GHz. The −3 dB bandwidth for the bandpass filter is from 1.9 GHz to 3.2 GHz with an insertion loss of 0.8 dB. For the bandstop filter loss is 0.3 dB and −10 dB rejection bandwidth is from 2.3 GHz to 2.6 GHz. DC bias lines of $\lambda/4$ lengths are integrated with radial stubs to ensure compact physical length of circuit. The key advantage of this type of filter is efficient switchability between two frequency responses. The filter is simulated on commercially available cost effective substrate. The proposed filter can be a good candidate date for communication in strong interference environments, for reconfigurable radios, or for alternating transmission and reception schemes, in the highly congested, 2.4 GHz frequency band.

Metallic Grating-dielectric-metal Microcavities for Far-infrared Narrowband Absorption

Pei-Kang Chung and Shun-Tung Yen
Department of Electronics Engineering and Institute of Electronics
National Chiao Tung University, Hsinchu 30010, Taiwan

Abstract— We study absorption properties of metallic grating-dielectric-metal microcavities for resonant absorbers in the far infrared. The microcavities are composed of a subwavelength silicon dioxide (SiO_2) film sandwiched between a flat bottom metal and a top metallic film perforated with a two-dimensional square hole array. We investigate the microcavities by measuring absorbance spectra and observing their variations with the size and the period of the holes. The experimental data agree well with theoretical ones calculated with the model expansion method. The absorbance spectra reveal two characteristic resonant modes which are strongly influenced in both the resonant frequencies and the absorbance magnitude by the hole size and array periodicity. The resonant frequencies correspond to emergence of the two lowest diffraction orders and hence depend on the grating period. The resonant absorption is therefore ascribable to the excitation of surface electromagnetic waves around the interfaces between the SiO_2 film and the top metallic film. Interestingly, as the hole size increases, the two resonant frequencies blue–shift slightly; the lower resonant frequency shifts less than the higher one. The two resonances are accompanied by strong localized fields around the edges of the holes and the lower-frequency resonance has a higher quality factor. The resonant absorption strength depends on the hole size and a maximal absorption occurs at a specific hole size for each of the resonant modes. Absorption depends also on the thickness and the material of the dielectric film. This study indicates that the proposed microcavity structure can act as a good reflective resonant absorber at a desired frequency by proper design of the structure.

Analysis of Substrate-defected Coplanar Waveguide of EBG

Lingyun Li, Tianyu Pen, Hao Sun, Qilian Zhang, Huifeng Ding, and Xiaowei Sun
Shanghai Institute of Micro-system and Information Technology, CAS, China

Abstract— The Electromagnetic Band-Gap (EBG) structures deduced from Photonic Band-Gap (PBG) have attracted much attention, and many works focused on the pattern of signal trace metal and Defected Ground Structure (DGS). However, along with the research progress, the patterns of the trace metal or defected ground become more and more complicated and result in difficulty in design and fabrication. In this paper, based on the concept of photonic crystal, a Substrate-Defected Coplanar Waveguide (SD-CPW) is presented, whose substrate is wet-etched to periodic pits, while the 50 Ohm metal trace and ground remaining intact. After the fabrication and measurement, a wide frequency band gap is observed and the EBG characteristic is proved.

The process of wet-etching was used, because it is more economical than Deep Reactive Ion Etching (DRIE). And by the wet-etching process, there is lateral erosion under the metal. So the actual pits' width is wider than the CPW gap, which is included in the simulation model too. Actually it is found that the cavity under metal layer can improve the stop band characteristic. The different percentages of etching length along the CPW line were analyzed. The depth of the stop band gap is altered with the etching ratio ($u = L1/T$), and it shows that 57.5% of the substrate's loss will provide the best stop band performance. And the central frequency of the band gap depends on the period length of the etched pits. If the length is increased while the etching ratio is fixed, the frequency of the stop band will be shifted toward lower band consequently. So the frequency response of the band gap can be controlled. A SD-CPW was

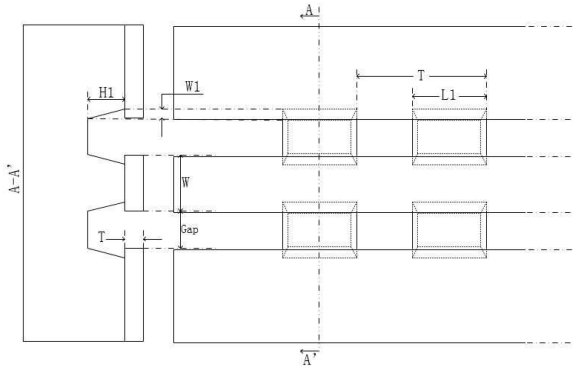

Figure 1: Structure chart of the substrate-defected coplanar waveguide.

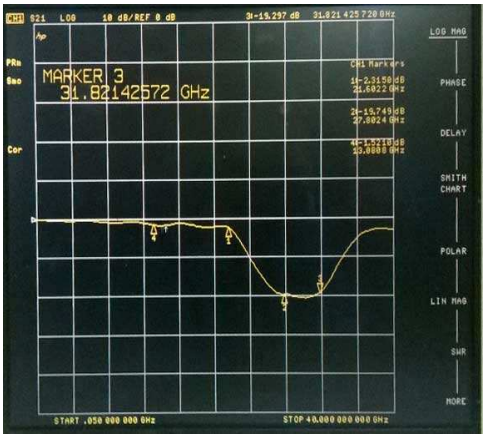

Figure 3: Measured S_{21} of the SD-CPW.

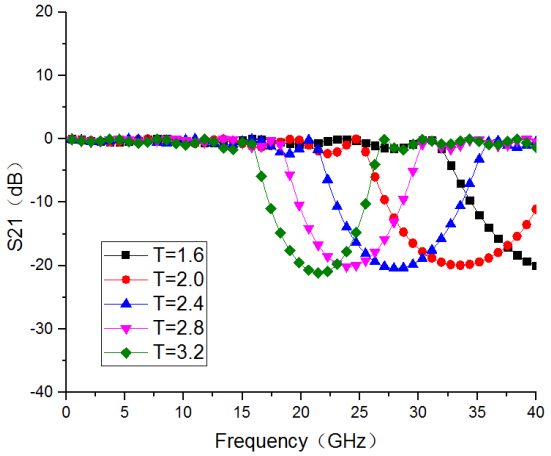

Figure 4: Band-gaps of different period length.

fabricated, whose etching length was 1.38 mm, period is 2.4 mm and 5 cycles repeated. The measurement shown there was a deeper than −20 dB band gap between 28–32 GHz, which was more than 4GHz bandwidth.

Power Electronics for an Energy Harvesting Concept Applied to Magnetic Resonance Tomography

L. Middelstaedt[1], **S. Foerster**[2], **R. Doebbelin**[1], **and A. Lindemann**[1]

[1]Otto-von-Guericke-University Magdeburg, Germany
[2]formerly Otto-von-Guericke-University Magdeburg, Germany

Abstract— Within Magnetic Resonance Tomography (MRT) applications magnetic fields of different orientations, magnitudes and frequencies are generated in order to produce images of different body tissues. Three main magnetic fields need to be distinguished:

- the strong static uniform magnetic field B_0 in z-axes,
- the high frequency excitation field B_1 ($\approx$ 123 MHz) rotating in the x-y-plane and having the highest amplitude in the isocenter,
- and the gradient field B_G, that changes properties along the z-axes.

In order to supply small power electronic applications for devices used in the interventional medical field, e.g., for the wireless power supply of small sensors and electronics in catheters, this paper investigates the approach of energy harvesting inside the MRI scanner. The magnetic fields of the scanner are transformed into electric energy supplying a device under test (DUT) using the method of induction. Considering the present magnetic fields and according to Faraday's Law, the B_1 and B_G fields can be utilized for this approach.

For designing and building a suitable energy harvesting device different aspects need to be taken into account. The effective area of the inductor needs to be orthogonal to the varying field and should be appropriately large. With excitation frequencies of 123 MHz the layout of the inductor should be chosen in a way, that the first resonant frequency is above the excitation frequency. Contrary, the small amplitudes of B_1 and B_G theoretically ask for a high number of turns in order to get sufficiently large induced voltages. However, the resulting large inductance and its parasitic inter-winding capacitances result in small resonant frequencies. The power electronic circuit needs to be built of small, non-magnetic elements with a minimum on-state voltage drop, to achieve significant maximum output voltage. Overall, the imaging process of the MRT should not be affected. In this study relevant magnetic fields are modeled with Empire XCcel^{TM} providing the basic environment for simulating induced voltages for different inductor geometries. Inductors with different resonant frequencies have been designed and tested in terms of induced open circuit voltage. Positioning the inductor inside or outside of the isocenter leads to different induced voltages. In the isocenter the B_1-induced voltage dominates, outside the B_1-influence decreases but B_G induces considerable voltages. Finally, a power electronic circuit has been designed and realized that fulfills the most important requirements of an MRI application for interventional medical applications, i.e., small size and the use of non-magnetic materials. Placing the device in the investigated MRI scanner lets the power supply operate and the LED luminate (see Figure 1(b)). The block diagram of the designed power electronic circuit and the test setup with the designed inductor is shown in Figure 1.

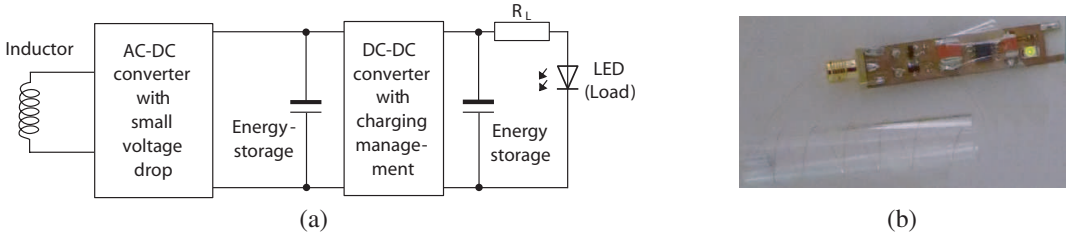

Figure 1: Developed power electronic circuit with an inductor as source and LED as load for energy harvesting in MRI-application. (a) Block diagram of power electronic circuit [1]. (b) Wireless power supply of an LED within an MRI [1].

Fast Time-domain Imaging for One-stationary Bistatic Forward-looking SAR

Hongtu Xie, Daoxiang An, Xiaotao Huang, and Zhimin Zhou
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— One-stationary bistatic forward-looking SAR (OSBFSAR) is a special bistatic SAR (BSAR) with a stationary radar, working in forward-looking mode. It has advantages of reducing military vulnerability and improving target detectability, and implements imaging in forward direction. However, its larger bistatic angle and synthetic aperture may induce the complicated range-azimuth coupling of echoes and increases the difficulty of the precise imaging by frequency-domain methods. So, such imaging usually relies on the time-domain backprojection algorithm (BPA), but it requires a high computational load. Fast BPA (FBPA) has been implemented for the strip-map BSAR imaging, but has not been mentioned for the OSBFSAR imaging in earlier publications. In this paper, a FBPA is presented to process the OSBFSAR echoes. It can keep the accuracy of the BPA but with a reduced computational load.

The key content of the proposed FBPA is organized as follows.

1. Definition of the polar subimage grid (See Fig. 1). First, the origin of the polar grid is defined as the central point of the subaperture center and stationary radar. Then, ρ_n is the range from the origin of a polar grid to the sample $\mathbf{r}$, and θ_n is the angle from the major axis a_n to the range ρ_n. Thus

$$\begin{cases} \rho_n = \sqrt{[x_S/2 - x]^2 + [y_M(\eta_n)/2 - y]^2 + [(z_S + z_M)/2]^2} \\ \theta_n = \arccos\left(\left(c_n^2 + \rho_n^2 - ((x_S - x)^2 + y^2 + z_S^2)\right) / 2\rho_n c_n \right), \ \theta_n \in [0, \pi] \end{cases} . \quad (1)$$

2. Sampling requirements of the polar subimage grid (See Fig. 2). The sampling requirements of the polar subimage grid are derived from the bandwidth angle, which is given by

$$\Delta\rho_n \le c_0 \sqrt{1 + \delta_n^2} \Big/ (2(f_{\max} - f_{\min})); \quad \Delta\theta_n \le c_0 \sqrt{1 + \delta_n^2} \Big/ (f_{\max} d_{Mn}). \quad (2)$$

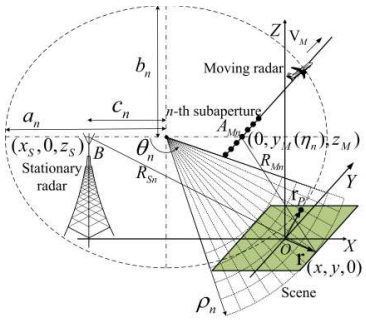

Figure 1: Imaging geometry of the OSBFSAR.

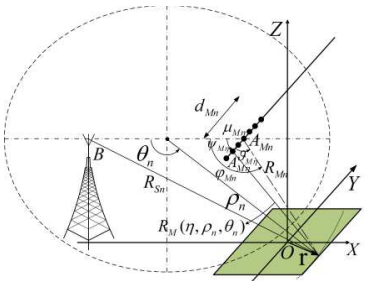

Figure 2: Bistatic range calculation for the sampling requirements derivation.

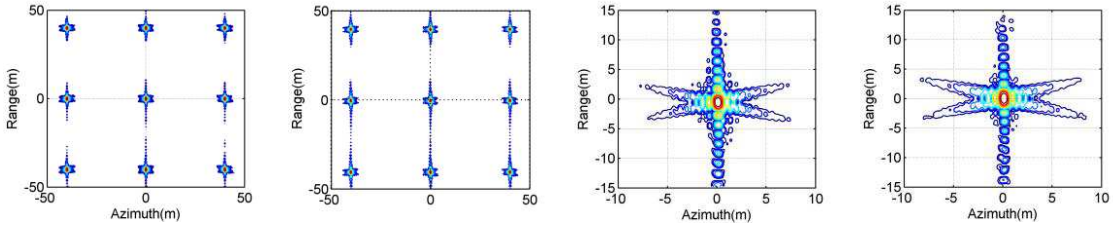

Figure 3: Imaging results obtained by different algorithms. (a) BPA; (b) FBPA; (c) Imaging result of the central target extracted from Fig. 3(a); Imaging result of the central target extracted from Fig. 3(b).

c_0 is the speed of light, δ_n is the ratio of c_n to ρ_n. d_{Mn} is the subaperture length of the moving radar. $f_{\max}$ and $f_{\min}$ are the maximum and minimum signal frequency.

To prove the validity of the proposed FBPA, the simulation is carried out to compare the performances of the proposed FBPA and BPA (See Fig. 3). From Figs. 3(a)–(b), it is seen that all the targets are focused well. Figs. 3(c)–(d) are shown that the focusing performance of the central target by the FBPA is very similar to that by the BPA. The processing time of the BPA and FBPA is 128.1 s and 11.2 s, respectively.

Rapid Echo Simulation for One-stationary Bistatic SAR Based on FFT and Subaperture Processing

Hongtu Xie, **Daoxiang An**, **Xiaotao Huang**, **and Zhimin Zhou**
College of Electronic Science and Engineering, National University of Defense Technology
Changsha, Hunan 410073, China

Abstract— One-stationary bistatic SAR (OSBSAR) is a special bistatic SAR (BSAR) with a stationary radar fixed on a tower. It has advantage of reducing military vulnerability and getting additional information. Echo simulation is important in the SAR research, such as the system design, algorithms test and so on. Echo simulation contains the scene simulation and rapid echo generation; we only focus on the rapid echo generation of the OS-BSAR in this paper. Echo simulation method main include the time-domain target by target (TBT) method, two dimensional fast Fourier transform (2DFFT) method and imaging inverse processing (IMIP) method. TBT method has high precision but with high computational load, while 2DFFT and IMIP methods has high efficiency but with some approximate processing. In this paper, a rapid simulation approach (RSA) based on the FFT and subaperture processing is presented to generate the OSBSAR echo. It can keep the accuracy of the TBT method but with a reduced computational load.

Imaging geometry of the OSBSAR in elliptical polar coordinate and subaperture processing in the echo simulation are shown in Fig. 1 and Fig. 2. Implementation of the proposed RSA is depicted as follow:

(1) Set the simulation parameters and scene scattering coefficients; (2) Generate the transmitted signal and compute its FFT; (3) Divide the moving radar synthetic aperture into subapertures; (4) Start subaperture processing, separate the scene into several equidistant elliptical ring domain and elliptical subscenes; (5) Calculate the equivalent scattering coefficients of elliptical subscenes at the subaperture central pulse. Based on the elliptical subscene scattering coefficients, calculate the equidistant elliptical rings' scattering coefficients for all the subaperture pulses using the FFT; (6) Calculate the system's impulse response function and its FFT for all subaperture pulses; (7) Multiply the results of (2) and (6), and then transform their product into time domain using

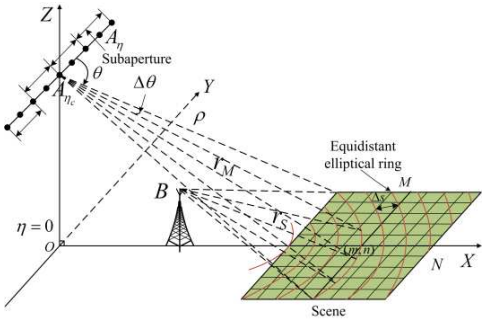

Figure 1: Imaging geometry in elliptical polar coordinate.

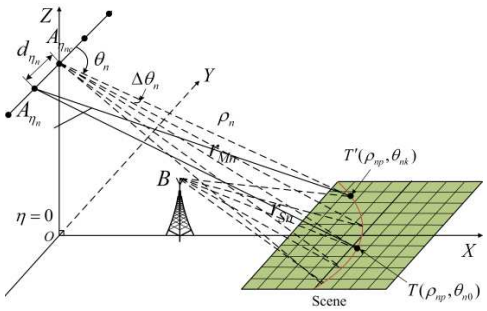

Figure 2: Subaperture processing in the echo simulation.

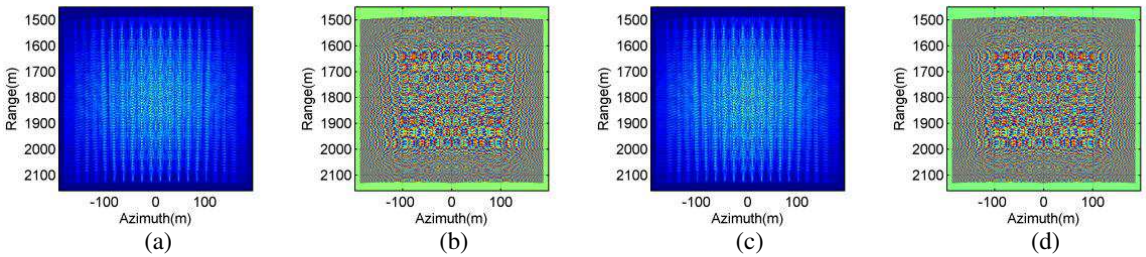

Figure 3: Scene echoes including 81 discrete point targets. (a) (b) Amplitude and phase of the scene echo simulated by the TBT method; (c) (d) Amplitude and phase of the scene echo simulated by the proposed RSA.

the IFFT and obtain the subaperture pulse echo; (8) In terms of the subaperture order, repeat (4)–(7), and then the scene echo can be simulated.

To prove the validity of the proposed RSA, the simulation is carried out to compare the performances of the proposed RSA and TBT method (See Fig. 3). It is seen that the scene echoes simulated by the two methods are almost identical. From Fig. 4, it is found that all the scattering targets are focused well, and the focusing performance of the central target in Fig. 4(d) is very similar to that in Fig. 4(c). Simulation time of the proposed RSA and TBT method is 1042.2 s and 21086.1 s, respectively.

Abstract— Eddy current test using a search coil detecting high frequency as magnetic nondestructive test (NDT) is widely used. When a defect inside or back side of the metal exists, the detection is very difficult because of shallow skin depth of the exposed high frequency magnetic field. To detect a deep defect, high sensitive magnetic sensor operable with wide range from extreme low to high frequency is necessary. In this study, we applied high sensitive magnetic sensor with nanogranular type tunnel magnetoresistive (TMR) thin film operable from DC to high frequency for NDT. TMR has an even functional characteristic to magnetic field. Therefore, DC magnetic field bias or additional circuit is necessary to obtain linear magnetic response. We developed a new second harmonic detection method without linearization. Moreover, eddy current distribution can be imaged by the detection of tangential magnetic field component from the sample. Using a pair of TMR sensor detecting x- and y-magnetic field components parallel to the metal surface. The sensor probe consists of the exposure coil and MR sensors. Each of the magnetic field vectors was calculated from two parameters of signal amplitude and phase obtained by a lock-in amplifier. Using these magnetic field vector, the eddy current in the subject was reconstructed. By the imaging of the disturbance of the eddy current distribution caused by the defect, defect imaging at not only surface but also deep inside the subject was enabled. Especially, the depth information of the defect was obtained by the changing frequency.

Iterative K-means Clustering Based Fast Hybrid Segmentation Method for Biomedical Optical Images

Seungbae Ji, Seung-Beom Yu, and Jae-Ho Han
Department of Brain and Cognitive Engineering, Korea University
145 Anam Rd., Seoul 02841, Republic of Korea

Abstract— Optical coherence tomography (OCT) is a well-established biomedical optical imaging technique that non-invasively provides high-resolution images for cross-sectional view of retinal structures [1, 2]. Retinal layers are observed in the acquired morphology depending on the optical properties of neurosensory tissues. Even though most of the functional layers present the changes of pixel intensities, it is not sufficient to find the precise retinal boundaries through simple edge acquisition. Instead, in order to accurately investigate them, graph-cut segmentation method has been widely employed [3, 4], which usually necessitates a high-time complexity for fully realizing this algorithm. In this work, we propose a fast method for layer segmentation with a high-accuracy with less time complexity than the conventional graph-cut method, which is based on a hybrid method employing iterative k-means clustering in conjunction with edge recognition. In our method, the former extracts the details at the interfaces of a similar pixel group and the latter handles a drastic change of pixel intensity which appears as thick lines. This introduced method can be expanded for other various image segmentation fields such as delicate brain and vascular images as well as the fundography images for diagnostic purposes.

Abstract—

Objective: Biodegradable polymer [Poly(L-lactide), PLLA] scaffolds have been popular used in the reconstruction of craniomaxillofacial defects because of their good biocompatibility and low toxicity after degradation in vivo. However, lower cell proliferation rate and poor cell attachment were reported when culturing osteoblst on the PLLA discs. The purpose of this study was to evaluate the biological effects of static magnetic fields from Nd-Fe-B magnets on the morphology and growth behavior of osteoblast-like cells cultured on the surface of a PLLA discs.

Material and Methods: PLLA discs (14-mm in diameter and 1-mm in thickness) were fabricated with an injection molding technique at an injection temperature of 185°C. MC3T3-E1osteoblast-like cells were cultured on the surface of a poly-L-lactide disc. These cells were continuously exposed to a 4000 Gauss-SMF for 5 days. Sham-exposed cells were served as controls. The morphologic changes of osteoblast-like cells were observed by scanning electron microscopy. The proliferation effects of the SMF were measured by MTT assay. In addition, the effects of the SMF on alkaline phosphatase activity levels were compared between exposed and unexposed cells.

Result: Scanning electron microscopy images revealed that SMF promote MC3T3-E1 cells express extracellular matrix on the Poly-L-lactide discs. The SMF exposed MC3T3-E1 cells exhibited increased MTT values at 3 and 4 days of culture. The SMF exposed MC3T3-E1 cells express the lower alkaline phosphatase-specific activity than that of the unexposed cells at 3 and 4 days of culture ($p < 0.05$).

Conclusion: These results demonstrated SMF can improve MC3T3-E1 cells growth on the Poly-L-lactide discs.

Effects of Static Magnetic Fields on the Growth of Dental Pulp Stem Cells

Yu-Chi Chang, **Wei-Zhen Lew**, **Kuo-Ning Ho**, **and Sheng-Wei Feng**
School of Dentistry, College of Oral Medicine, Taipei Medical University, Taipei, Taiwan

Abstract— Dental pulp stem cells (DPSCs) have multiple superior growth capacities when compared to bone marrow stem cells. Therefore, it could be as a potential resource for clinical cell therapy and tissue engineering. However, large amount of time are needed to generate sufficient number of cells for tissue defects repairing. Therefore, the aim of this study was to evaluate whether 0.4-Tesla static magnetic fields (SMF) can enhance the proliferation of dental pulp cells (DPCs) and DPSCs in vitro.

Cells extirpated from dental pulp tissue were identified by surface markers expression and differentiation stimuli. Our results showed that these cells can express the same characteristics as the mesenchymal stem cells. Positive expressions of CD70, CD90, CD105, CD146, STRO-1 and negative expression of CD14, CD34 were demonstrated from these dental pulp cells. Moreover, calcium deposition, intracellular lipid droplets formation and GAG matrix deposition were found after different kinds of stimulation. Therefore, we can confirm that these cells are DPSCs. After that, the isolated DPSCs were cultured with 0.4 T SMF exposure and exhibited a higher proliferation rate when comparing to control group. Stem cells identification assays as mentioned above were performed to exposure cells to characterize its stem cells properties. We found that either exposure cells or sham cells have similar results. DPSCs cultured in SMF environment have no adverse effects on the CD marker expression and their differential potential.

Thus, we suggest that in vitro 0.4 T SMF stimulation is positive for the proliferation rate of DPSCs without adverse effect on its characteristic and differential potential.

Impact of Static Magnetic Fields on the Microscopic Changes of Dental Pulp Stem Cells

Pei-Yu Tsai[1], **Ching-Hua Su**[2], **Chia-Chen Hsu**[3], **and Sheng-Wei Feng**[1]

Abstract— 0.4 T static magnetic fields (SMFs) can enhance the proliferation of dental pulp stem cells (DPSCs) in vitro. However, the microscopic subcellular changes of the exposed cells are still unknown. Therefore, the aim of this study was to investigate the actual mechanism activated by the stimulus of SMFs.

Because cell membrane is the biosensor of external applied SMFs, anisotropy of lipid bilayers was examined by fluorescence polarization-depolarization assay. TMA-DPH labeled results showed that exposed cells had higher anisotropy value, indicating that SMFs changed the order of lipid bilayers. Because the actin cytoskeleton is link to cell membrane by a complex protein structure, the change of cell membrane may affect the actin cytoskeleton. For this reason, we labeled the cytoskeleton of exposure and sham cells by phalloidine fluorescence. Confocal microscope images estimated that exposed cells had more order and thicker actin cytoskeletal structure,while the actin cytoskeleton of sham cells was randomly oriented. Then, we focused on the MAPK pathways to find out the possibility signaling cascade which induce the proliferation of 0.4 T SMFs exposure cells. ERK inhibitor PD98059, JNK inhibitor SP was supplied to cultured medium respectively. MTT results showed that p38 signaling pathway may be the possibility signaling cascade activated by 0.4 T SMFs.

According to our results, we suggest that 0.4 T SMFs will affect the cell membrane and reorganized of the cytoskeleton. Besides, p38 signaling pathway also will be activated to increase DPSCs proliferation.

7 Tesla Magnetic Resonance Imaging Does Not Induce DNA Double-strand Breaks in Isolated Human Lymphocytes

Abstract—

Purpose and Introduction: Magnetic resonance imaging (MRI) is a powerful, non-invasive diagnostic medical imaging technique which has experienced increasing demand over the past decades to also be used in the research with higher strength of magnetic fields (mainly 7T). Although ultra-high field MRI has shown a very good safety record for 10 years, the scientific basis for safe use in broader clinical applications is weak. Despite a fair number of studies in this field, overall, the published data about the potential effect of UHF MR on inducing genetic damage is not sufficiently conclusive. Most of the available literature reported no genetic effects; however a few studies, including a recent study reported DNA damage detected after cardiac MRI and suggested similar restrictions as for ionizing techniques [1].

In this *in vitro* study, we aimed to investigate the genotoxic and cytotoxic potential of 7T MRI on isolated human peripheral blood mononuclear cells (PBMCs). Hence, unstimulated PBMCs were exposed to 7T static magnetic field alone or in combination with maximum permissible gradient fields and radio frequency pulses as well as ionizing radiation.

Methods: Peripheral venous blood was drawn from 16 healthy volunteers (8 male; 8 female; age 25–58 years, mean 36 years). To detect and validate the MR-related effects, particular care was taken in choosing ideal conditions for negative and positive control groups. Isolated PBMCs suspension of each donor was divided into five sample tubes; unexposed, 7T static magnetic field, echo-planar imaging (EPI), CT and γ-radiation. The echo-planar imaging sequence was employed on a 7T whole-body MR scanner (Siemens AG, Healthcare Sector, Erlangen, Germany) and tailored to the maximum switched gradient as well as 100% permissible specific absorption rate (SAR) in 1 hour scanning. We used immunofluorescence staining of phosphorylated serine 139 in the core histone variant H2AX (γH2AX) which forms a distinct focus at each break site in DNA strands [2]. Automated fluorescence microscopy (AKLIDES system, Medipan GmbH, Germany) and flow cytometric analysis were used to quantify the γH2AX foci intensity immediately (0 hour) as well as 1 h and 20 h after the exposure.

Results: Exposure of unstimulated PBMCs to 7T static magnetic field alone or combined with gradient magnetic fields and pulsed radiofrequency fields did not induce DSB, whereas irradiation with X- and γ-ray led to a dose-dependent induction of γH2AX foci. Further, there was no evidence for altered proliferation responses after cells were exposed to 7T MRI.

Conclusions: In this study, we evaluated the impact of 7T MR-generated electromagnetic fields on the induction of DNA DSBs in human PBMC. We examined and compared the extent of damage with that observed in un-exposed and irradiated cells. Our results showed no significant increase in DSBs level, in all individuals, immediately (0 hour), 1 h and 20 h after UHF MRI exposure, compared to the unexposed group. Further, in *vitro, in vivo* and large scale epidemiological studies with sufficient statistical power which include several genotoxic endpoints, such as, chromosomal aberrations (CA) and micronuclei (MN) may further enrich the findings of the present study. Data from such comprehensive studies are useful to pave the way for transferring ultra-high field MRI to clinical adoption.

Shielding and Mitigations of the Magnetic Fields Generated by the Underground Power Cables

N. İl, S. Ozen, M. Çakir, and H. F. Carlak
Electrical & Electronics Engineering, Akdeniz University, Antalya 07058, Turkey

Abstract— In urban areas, especially in city centers, underground power cable usage in power distribution lines has been increasing dramatically. Increasing energy demand results in more loading in the power transmission lines and correspondingly more magnetic field occur around transmission lines. These excessive magnetic fields can cause harmful effects on human health. These fields can also cause deteriorating effects on the sensitive electronic equipment due to the electromagnetic interference. Therefore, the investigation of the magnetic field that occurs around the underground cable lines used in the energy distribution network become an important research topic. There are number of design options that would mitigate the magnetic field. However, magnetic field management can be basically classified into two main categories; which are shielding the subject and shielding the source. In this study, shielding the source and shielding the underground power cable raceway are investigated. In order to mitigate the magnetic field caused by underground power cables, two different shield topologies, the flat plate and reverse-U shape shielding screens, are examined theoretically and practically on currently used cable raceways. The most appropriate shielding type was investigated.

The analysis of different shielding configurations with flat plate material denoted that, the efficiency of the shielding strongly depends on the employed material. In case of reverse-U shield configuration, higher shielding efficiency is obtained as shown in Figure 1.

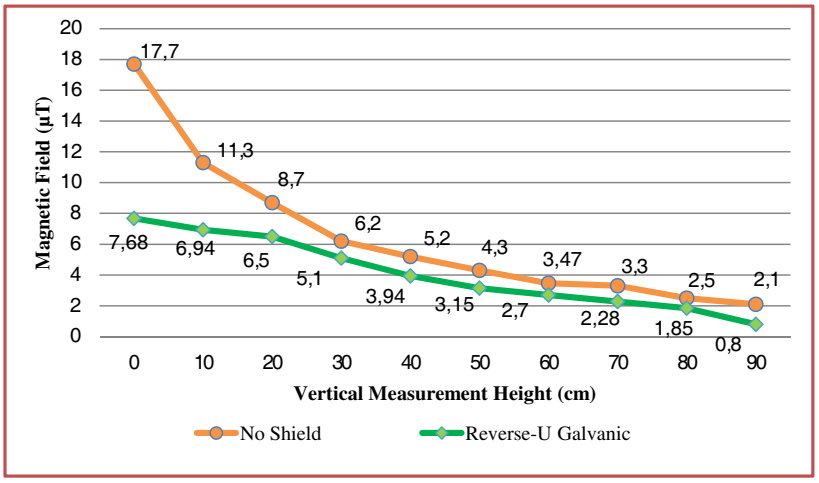

Figure 1: Shielding efficiency of reverse-U shield.

It is concluded that, better shielding efficiency is achieved when closed shields are used. On the other hand, in case of the flat plate shield usage, the efficiency depends on the electrical features and the thickness of the material.

Occupational Exposure Assessment of Power Frequency Magnetic Field in 154/31.5 kV Electric Power Substation in Turkey

S. Ozen, **S. Helhel**, **and H. F. Carlak**
Electrical & Electronics Engineering Department, Akdeniz University, Antalya 07058, Turkey

Abstract— The effects from exposure to power frequency electromagnetic fields are of interest to the public. These 50-Hz field exposures raise the question of what effects these may have on human health. Power subsystems are expected to produce very high magnetic field, since they are driving very high electric current density that results in an accumulating exposure to electric, magnetic and electromagnetic fields that cause some health problems if systems are designed without obeying the standards. Some epidemiological studies have found weak associations between exposure to power-frequency EMFs and some forms of cancer, such as leukemia; while other studies have failed to find such associations.

In this study has been proposed the survey of magnetic field measurements taken in a 154/31.5 kV substation in the City of Antalya for occupational exposure assessment. The magnetic field measurements carried out from substation equipment, including all transformers, circuit breakers, feeders and buses, under the in-coming and out-going power lines and operator tables surrounding the substation. Operator desk at read a lowest magnetic field of 0.46 μT at minimum loaded season and reached up to 1.34 μT at maximum loaded season that means operators exposed to a magnetic field of 0.3 μT and more by eight hours a day. In switchgear regions, maximum magnetic field reading is 20 μT at minimum loaded season and reached up to 65 μT. Outdoor magnetic field measurement at circuit breaker region goes up to 45 μT with respect to operator heights.

Table 1: Maximum induced electric fields and current densities for different locations in the substation.

Measurement Locations	**Magnetic field (μT)**	$\boldsymbol{J}$ **(μA/m²)**
Operator desktop	0.35	1.517
In front of 31.5 kV Command panel for main bar	40	173.416
31.5 kV side of TR-A	4.7	20.376
31.5 kV side of TR-B (2 m from TR-B)	7.4	32.082
In front of the circuit breaker (SF6)	8.8	38.15
Under the 154 kV busbar for TR-B input	3.95	17.124
Under the 154 kV busbar for TR-A	**6.5**	**28.18**

Effect of Renewable Energy Sources to the Stability of the Low Voltage Distribution Networks

Abstract— The paper describes the recent development in the area of renewable energy sources (RES). Shows the situations in countries supporting a great growth of RES, particularly in photovoltaic energy what leads to the big problems. The modelling of situation shows that in a very near future there will be a big overflow of electrical energy production in the low voltage networks (LVN). It would evoke necessity to transfer energy into higher voltage networks. However it's not possible, because of the protection systems of high voltage networks (HVN) are developed for the opposite flow of energy. The traditional power engineering industry assumes centralized energy sources (power plants), and delivers electrical energy into consumers via very high voltage networks (transition networks VHN), high voltage networks (HVN) into LVN. In the low voltage networks the energy is totally consumed. Because of the existing protection systems in the HVN, and the recent energy distributors and producers correspond with this traditional conception, is necessary to consume all energy from RES in the low voltage networks where it was produced. Our contribution deals with this phenomenon and offers some part solution of the problem.

Sensor Design and Data Transfer in a Smart Grid

Abstract— It this paper is showed design sensors physical variables, which is using for modelling power in smart grid. In the next step is showed transfer data using GPRS and modelling power provided renewable energy sources. In our distant sources we measure depend between physical variables as lighting and photovoltaic power plants, the water level and hydroelectric power plants. The power wind power plat is measure directly using wattmeter between plat and battery. For transfer data is used datalogger DA4, which used GPRS and data represented physical variables is storage in SQL database. In our 24 V smart gird is modelled power using power source. In the hydroelectric power plants was problem with non-harmonic voltage and current generated turbine. The design module includes analog multiplier for accurate measure power, necessary for give depend power to the water level. This module and datalogger DA4 is powered small photovoltaic panel. The module measure lighting between photovoltaic power plants is directly connection cable to the Compact Rio. The last renewable energy sources power wind power plat is powered battery and charged power give power wind power.

A Novel Design of the Wearable Antenna

Cheng-Nan Hu, **Jhih-Neng Yang**, **Siam-Chen Huang**, **and Ju-Chun Lin**
Communication Research Center, Oriental Institute of Technology, Taiwan

Abstract— Utilization of wearable textiles in the antenna segment is on demands for the blooming development of the body-centric communication systems. A wearable antenna is meant to be a part of the clothing used for communication purposes, which includes tracking and navigation, mobile computing and public safety. In this study, a proof-of-concept dual-band (2.4/5.7 GHz) wearable antenna design is realized using a multiple inverted-L antenna printed on a circular FR4 substrate above a ground plane with shape of button, termed as a button antenna. Due to its shape (like button) and compact volume (12 mm in diameter and 5 mm in height), the antenna can be easily implemented onto the wearable textiles for body PANs applications. Numerical and experimental study are presented herein.

Low-complexity Design of an 8×8 Modulation Configurable K-best MIMO Detector

Muh-Tian Shiue and Syu-Siang Long
Department of Electrical Engineering, National Central University, Zhongli 32001, Taiwan

Abstract— With growth of high throughput requirement in advanced communication standards such as IEEE 802.11ac, multiple-input multiple-output (MIMO) spatial multiplexing is an important technique to increase data throughput in a limited bandwidth. In this paper, a high power-efficiency 8×8 MIMO detector which supports multiple modulation schemes is presented. According to the tree-type decoding process, a pipelined circuit architecture suitable for high throughput is proposed for breadth-first type algorithm. To further reduce the circuit complexity, a shift-multiplier is proposed to avoid a conventional multiplier in our design. Multiple data modulation is also supported by flexibly extending the enumeration signal range. The circuit implementation has proved that our design has high power efficiency comparing with other works.

In algorithmic aspect, a breadth-first type algorithm can achieve near-ML performance and a fixed throughput, an algorithm modified from conventional K-best which is named distributed K-best (DKB) is applied in our design. Comparing with the conventional K-best algorithm, DKB can reduce the number of visiting nodes to 23.8% at each searching layer under 8×8, 64-QAM and $K = 10$ condition, i.e., prevents unnecessary power consumption. The MIMO system model in our design is converted into a real-numbered one, and we modify the enumeration scheme to further reduce computing power. Therefore, a shift-multiplier can be applied with only bit-shifting and addition operations. Furthermore, multiple data modulation schemes are supported by 1-D SE-enumeration without increasing algorithmic complexity.

In hardware aspect, our design applies multistage pipelined architecture to achieve high throughput requirement. Each stage processes one tree-searching layer with DKB algorithm, a single DKB block contains a first-child (FC) and a next-child (NC) functional block. The FC and NC operate exclusively to find best K candidates within only K clock cycles. Thanks to DKB algorithm, the sorting circuit in conventional K-best algorithm is avoided in our hardware architecture. The center calculation in order to find a FC is achieved by shift-multiplier which only contains a few adders and MUXs. Since the proposed hardware architecture is very regular, it has flexibility extending to other antenna configurations.

The proposed 8×8 MIMO detector has been implemented in a 90-nm CMOS technology with core area of $0.99 \times 0.99\,\mathrm{mm}^2$. The maximum throughput achieves 710 Mbps at operating frequency 74 MHz. At this condition, the power consumption is 17.2 mW at 1 V supply voltage. The normalized power is 24 pJ/bit, comparing with other works in the literatures, our proposed design delivers very high power efficiency.

Analysis and Construction of Static Inverter with Multi-windings Transformer for High Power Voltage Source

J. M. Grochowalski and Z. Frąckiewicz
Faculty of Electrical Engineering, West Pomeranian University of Technology, Szczecin, Poland

Abstract— High power static voltage inverters found their application in a power conversion for isolated power grids, especially in the shipbuilding and the maritime industry. When there is a need for interconnecting ship with an external electric power source for technical (i.e., a vessel is under a maintenance is shipyard, and it cannot use its own onboard power generator) or economical (a ship is being unloaded in a harbor) reasons there are a few options. One of them is to supply electrical energy from a static power inverter, which converts energy from a public grid to the appropriate frequency and voltage needed on board.

Most of the problems related to the design of such inverters are that very often nominal power of such devices is comparable to nominal power of its load. In case of a ship the major part of the load are cranes, pumps, fans and so on, all driven by electrical machines (most frequently induction machines). Starting current of the induction electrical machine is about $6 \div 7$ times nominal current. And this starting current must be withstood by a static power inverter, which place great demands on its design.

The voltage source presented in this paper consist of two main elements: a static inverter and a multi-windings transformer. To meet the requirements of ship electrical network, namely frequency (60 Hz), voltage (440 V, 690 V) and high overload current it is proposed to use thyristors as switching devices. The downside of this approach is that operating frequency of the inverter cannot be as high as in a case of IGBT or other transistors, so a total harmonics distortion in output voltage is high. To counter this effect and lower the THD to required by law or other regulations a specially designed and connected multi-windings transformer is used. It also adjust the output voltage level to the required one.

In this contribution a design of proposed voltage source, its computer simulations and experimental results are shown.

Modelling and Analysis of an Electro-optical System with an Off-quadrature Biased Modulator

D. M. S. Morais[1], **J. Panasiewicz**[1, 2], **and G. M. Pacheco**[1]

[1]Aeronautics Technical Institute, Brazil
[2]National Institute for Space Research, Brazil

Abstract— This paper describes the behavior of a microwave external modulation link composed of: optical and radio frequency sources, Mach-Zehnder modulator (MZ), optical fiber and photodetector. The electro-optical circuit modulates the RF signals and transmits them to the detector through the optical fiber. The main contribution of this paper lies on the different approach to the system analysis; we consider an off-quadrature biased MZM.

By extending the mathematical model found in the literature for the case of different bias voltages, we compute a few performance parameters of the system like Gain and SFDR. For computing those parameters we use a custom made program written in the MATLAB environment.

In addition to the system's characterization and insights on its off-quadrature operation, another contribution of this article is the model validation. We assembled the electro-optical circuit and measured some performance parameters for different values of bias voltages. By comparing the experimental results with the theoretical ones, we validated the model. Finally, we also consider the applications for microwave signals distribution by optical fiber links.

Studies on the Photoluminescence of a Novel Europium (III) Complex in Solution

[4]Department of Physics and Electronic Science, Tongren University, Guizhou 554300, China

Abstract— The novel ternary europium (III) complex is synthesized. The photophysical sensitization process involves an energy transfer from functional hemicyanine (aminostyrylpyridinium) cation. The sensitization mechanism follows the F?rster, which is significantly different from the Dexter, the most commonly used energy transfer mechanism from ligand. When the complex is dissolved in a variety of solvents (acetone, dimethylformamide, ethanol and acetonitrile), a remarkable solvent effect is observed. The emission intensity of europium (III) complex in acetonitrile is much stronger than that in other solvents. The solvent effect on the photophysical properties is studied. The result indicates that the solvent influences the emission intensity by aid of many factors not only polarity.

Numerical Study of Electrically-induced Physiotherapy: Influence of Working Frequency and Electrode Type on Temperature Distribution

J. Vrba[1], **D. Vrba**[1], **and M. Lorenc**[2]

[1]Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic
[2]Faculty of Electrical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— Temperature increase has a proved positive effect on pain relief, inflammation and muscle spasms treatment. It is therefore utilized in physiotherapy as well as in other biomedical applications. Temperature increase of the treated biological tissues is often performed by a well-controlled exposure of the tissues to time-harmonic electric fields. To obtain only localized and safe heating active electrode and return pad electrode differ by their size and shape. In this paper, a numerical study of influence of working frequency and electrode type on power loss and corresponding temperature distribution in exposed biological tissues was performed and some results are presented and discussed.

A simplified 2D numerical model in the well-proven numerical simulation tool COMSOL Multiphysics was created. The human body was represented by an elliptical layered model consisting of skin and an inner region modeled as a muscle tissue. In the presented numerical study, thermal material properties as well as frequency-dependent dielectric properties of the biological tissues were considered. Within this study three working frequencies $f = 0.5$, 1 and 1.5 MHz and following two types of electrodes are included. Resistive electrodes are in a direct contact with treated biological tissues and capacitive electrodes which are equipped with a thin nonconductive coating. Active electrode is circular with 15.9 cm^2 area. Grounding pad is of rectangular shape and approximately 7.5 times larger.

Main outcome of the performed numerical simulations is a prediction of spatial distribution of power losses induced in the treated tissues. Corresponding temperature distribution obtained by solving the Pennes' bioheat equation is displayed graphically and further discussed.

The Bone Regeneration Effect of 3D Printed Ferromagnetic Magnetite-based Polylactide Composite Bone Screw

Haw-Ming Huang[1], **Jy-Jiunn Tzeng**[1], **Ya-Hui Chan**[1, 2], **and Chien-Fang Tseng**[3]

[1]Graduate Institute of Biomedical Materials and Engineering, Taipei Medical University, Taipei, Taiwan
[2]Dental Department, En-Chu-Kong Hospital, Taipei, Taiwan
[3]School of Dentistry, Taipei Medical University, Taipei, Taiwan

Abstract— Polylactic acid (PLA)-based composites were used as bone/tissue regeneration materials for many years. Recently, how to modify the physical, chemical and biological properties of the PLA-based materials for improving its medical application has become an issue for biomaterial sciences. It has been reported that iron oxide magnetic nanoparticles exhibit not only biocompatibility, but also bioactive effect on the osteoblastic proliferation. Accordingly, the aim of this study was to develop a novel nano-magnetic bioresorbable bone screw by using both injection molding and 3D printing techniques. For methodology, nanoscale magnetite was incorporated into the PLA matrix with various nano-Fe_3O_4/PLA mixing ratios. Pure PLA samples were carried out as a control. Thermodynamic, mechanical, and biocompatibility of the materials were tested to confirm the performance of this composite. Then nano-Fe_3O_4/PLA bone screws were fabricated by injection molding and 3D printing techniques. The mechanical properties of these bone screw were tested by simulated model in vitro. In addition, animal studies were performed to test the healing status between nano-Fe_3O_4/PLA screw and bone tissue. In the strength tests, our results showed that the screws produced by 3D-printer are weaker than the screws made by injection molding. In animal study, we found the implant side with screws that contain ferromagnetic particles showed more regenerated bone volume and induce less inflammation and tissue mass. The CT imaging enhancement of the nano-Fe_3O_4/PLA bone screw was proved. With these results, we concluded that this novel magnetic bioresorbable screw can be applied in future orthopaedic treatment.

The Gene Expression of Dental Pulp Stem Cells Due to 0.4 T SMF Treatment

Abstract—

Objective: Human dental pulp stem cells (DPSCs) have become an alternative source for tissue engineering. Accordingly, how to increase viability of human DPSCs is vitro has become an important issue in medical applications. Several studies showed that static magnetic field (SMF) has positive biological effect on stem cells. However, the real signal transduction mechanisms are still unknown. In this study, we focus our aim test the effect of SMF on human DPSCs. The possible gene expression of DPSCs after exposure to SMF was explored.

Materials and methods: In this study, human DPSCs were isolated using magnetic activating cell sorting technique. The test cells were treated with 0.4 T SMF exposure. A neodymium disc was used to provide the magnetic field. For control group, the cells were exposed to a non-magnetized neodymium disc. The cell proliferation rate and gene expression profiles were performed by MTT assay and RNA microarray, respectively.

Results: Our results showed that the proliferation rate of SMF-treated human DPSCs significantly increased. A total of 216 genes changed with a 2-fold or more ratio was found in SMF-treated human DPSCs. In addition, Slightly increase of TGFB-2 and Col III genes were noted after 24-hour exposure. Moreover, FGF2 gene increased after 48-hour exposure.

Conclusion: According to these results, we conclude that 0.4 T SMF significantly improve the proliferation and gene expression of human DPSCs.

Increases Cryopreservation Efficiency of Stem Cells Using Static Magnetic Field

Kan-Shin Fan[1], **Chun-Yen Lin**[2], **Haw-Ming Huang**[3], **and Jen-Chang Yang**[4]

[4]School of Dental Technology, Taipei Medical University, Taipei, Taiwan

Abstract— How to successful cryopreservation of stem cells is a key issue for application of regenerative medicine. Recently, magnetic cryopreservation has been reported to be an efficient method for cell banking and cryopreservation. The purpose of this study was to test whether static magnetic fields can improve cryoprotective effects of stem cells during cryopreservation process. In methodology, human dental pulp stem cells were frozen with a 0.8-T SMF and then stored at −196°C for 24 hr. During freezing, the cells were suspended in freezing media containing with 0%, 3%, or 10% DMSO. After thawing, the survival rate of the stem cells were tested and compared to the control cells which were frozen without SMF. In addition, physical property of the cellular membrane was determined to understand the possible cryoprotective mechanisms of the SMF. The results indicated, the positive cryoprotective effect of SMF can be observed when the freezing medium was DMSO-free. The survival rates of the thawed stem cells increased up to 2.5-fold when the cells were exposed to a 0.8-T SMFs, respectively ($p < 0.01$). Meanwhile, our results showed that the major mechanism of SMF-induced cryopreservation is due to the membrane distortion due to magnetic force applied. These results suggested that SMF exposure improved stem cell cryopreservation at DMSO-free environment. This phenomenon can be a useful reference for future tissue engineering application.

Metamaterial Terahertz Bandpass Filters: A Comparison between Metallic and Graphene-based Structures

M. Bana Kermani[1], **M. Khodaee**[1], **A. Nasiri**[2], **and H. Baghban**[1]

[1]School of Engineering-Emerging Technologies, University of Tabriz

[2]Department of Engineering, University College of Nabi Akram, Tabriz 51385-1488, Iran

Abstract— Metamaterial-based optoelectronic devices including Terahertz filters play a definitive role in advancement of THz technology. In this article we present a design procedure to obtain voltage-dependent carrier density control in a GaN-based hetero structure with a Schottky gate configuration which serves as the substrate for a THz bandpass filter (BPF). The introduced structure consists of a cross shaped metallic layer on the AlGaN/GaN hetero structures as presented in Figure 1(a). Then, we investigate tuning of transmission properties and the tunability of the filter. Figure 1(b) illustrates the transmission properties of the designed structure at different bias voltages. An overall tunability of about 103 GHz in the resonance frequency was obtained by varying the applied voltage from −8 V to 2 V. Also, a plasmonic metamaterial based on the graphene cross-shaped structure is studied and a comparison has been performed between the optical properties of graphene-based cross-shaped structure and the original structure. It is noteworthy to mention that graphene-based THz filters are more flexible to achieving tunability, and the continuous forms of graphene can be transferred to a flat substrate and the carrier concentration of each layer in a graphene-based multi-layer filter can be dynamically tuned.

The surface conductivity of graphene that contains the effect of interband and intraband transitions has been calculated through the local limit of random-phase approximation (RPA). The surface conductivity depends on the temperature, the intrinsic carrier relaxation time, τ, and the Fermi level (which depends on the external bias voltage). Obtained results show considerable resonance strength and dynamically controllable feature. Both of the presented structures can be promising for developing electrically tunable THz BPFs.

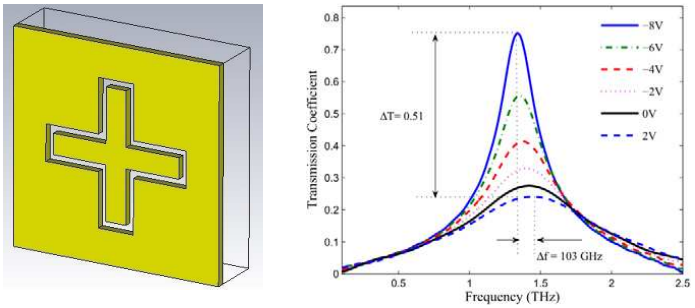

Figure 1: Cross-shaped THz BPF (a) and the obtained transmission characteristics as a function of applied bias voltage.

Continuous Wireless Monitoring and Wireless Power Transfer for Leadless Pacemaker Systems

Rupam Kumar Das[1], **Dong Sik Woo**[2], **and Hyoungsuk Yoo**[1]

[1]University of Ulsan, Ulsan, South Korea
[2]Kyungpook National University, South Korea

Abstract— Pacemakers provide electrical stimuli to cause cardiac contractions when intrinsic cardiac activity is inappropriately slow or absent. Traditional cardiac pacing or pacemaker systems comprise an implantable pulse generator and lead system. A conventional pulse generator has an interface for connection to and disconnection from the electrode leads that carry signals to and from the heart. The complex connection between connectors and leads provides multiple opportunities for malfunction. Moreover, the pacemaker lead may also interact with magnetic resonance imaging (MRI) systems, which can cause tissue damage. Recently, an MRI-compatible capsule-type leadless pacemaker was introduced to resolve these problems. A leadless pacemaker has several advantages, such as being less invasive (no surgery, more cosmetically pleasing for the patient, i.e., invisible), improved efficiency (no system connections, more readily MRI-compatible), and cost-effectiveness (reduced length of hospital stay, less infection or erosion). However, the potential disadvantages or technical challenges of the leadless pacemaker cannot be neglected. These challenges include multiple chamber pacing, novel delivery systems, battery longevity, telemetry and long-term efficacy.

The leadless pacemaker's telemetry might facilitate a development that would allow healthcare professionals to control the device and monitor patients using a standard programmer via smart phones, thereby providing individual treatment to patients in the most rural of areas. Moreover, the leadless pacemaker must remain in place even after the batteries are exhausted. If a noninvasive method of recharging the batteries or powering the leadless pacemaker could be found then this would cease to be a problem and could even be considered an advantage. The implantable antenna allows for wireless monitoring and device control in patients, and the inclusion of wireless power transfer allows for continuous monitoring beyond normal battery lifetimes.

Here, we introduce an implantable antenna which can be incorporated into a capsule-type leadless pacemaker for telemetry. This antenna was designed at Medical Implanted Communication Service (MICS) band ($\sim 400\,\mathrm{MHz}$). We also utilize the recently published midfield energy transfer technique to check the likeliness of wireless powering of the leadless pacemaker and for removal of batteries. A midfield transmitter antenna was designed for this purpose at 1.5 GHz. Finally, we simulated and measured the performance of both antennas, and we also checked any significant coupling between these two schemes.

Some Effects of Specific Interest on the Brain of Children with Autism Spectrum Disorder (ASD): A Functional Near-infrared Spectroscopy Study

Abstract— Autism spectrum disorder (ASD) is a neuro-developmental disorder, characterized by two major domains: impairments in the social cognition and communication as well as restricted, repetitive, stereotyped interests and behaviors. In this study, functional near-infrared spectroscopy (fNIRS) was applied to investigate the atypical activation pattern of language areas (bilateral inferior frontal gyrus and bilateral temporal cortex) and uncover the impact of a specific interest on the brain function of children with ASD. We employed a listening comprehension task to stimulate the language areas of 2 ASD boys (A1 and A2) who had strong interests in the experiment material ("Lightning McQueen") and another 2 ASD boys (A3 and A4) who were matched with A1 and A2 respectively by age, intelligence quotient, language ability and the severity of symptoms. Our results showed that, during the task, the picture of "Lightning McQueen", but not the words of "The little red car", elicited stronger activation in the bilateral inferior frontal gyrus and temporal cortex of A1 and A2 than A3 and A4. These results could facilitate our understanding of language development of ASD and reconsider the role of specific interests (especially visual stimuli) played in the brain functional development of ASD.

Broadband Cross Polarization Converter Formed by Twisted F-shaped Chiral Metamaterial

D. K. Sharma and S. K. Pathak
Microwave and ECE Diagnostic Division, Institute for Plasma Research, India

Abstract— A broadband cross polarization convertor (CPC) formed from Twisted-F Shaped Chiral Metamaterial (TFSCM) having high optical activity is reported in this work. The proposed structure supports high polarization conversion efficiency which has been demonstrated numerically. The achieved optical activity in the structure is due to the presence of cross coupling phenomena between electric and magnetic fields. The coupling mechanism is explained on the basis of surface current distribution in between top and bottom metallic plates of TFSCM. The TFSCM is a bilayered structure having F-shaped metallic inclusions on both sides having twist in opposite direction and separated by FR-4 dielectric spacer. In direction of EM wave propagation, structure lacks mirror symmetry which provides structure the property to have strong optical activity in order to realize cross polarization conversion [1].

In Figure 1(a) numerical results of co- and cross polarization transmission coefficients of the TFSCM are presented. At frequency of 25.8 GHz the observed maximum cross polarization efficiency (CPC) is very high. At that frequency the distribution of surface current is as shown in Figure 2. It observed that incident electric field in y-direction excites symmetric current in front and back metal strips. Due to this a dominant electric dipole coupling is observed at resonance frequency [2]. The proposed broadband TFSCM cross polarization convertor is anticipated to have applications in microwave and photonics in the fields of communication, polarization spectroscopy, imaging microscopy etc..

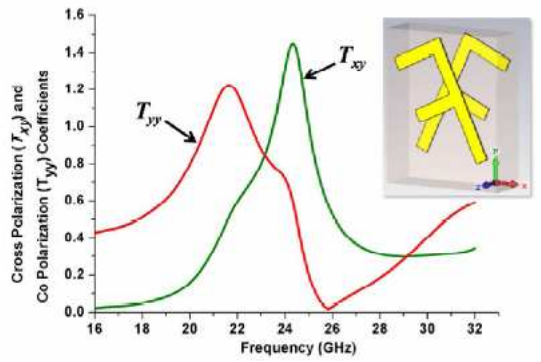

Figure 1: Cross and Co polarization coefficients of TFSCM structure.

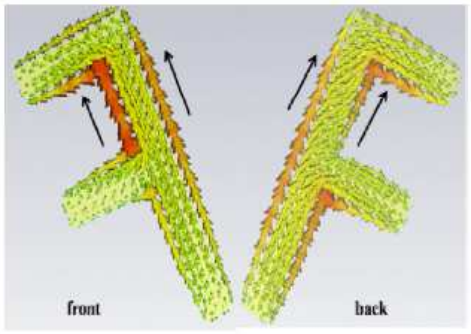

Figure 2: Surface current distribution of front and back metallic plate of TFSCM structure at frequency of 25.8 GHz.

Abstract— Functional near-infrared spectroscopy (fNIRS) is an emerging brain-imaging technique which has been used to various areas. Previous studies have indicated that frequent deceiving would make deceiving easier. In this study, fNIRS was used to explore the effect of frequent degree of deceiving on the prefrontal cortical response to deception. Self-related questions were used in the experiment. The results showed different patterns of neural activation between non-frequent deceiving and frequent deceiving. In Channel 11 (in the left prefrontal cortex), non-frequent deceiving led to a greater neural activation than telling the truth, while this pattern did not appear in frequent deceiving. Our finding suggested that fNIRS has ability to detect deception under different situations.

Phononic Metamaterials: Past, Present and Future Challenges

Johan Christensen
DTU Fotonik, 2800 Kgs. Lyngby, Denmark

Abstract— The boost experienced by acoustic and elastic (phononic) metamaterial research during the past years has been driven by the ability to sculpture the flow of sound waves at will. Motivated by the desire to engineer artificial structures in the form of metamaterials and the quest to map quantum mechanical phenomena onto classical waves such as sound has led to vast possibilities in material designs for control of wave motion and the potential for engineering applications. Some striking material properties have shown in the past to be able to leave an objective acoustically concealed, hence they are cloaks of "unhearability". Also, fascinating materials have been designed to be able to bend a ray of sound the "wrong" way when, for example, a loudspeaker turned on irradiates such artificial structure with a negative refraction index. In this talk, I like to review some of the key achievements made in this field and wish to address some of the unanswered questions that might lead to a breakthrough in the future.

Elastic Wave Propagation in Soft Matter Materials

Stephan Rudykh
Department of Aerospace Engineering, Technion-Israel Institute of Technology, Israel

Abstract— We study elastic wave propagation in finitely deformed soft materials [1]. First, we derive explicit dispersion relations for homogeneous materials undergoing large deformations [2]. We show that large deformations significantly affect elastic wave propagation in soft materials. Next, we analyze a class of periodically structured phonon crystals with layered microstructures. These structures are known to develop elastic instability-induced wrinkling of interfacial layers [3]. The onset of a wrinkling instability in initially straight interfacial layers occurs when a critical compressive strain or stress is achieved. Further compression beyond the critical strain leads to an increase in the wrinkle amplitude of the interfacial layer. This, in turn, gives rise to the formation of a system of periodic scatterers, which reflect and interfere with wave propagation. We demonstrate that the topology of wrinkling interfacial layers can be controlled by deformation and used to produce band-gaps in wave propagation and, hence, to selectively filter frequencies [1]. Remarkably, the mechanism of frequency filtering is effective even for composites with similar or identical densities, such as polymer-polymer composites. Since the microstructure change is reversible, the mechanism can be used for tuning and controlling wave propagation by deformation.

Single Negative Metamaterials Take on Negative Indices Owing to Multiple Scattering: Demonstration with an Acoustic Super-lens

N. Kaina, **F. Lemoult**, **M. Fink**, **and G. Lerosey**
Institut Langevin, ESPCI ParisTech, France

Abstract— We evidence that single negative metamaterials can turn into double negative ones, hence leading to a negative band solely by breaking the symmetry. We explain this phenomenon from multiple scattering effects and give an analogy with the phonon optical branch. We experimentally demonstrate a negative index acoustic super-lens using a soda can hexagonal array with $\lambda_0/15$ spot.

Media presenting negative indices of refraction were first considered theoretically by Veselago in the 60's [1]. They have recently become a very attractive field of research since they theoretically offer the compelling possibility of designing flat super-lenses that can beat the diffraction limit, as suggested by Pendry [2]. This negative refraction can be achieved using metamaterials presenting simultaneously two negative effective properties (permittivity and permeability in electromagnetics or modulus and mass density in acoustics). From a practical point of view, this requires to combine two single negative locally resonant meta-atoms, each bringing one of the negative properties. On the other hand, it was highlighted that the negative refraction may also occur from the superposition of a monopolar and a dipolar resonance of a single acoustic Mie scatterer [3]. In this work, we show analytically and numerically, that, contrarily to previous ideas, double negative media can be created from a single negative metamaterial, that is a metamaterial having a single resonant atom. We chose to work with an acoustic metamaterial made out of soda cans as Helmholtz resonators. We start from a periodic one dimensional medium, for which the elementary cell, of deeply subwavelength dimension, is composed of a single acoustic resonator and whose dispersion relation is polaritonic (Fig. 1(a)). By slightly breaking this medium's symmetry, thus creating a bi-periodic medium (Fig. 1(b)), we evidence the creation of a negative band in the bandgap of the original medium. We prove that this can be explained only by considering the multiple scattering within the unit cell, which allows the rise of a dipolar mode otherwise inexistent. An analogy with the phonon optical branch will be provided. We then experimentally demonstrate a negative index acoustic super-lens for a frequency within the negative band of an hexagonal array of soda cans, that focus sound on a $\lambda_0/15$ focal spot behind the lens, in the vicinity of the output surface.

This new approach of a double negative medium from symmetry broken metamaterials stresses the importance of multiple scattering at subwavelength scales that is generally considered unimportant, as metamaterials are considered as effective media. We believe this work simplifies the design of negative index materials and paves the way to the design of new and exotic metamaterials.

Av. O. Messiaen, Le Mans 72085, France
[2]LUNAM Université, Université du Maine, Av. O. Messiaen, Le Mans 72085, France

Abstract— We demonstrate that the phenomenon of slow sound propagation associated with its inherent dissipation (dispersion + attenuation) arising from visco-thermal losses can be efficiently used to design broadband sound absorbing materials. The propagation in straight pores of rectangular cross-section loaded with tuned or detuned resonators is first analyzed. Below the bandgap associated with the resonance, the sound speed is slow down inside the pores and depends on the dimensions of both the pores and the resonators. Between the two resonances, a transparency band is open also associated with a speed of sound much smaller than the one in the air. We show that this speed is necessarily dispersive within the transparency band, while it possesses a plateau at low frequency.

The absorption coefficient of a periodic arrangement of one straight pore loaded with detuned resonators is then analyzed to obtained a perfect absorption condition, via an analysis in the complex frequency domain. Perfect absorption is obtained for a wavelength in the air much larger than four times the thickness of the structure, whose efficiency largely overcome the absorption properties of usual air saturated porous materials. It is shown that this perfect absorption arises from a critical coupling condition, the radiation loss being exactly compensated by the visothermal ones for specific dimensions of the structure.

The absorption of a metamaterial consisting of a periodic arrangement of pores with different lengths and cross-sections loaded with tuned or detuned resonators is finally shown to be unity or close to unity over a broad frequency range due to a correct frequency distribution of the resonances.

These conclusions are supported by experimental results.

Boundary Layer Effects on Acoustic Transmission through Narrow Slit-cavities

G. P. Ward[1], **R. K. Lovelock**[1], **A. R. J. Murray**[1], **A. P. Hibbins**[1], **J. R. Sambles**[1], **and J. D. Smith**[2]

Abstract— We explore the slit-width dependence of resonant transmission of sound in air through both a slit-array formed of aluminium slats, and a single open-ended slit-cavity (not shown in this abstract) in an aluminium plate. By studying Fabry-Perot-like cavity resonances, we find significant attenuation of the transmitted signal, and a reduction of the effective speed of sound through the slits by as much as 18%, for slit sizes narrowed below 2% of the free space wavelength. Our experimental results agree with numerical modelling and with theory which stems from Lord Rayleigh [1], concerning how viscous and thermal boundary layers at the slit walls effect the acoustic wave across the whole slit-cavity.

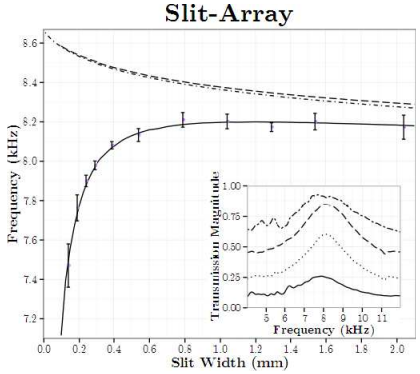

Figure 1: Dependence of the frequency of the fundamental Fabry-Perot resonance on slit width for the slit-array with slats of length $L = 19.80 \pm 0.12$ mm. The data was taken under different temperature, pressure and humidity, and then normalised to 293.15 K, with the other variables having negligible effect. The long dashed line represents a lossless FEM numerical prediction, the solid line a numerical prediction that includes the viscous and thermal properties of the system, and the circles the experimental results. Also shown as a dot-dash line is the prediction of the lossless model-matching model proposed by Christensen [1]. (Inset) Examples of the experimentally measured transmitted frequency spectra for the slit-array sample. Four different slit widths 2.0 mm, 1.0 mm, 0.5 mm and 0.2 mm, are represented by the dot-dashed, long-dashed, dotted and solid lines respectively.

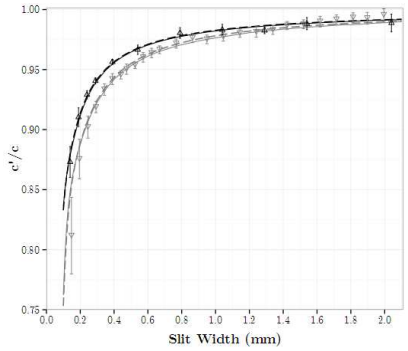

Figure 2: Ratio of the effective speed of sound c' to bulk speed c in each slit-cavity. Black represents the array sample, and grey the single slit sample. The solid lines show the result extracted from the finite element method model, the dashed lines are Stinson's [2] simplified analytic theory. Points are experimental data.

Abstract— We have adapted the concept of transformational thermodynamics, whereby the flux of temperature is controlled via anisotropic heterogeneous diffusivity, for the diffusion and transport of mass concentration. The n-dimensional, time-dependent, anisotropic heterogeneous Fick's equation is considered, which is a parabolic partial differential equation also applicable to heat diffusion, when convection occurs, for example, in fluids. We initially used finite-element computations to model liposome particles surrounded by a cylindrical multi-layered cloak in a water-based environment, and for a spherical multi-layered cloak consisting of layers of fluid with an isotropic homogeneous diffusivity, deduced from an effective medium approach [1]. Independent research groups have applied our model to applications implicating the protection of steel by protecting concrete against chloride ions penetration [2] as well as for the design of water-based invisibility cloaks [3]. We now investigate the utility of the biocloak for vectorization of drugs [4].

Topological Acoustics

Zhaoju Yang[1] **and Baile Zhang**[1, 2]

[1]Division of Physics and Applied Physics, School of Physical and Mathematical Sciences
Nanyang Technological University, Singapore 637371, Singapore
[2]Centre for Disruptive Photonic Technologies
Nanyang Technological University, Singapore 637371, Singapore

Abstract— The concept of topologically nontrivial bandstructures, which originally arose in the study of the quantum Hall effect and topological insulator materials, has recently led to the emergence of the field of "topological photonics". Here, we further extend the concept to acoustics by designing a phononic crystal which maps theoretically onto the integer quantum Hall effect. Time-reversal symmetry is broken by a circulating fluid flow in each unit cell, which corresponds to nonzero periodic effective magnetic flux density. We derive the bandstructure, and show the existence of topologically nontrivial bands possessing nonzero Chern numbers. Numerical simulations reveal the existence of unidirectional acoustic modes at the boundaries of the phononic crystal, which are topologically protected against backscattering from disorder. Such topological phononic crystals may have novel applications in acoustics.

Phonon Tunneling Times of Semiconductor Heterostructures with Different Tunneling Channels

Abstract— Theoretical and experimental studies of periodic structures that exhibit the so-called phononic band gaps have received great interest in recent years due to their potential applications. Recently, a long-wavelength continuum phenomenological model [1, 2] has been employed to study the phonon tunneling time at normal incidence in semiconductor heterostructures [3].

In this work, we study the phonon tunneling times at oblique incidence in asemiconductor heterostructure. Using the continuity equation for the vibrational energy density inside the system, we deduce ageneral analytical formula containing the different tunneling times. In particular, we demonstrate that this relation is reduced to the equation for the tunneling time at normal incidence, corresponding to uncoupled modes. We present analytical expressions for the transmission, reflexion, interference, and dwell times, for both, longitudinal and transversal modes. We show that the interference time is a dwell time associated with the interference effect in front or behind the barrier. As an additional complement, analysis for the vibrational energy and for the energy density flux of the system is considered. We carried out numerical calculations based on the transfer-matrix method. This study is easily extrapolated to other systems, and our results could be useful for the design of acoustic devices.

Abstract— We report the development of film type acoustic metamaterials by utilizing micro scale resonators. In detail, we show the establishment of fabrication techniques for micro resonator by using photolithography and replication processes. Throughout the research, we have verified geometrical, material properties of metamaterials and target sound properties for better optimizing acoustic attenuation. We observed micro-structured resonator has acoustic attenuation at specific frequency range and absorbing resonant frequency can be adjust as change the resonator's geometrical values. Also, we developed mass production system by overcoming traditional wafer scale fabrication system by using visually tolerable tiling method and roll to roll imprint system. Ultimately, we hope to apply these acoustic metamaterials to various applications such as national defence area and medical field.

Airborne Acoustic Transmission through Compound Arrays of Subwavelength Slits

G. P. Ward, A. P. Hibbins, and J. R. Sambles
Electromagnetic and Acoustic Materials Group, Department of Physics and Astronomy
University of Exeter, Stocker Road, Devon, EX4 4QL, UK

Abstract— The angular dependence of the transmission of sound in air through four different arrays of 2D slit-cavities formed from aluminium slats is explored, both experimentally and numerically. For a simple array of geometrically identical and equally spaced slits, it is well known that Fabry-Perot-like wave-guide resonances, supported by the slit-cavities, result in 'Enhanced Acoustic Transmission' at frequencies determined by the length, width and separation of each slit-cavity [1, 2]. We demonstrate that altering the spacing or width of some of the slits (i.e., the structure factor) to form a compound array results in sharp dips in the transmission spectra, that may have a strong angular dependence. These features correspond to 'phase resonances', which have been studied extensively in the electromagnetic case [3, 4]. The introduction of structure factor to each array period allows additional near-field configurations, whereby the field in adjacent cavities can be out-of-phase. Useful insight is gained by employing a surface-wave band-folding picture to describe the phenomena as 'Spoof Acoustic-Surface-Waves' (SASWs) propagating along a very deep grating structure, that arise from the strong coupling of Fabry-Perot cavity resonances between adjacent slits. One of the structures investigated is optimised to minimise the effect of boundary-layer loss mechanisms present in each slit cavity, thereby achieving broad and deep transmission minima.

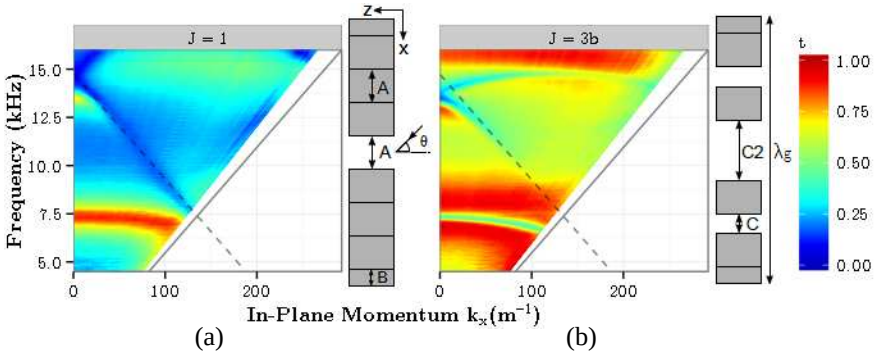

Figure 1: (Schematics) Periodic unit cells for a (a) simple and (b) compound array structure. The grey blocks represent the aluminium slats that form the sample walls. Labelled dimensions are $B = A/2$, $A = 2.9\,\text{mm}$, $L = 19.8\,\text{mm}$, $C2 = 5.9\,\text{mm}$, $C = 1.5\,\text{mm}$ and $\lambda_g = 23.3\,\text{mm}$. (Colour Plots) The corresponding experimentally recorded transmission of sound (colour scale) through each sample, plotted as a function of frequency vs in-plane momentum ($k_x = k_0 \sin(\theta)$). For reference, a solid line representing grazing incidence k_0 is included on each plot. The first order diffracted sound line k_g calculated from the unit cell periodicity is represented by the black dashed line.

SC2&3: Manipulating and Control of Light-matter Interactions with 2D Materials and Meta-Materials

Graphene Plasmonics and Beyond

Tony Low
University of Minnesota, USA

Abstract— I will review our recent work on graphene plasmonics and nanophotonics based on other 2D materials, such as black phosphorus, transition metal dichalcogenides, boron nitrides and their heterostructures.

Strong Absorption in a 2D Materials-based Spiral Nanocavity

Mohammad H. Tahersima and Volker J. Sorger
Department of Electrical and Computer Engineering, The George Washington University
Washington, D.C. 20052, USA

Abstract— Recent investigations of semiconducting two-dimensional (2D) transition metal dichalcogenides have provided evidence for strong light absorption relative to its thickness attributed to high density of states. Stacking a combination of metallic, insulating, and semiconducting 2D materials enables functional devices with atomic thicknesses. While photovoltaic cells based on 2D materials have been demonstrated, the reported absorption is still just a few percent of the incident light due to their sub-wavelength thickness leading to low cell efficiencies. Here we show that taking advantage of the mechanical flexibility of 2D materials by rolling a molybdenum disulfide (MoS_2)/graphene (Gr)/hexagonal Boron Nitride (hBN) stack to a spiral solar cell allows for solar absorption up to 90%. The optical absorption of a 1 m long hetero-material spiral cell consisting of MoS_2, graphene and hBN is about 50% stronger compared to a planar MoS_2 cell of the same thickness; although the ration of the absorbing material, here Gr and MoS_2, relative to the cell volume is only 6%. We anticipate these results to provide guidance for photonic structures that take advantage of the unique properties of 2D materials in solar energy conversion applications.

Hyperbolic Media

Zubin Jacob
Department of Electrical and Computer Engineering
University of Alberta, Edmonton, AB T6G 2V4, Canada

Abstract— We review the recent progress in the field of hyperbolic media and in particular the exciting developments of hyperbolic modes in graphene multilayers and hexagonal boron nitride.

Polaritons, collective excitations of light and matter are uniquely poised to usher a generation of applications beyond the reach of conventional electronics and photonics. From exciton-polaritons combining semiconductor electron-hole pairs with light for low threshold lasing [1] to plasmon-polaritons which mix metallic free electrons and photons for nanoconfinement [2], unique applications exist for each polariton. Recent discovery of strongly confined phonon-polaritonic modes in hexagonal boron nitride (hBN) can usher in new imaging, thermal and quantum applications in the mid-infrared wavelength region [3–5].

Phonon-polaritons are collective oscillations of phonons (lattice vibrations) and light in polar dielectrics such as silicon carbide (SiC), silicon oxide (SiO_2) and strontium titanate ($SrTiO_3$). The characteristic frequencies at which these modes occur are related to the ionic mass ($\omega \propto 1/\sqrt{M_{ion}}$) and fall in the mid-infrared wavelength range for most materials. The dielectric permittivities take on unique forms at phonon-polaritonic resonances either passing through a zero ($\varepsilon \approx 0$) or being enhanced to large values at a pole ($\varepsilon \gg 1$). In between the epsilon-near-zero (ω_{LO}) and epsilon-near-pole (ω_{TO}) frequencies, these naturally occurring media behave like a simple conventional metal and strongly reflect incident radiation. This range of frequencies is called the "Reststrahelen band" which is forbidden for propagating rays of light.

However recent work has shed light on fundamentally interesting phenomena precisely within this forbidden band of a unique phonon-polaritonic medium: hBN. The weak Van der Waals bonded nature makes this medium optically anisotropic due to different effective masses of phonons along the crystal axes. An unusual anisotropy leads to dielectric responses of opposite signs in perpendicular directions ($\varepsilon_{\parallel}\varepsilon_{\perp} < 0$). This gives rise to hyperbolic polaritons within the bulk medium allowing electromagnetic modes to propagate in the forbidden band which is not possible for conventional polar dielectrics. The word hyperbolic derives from the topology of the isofrequency surface which is a hyperboloid in contrast to a closed sphere as in conventional dielectric media [6, 7].

I will discuss many of the above properties and multiple new directions for the field.

Metamaterials for Solar Energy Conversion and Chiral Sensors

Vivian Ferry
Department of Chemical Engineering and Materials Science
University of Minnesota, 421 Washington Ave SE, Minneapolis, MN 55455, USA

Abstract— The combination of plasmonics and metamaterials with tunable materials offers new possibilities to manipulate optical and device properties. This talk will discuss the integration of plasmonics into two application areas: solar energy conversion, and chiral nanoscale structural sensors.

The first part will focus on combining photonic structures with semiconductors to enhance solar energy conversion, and particularly on the design, fabrication, and characterization of luminescent solar concentrators. In a standard LSC, light is absorbed by a dye and re-emitted at a longer wavelength which is guided by total internal reflection to an adjacent solar cell. LSCs offer many benefits compared to traditional concentrator designs, including the ability to operate under both direct and diffuse incident sunlight, but are limited by parasitic losses. I will discuss recent efforts to improve the concentration ratio of LSCs by combining narrow emission band light emitters with wavelength-selective photonic structures.

The second portion of the talk will focus on tunable chiral metamaterials. Using DNA as a scaffold, we self-assemble nanoparticles into chiral geometries where the circular dichroism response arises from the spatial arrangement of nanoparticles rather than the DNA. These structures can be made tunable by targeting interactions to specific DNA sequences, thereby changing the distances between nanoparticles in the chiral assembly. These assemblies can be used as nanoscale distance sensors, as the wavelength, intensity, and sign of the CD spectra all encode information about the nanoscale distances that are present. Through small structural modifications, these assemblies can be made to flip handedness. In this geometry, CD spectra also arise from interactions between nonresonant nanoparticles, and we show how different combinations of materials produce spectroscopic signatures.

Exact Solution for the Reflectivity of Grapheme at Nonzero Temperature over the Wide-band Frequency Range

[3]Central Astronomical Observatory at Pulkovo of the Russian Academy of Sciences, Institute of Physics Nanotechnology and Telecommunications, St.-Petersburg Politechnical University, Russia

Abstract— The quantum field theoretical consideration for the reflectivity of graphene will be presented. This consideration exploits the polarization tensor of graphene at nonzero temperature in (2+1)-dimensional space-time. The obtained form of polarization tensor possesses the required analytic properties over the entire plane of complex frequencies. At zero temperature obtained tensor coincides with that obtained in [1]. At nonzero temperature it takes the same values as the one obtained in [2] at all Matsubara frequencies. This justifies all numerous applications of the polarization tensor [1, 2] used for calculation of the Casimir interaction for graphene and graphene-coated substrates [2–4]. However, as will be shown in our report, the polarization tensor [2] is an oscillating function along the imaginary frequency axis, and this precludes the use of its analytic continuation to real frequency axis for further theoretical description. In our case, the obtained form of the polarization tensor is a monotonously decreasing function of the imaginary frequencies and admits the analytic continuation to real frequency axis satisfying all physical requirements.

The analytic expressions for the reflection coefficients and reflectivities of graphene for two independent polarizations for high and low frequencies were obtained by us using the derived form of the polarization tensor at nonzero temperature. Finally, we have performed numerical computations of the TM and TE reflectivities of graphene over the wide frequency range.

Abstract— The past decades have seen concerted efforts to combine optical and electrical components into optoelectronic integrated circuits for a range of applications, including optical interconnects, sensing, and signal processing. The leading architectures for electro-optic integration today are based on bulk semiconductor materials — for example, for detectors, predominantly bulk Ge, InP, and InGaAs. However, the integration of bulk semiconductor-based detectors has faced important challenges, including for instance the need for frontend changes in complementary metal-oxide-semiconductor (CMOS) processing, fixed spectral response due to material's bandgap, and an intrinsic speed limited by material's carrier mobility. In addition, optical nonlinearities are typically low in bulk semiconductor materials. Recently, the family of twodimensional (2D) materials has been shown to offer new functionalities for optoelectronic applications, including onchip electro-optic modulation, ultrafast broadband photodetection, light emission, and non-parametric and parametric nonlinearities. Moreover, it has been shown that different types of 2D materials can be assembled nearly defect-free into entirely new types of 2D heterostructures, producing optoelectronic properties and device concepts that were not feasible or very difficult using bulk semiconductors.

Here, we describe recent work on 2D materials and 2D heterostructures for on-chip photodetectors, modulators, and light emitters in photonic integrated circuits, see Figure 1. First, we discuss a new type of waveguide-integrated photodetector consisting of a single-layer graphene (SLG) encapsulated by hexagonal boron nitride (hBN) that enables both high-responsivity photodetection and ultrafast pulse measurements in a compact and efficient waveguide-integrated design [1, 2]. Second, we discuss a high-speed graphene electro-optic modulator design based on a SLG-hBN heterostructure integrated with a silicon photonic crystal nanocavity. Strongly enhanced light-matter interaction of graphene in this sub-wavelength cavity enables efficient electrical tuning of the cavity reflection with a modulation depth of 3.2 dB and a cut-off frequency in excess of 1 GHz [3]. Finally, we describe how nanophotonic device concepts for slow-light and modification of radiative rates via the nanocavity Purcell effect can be used to enhance light emission from 2D materials [4].

Abstract— Nowadays, there is an increase in the interest of the metamaterials (MTMs) and their applications and this development has already altered the direction of the electromagnetic wave scattering including cylindrical media. This is an important development in the field since these types of structures can open a new way to design and characterize novel devices based on MTMs. In this manner, a frequency dispersive MTM scatterer [1], the case of a metallic cylinder coated by MTM [2], the fields in a multilayered cylinder containing MTMs, multiple scattering by MTM cylinders, and scattering by two MTM cylinders have been already investigated by different researchers. In [3] it is shown that the proper posing of the scattering problem necessitates originating the standing and travelling wave Rayleigh modes in the circular cylindrical regions from the Green's integral formulae. The truncation of the obtained linear algebraic equations via such approach requires physical check of the boundary conditions to obtain a reasonable solution. But via regularization, this requirement is alleviated and the solution becomes immune to the round-off errors [4, 5]. In this study, this new numerically stable version of modal scattering formulation of circularly cylindrical boundaries is applied to the problem of scattering by an eccentrically metamaterial coated wire antenna where wire is assumed perfectly conducting. Here, all formulations will be for the TM mode since the main focus does not differ from the corresponding TE mode formulations. The stability of the algorithm which is free from checking of the boundary conditions [1] and special considerations on geometry to ensure convergence [2], under various metamaterial parameters and different geometries and a wide frequency range will be demonstrated.

Probing Graphene-nanoparticle Interactions via Hot Carrier Dynamics

Adam Gilbertson, Yan Francescato, Viktoryia Shautsova, Vincenzo Giannini, Stefan A. Maier, Lesley F. Cohen, and Rupert F. Oulton
Blackett Laboratory, Imperial College London, Prince Consort Rd, SW7 2BZ, UK

Abstract— Hybrid graphene-metal plasmonic systems exploit the near-field coupling between graphene carriers and surface plasmon (SP) excitations supported in the metal, and are emerging as a class of optical metamaterials that facilitate strong light-matter interactions and are of potential importance for hot carrier graphene-based light harvesting [1] and active plasmonic applications [2, 3]. Central to the physics of such systems are plasmon-induced hot carriers, generated directly in the graphene via the intense near-fields and in the metal nanoparticle (NP) via absorption (plasmon decay). However, a complete understanding of the near-field interaction between graphene and nearby plasmonic nanoparticles is lacking.

In this talk, we report the plasmon-induced hot carrier dynamics of a hybrid metal-graphene system consisting of a gold plasmonic nanodisk resonators coupled to a graphene overlayer. Nanodiscs are an ideal test structure due to their ease of fabrication that allows close packing and readily tunable dipole resonance that couples strongly to the far-field. By selectively probing the photocarrier dynamics in the graphene layer, following excitation at the SP band of the NP array, we gain direct access to the influence of graphene-NP interactions on the transient hot carrier population in the graphene. In order to distinguish between plasmon-induced hot carrier generation processes we compare samples where graphene is in direct contact with the metal NP (sample A) to those in which a hexagonal boron nitride (BN) monolayer has been introduced at the graphene-metal interface (sample B), shown schematically in Fig. 1a. The BN spacer layer serves as an effective barrier to charge transfer, while being just angstroms thick it has little effect on the plasmon-mediated electromagnetic field intensity at the graphene (verified by numerical simulations). We demonstrate that direct near-field photo-excitation is the dominant process for plasmon-induced hot carrier generation in the graphene and gives rise to a strong optical anisotropy in the hybrid samples, absent in bare graphene and NP control samples, as revealed by polarisation-resolved measurements. Intrinsic optical anisotropy, driven by the preferential occupation of specific states in k-space through to the carrier-field interaction, is known to occur in various semiconductors including graphene, but is generally short lived due to fast carrier-phonon scattering (~ 100 fs) that redistributes the photo-carrier momentum. Here we show that the strong optical near-field coupling of graphene to plasmonic NPs underpins a long lived extrinsic optical anisotropy. The effect arises from the action of highly localised hot carriers in the graphene on the sub-resonant NP polarisability, and persists for several 100 fs, determined by the diffusion of hot carriers away from hot-spots. Our observations highlight the rich physics associated with the graphene-NP interaction, and the potential to exploit plasmonic metal-graphene nanostructures in photo-thermoelectric applications.

Faraday Rotation in Periodic Graphene Structures

L. Martin-Moreno[1], **T. M. Slipchenko**[1], **and A. Yu. Nikitin**[2]

[1]Instituto de Ciencia de Materiales de Aragon, Zaragoza, Spain
[2]CIC nanoGUNE Consolider, Donostia, San Sebastian, Spain

Abstract— It is known that a graphene sheet, under the action of a perpendicular static magnetic field, provides a Faraday rotation that, per atomic layer, is much larger than that of any other known material [1]. The Faraday rotation in continuous graphene originates from the cyclotron resonance of massless carriers, which in turn depends on the carrier concentration. This property allows for dynamical tuning of the Faraday angle through either external electrostatic or magneto-static setting. Furthermore, the rotation direction can be controlled by changing the sign of the carriers in graphene, which can be done by means of an external electric field.

However, large Faraday rotation in the THz regime still requires large magnetic fields. In a previous work [2], we demonstrated that the needed magnetic field can be reduced in arrays of graphene microribbons (alternatively the working frequency can be larger for a given applied magnetic field) through the excitation of the magnetoplasmons of individual ribbons. This 1D geometry is just one of the many possibilities which can lead to useful Graphene-based non-reciprocal devices, for which the fundamental limits set by physical constrains [3] do not severely limit useful applications. For instance, recently, it has been shown that strong Faraday rotation can be achieved in lattices of graphene meta-atoms [4].

In this talk we consider the general situation of a 2D periodic metamaterial, and relate the Faraday rotation resonances to the excitation of the different magnetoplasmon modes that can be excited in the system.

Abstract— Two-dimensional (2D) materials such as graphene possess unique electrical and optical properties that are not present in bulk materials. Due to their atomic-scale thickness, however, 2D materials usually interact only weakly with electromagnetic waves, presenting challenges for realizing high-performance optoelectronic devices. This work demonstrates that by confining light into ultra-small metallic gaps, it is possible to dramatically boost this interaction with graphene. As an extreme case, terahertz (THz) waves are squeezed into gaps about 10^5 times smaller, allowing them to interact with 99% efficiency with a 0.3 nm-thick graphene layer.

To realize this experiment, we used atomic layer lithography to define 2-nm-wide gaps in a thin gold film. While the resulting gaps cover only 0.002% of the sufrace, 25% of incident THz energy passes through the metal film. Surprisingly, placing a monolayer graphene at the exit side of these gaps without an Al_2O_3 spacer allows 99% THz extinction leading to a reduction by another 2 orders of magnitude at the resonance, while the graphene on the bare substrate shows a typical extinction of $\sim$ 20% over a broad THz frequency range. This huge extinciton is mostly caused by strong absorption near the nanogaps.

As an application of this strong absorption, we also demonstrate high-contrast modulation of THz transmission using monolayer graphene. We constructed an electrically controllable hybrid material platform, consisting of the 2-nm-wide annular gaps, monolayer graphene, and an ionic gel layer. The enhanced intraband absorption in the graphene leads to a very large modulation depth of 80% with an operational voltage as low as 1.5 V. In addition to graphene, such ultra-strong light-matter interactions mediated by nanogap structures could benefit a wide range of applications involving 2D materials.

Abstract— Optofluidics, the science and technology of integrating optical systems with fluids, have been demonstrated a wide range of applications in areas including analytical chemistry, biotechnology sensing, nanofluidic concentration, DNA manipulation, and virus detection. Optofluidic systems can synthesize the advantages of hydrodynamics and optics such as reduced sample consumption, improved sensitivity and detection time, representing a new evolution of microfabrication techniques. Over the past decade, optofluidic systems can be categorized into three major groups: (1) A fluids-in-solids system by introducing fluids with specific optical properties into the porous solid to elicit changeable optical effects. (2) A fluids-in-fluids system by mixing fluids in other fluids with relevant optical properties to enhance the controllability and flexibility of the resulting system. (3) A solids-in-fluids system by manipulating solid particles in a fluid to enable large changes in the optical properties of the resulting system. And its development requires more novel devices to outreach the other application fields and deepen the fundamental research. This we present and demonstrate a simple optofluidic device served by assembling graphene oxide (GO) into micro/nanofibers (MNFs). By integrating the excellent absorption and scattering properties of GO with attractive waveguide dispersions of MNFs, it is possible to elicit the extraordinary photothermal effect from GO under light illumination. The controllable vapor microbubbles can be generated from the excited GO. Theoretical and experimental studies show that thermocapillary convection can be initiated by the microbubbles to manipulate particles.

Modified Periodic Method of Moments for the Analysis and Design of Metasurfaces Consisting of 2D Materials

Arya Fallahi
DESY-Center for Free-Electron Laser Science, Notkestrasse 85, Hamburg D-22607, Germany

Abstract— A full-vector semi-analytical numerical technique for the analysis of metasurfaces made out of 2D materials is presented. The method is based on the periodic method of moment for the analysis of general frequency selective surfaces. The required modifications to consider the anisotropic conductivity model as well as the spatial dispersion are described. The paper is intended to serve as a general and complete reference for modeling planar metamaterials containing 2D materials. Therefore, the various computational aspects of the method, such as effect of basis functions type and combination with transmission line model for studying periodically inhomogeneous substrates, are also investigated. As the choice for the 2D materials, we mainly focus on graphene and black phosphorous. Through the analysis of some examples, the properties of a periodic structure containing the aforementioned 2D materials are investigated.

Nano-resolving the Optical and Electronic Properties of Graphene Encapsulated in Boron Nitride

M. B. Lundeberg
The Institute of Photonic Sciences (ICFO), Spain

Abstract— Since a couple of years, a new dry transfer method has been producing clean heterostructures of graphene encapsulated in hexagonal boron nitride (BN). The graphene in these devices shows exceptional electronic quality, with carrier mobilities no longer limited by disorder.

Besides the improvement in DC electrical properties seen in these heterostructures, improvement is likewise expected for the optical, or AC, response. In particular, graphene's propagating plasmons were observed to damp out quickly in traditional graphene devices, a consequence of the high electronic resistance. We show with scanning near field optical microscopy (SNOM) that the plasmons in BN-graphene heterostructures show a dramatic improvement in propagation time, approaching the intrinsic limits at room temperature [1, 2]. The measurements also demonstrate the extreme size confinement for plasmons, enhanced by the high permittivity environment offered by BN.

Time permitting, other practical aspects of encapsulated graphene devices will be discussed: conductivity inhomogoneities, and induced photocurrents.

Abstract— The main drawback of silicon for nonlinear application is its absence of second order nonlinear effects ($\chi^{(2)}$) and the strong free-carrier phenomena (Free Carrier Dispersion: FCR, Free Carrier Absorption: FCA) accompanying the Kerr effect when using $\chi^{(3)}$-processes.To overcome this problem, the design and fabrication of Silicon guiding structures under different geometries is reported with particular emphasis in Slot Photonic Crystal Waveguides [1, 2]. The latest offers a natural potential for nonlinear $\chi^{(3)}$ optical applications, due to the strong enhancement of the electric field in the slot region and further more in the slow light regime.Chosen according to its second and third order non-linear susceptibilities $\chi^{(2)}$ and $\chi^{(3)}$, the low index material that fills the slot and the holes can dramatically enhance the non-linear effects in the photonic crystal waveguides. $\chi^{(2)}$ electro-optic modulation in slotted photonic crystals and $\chi^{(3)}$ Four-Wave Mixing in slot waveguides have been for instance, successfully demonstrated [2, 3].

The samples under analysis consist of SOI wafers (Soitec) with a 260 nm-thick silicon film over 2 µm of buried oxide. Patternsare defined in ZEP-520A resist (Zeon Chemical Co.) by 80 kV electron beam lithography (Nanobeam nb4 system) and then etched by Inductive Coupling Plasma Reactive Ion Etching process using SF6 gas. The facets of the sample were finally cleaved after removal of the resist.The surface of the samples is covered by a refractive liquid (Cargille) with an index of 1.46 infiltrating both the holes and the slot. The total length of the sample is 4.5 mm, which includes 3 µm-wide access waveguides intended for end-fire coupling. These waveguides are tapered down along 300 µm to match the 400 nm-wide wire waveguides, which are then connected to the SPCW through a three-stage converter [4]. A SEM image of the structure is shown with a respective zoom in Fig. 1(a), the optical linear transmission for different length SPCW in a wavelength range of 100 nm, starting from 1510 nm until 1610 nm is shown in Fig. 1(b), the transmission of a strip waveguide is added as a reference, allowing to distinguish clearly the light cone effect, the fast and slow light regimes and the bandgap, higher than 20 dB in less than 5 nm.

The nonlinear response of SPCW has been measured under a pulsed excitation of 7 nm bandwidth and duration time of 2 ps varying the input average powers until 15 mW as shown in Fig. 1(c), which given the duty-cycle of the laser correspond to maximum peak powers of around 5 W coupled into the waveguide. Emphasis is put on the slow light properties and the bandgap effect of the investigated waveguide. For instance the asymmetric output spectra, unexpected due to the normally symmetric broadening given by the Kerr effect could be explained by the inhibition due to the forbidden band of the photonic crystal From this analysis the TPA saturation curve could be extracted and compared with the reference strip. These experimental measurements

Nonlinear Optimization of Slot Si Waveguides: Effective Mode Area vs FOM_{TPA}

Weiwei Zhang[1], **Samuel Serna**[1,2], **Nicolas Dubreuil**[2], **and Eric Cassan**[1]

Abstract— In the context of the planar silicon photonics technology, optical nonlinear ($\chi^{(3)}$) Kerr effects are every easily obtained by using submicron silicon wires in the telecommunication wavelength window due to a dramatic reduction of the needed power compared with fibres Unfortunately, the third order effects ($\chi^{(3)}$) are partially spoiled due to the strong strength of the two-photon absorption (TPA) effect, which in turn generates free-carriers and induces additional absorption and refractive index changes. The relative competition between the optical Kerr and TPA effects is usually quantified by the use of the figure of merit $FOM_{TPA} = n_2/\alpha_2\lambda$, with n_2 the nonlinear refractive index and α_2 the TPA coefficient.

One of the key solutions to minimize the detrimental effects of free carriers in silicon while still benefiting from the high index core/cladding contrast of silicon on insulator (SOI) waveguides relies on the use of hollow core silicon guiding structures, the so-called slot waveguides [1], filled by highly nonlinear materials, for instance polymers. Under such a guiding geometry, the light power confinement in the silicon rails can be reduced, leading to the reduction of the TPA effect. This approach has received a considerable interest in the last years, showing demultiplexing capabilities of 170 Gbits $\cdot$ s^{-1} data, 100 Gbits $\cdot$ s^{-1}/1 V electro-optical modulation and the demonstration of slot waveguides with FOM_{TPA} up to the record value of 2.19 [2], i.e., far above the intrinsic silicon FOM_{TPA} material value, which is around 0.38 [3].

In this context, we will firstly present results obtained by the conventional optimization method based on minimizing the waveguide mode effective areas A_{eff} (Fig. 1(b)) in order to maximize the nonlinear Kerr coefficient $\gamma = n_2\omega/cA_{eff}$ in the assumption that the introduced nonlinear material dominates the nonlinear behavior of the slotted waveguide and that strong light confinement in the slot allows neglecting TPA process in the silicon rails [4, 5]. On contrary, we will come up in a second step with a semi-analytical approach fully accounted all nonlinear contributions from the different materials on the whole mode profile area in order to investigate the FOM_{TPA} evolution. We will show that FOM_{TPA} can vary from 1.8 to 4.25 in the case that nonlinear cladding material has a bulk FOM_{TPA} of 5. This strategy of nonlinear slot waveguide's design for on-chip all-optical signal processing will be thoroughly discussed at the conference.

Abstract— Silicon-based integrated photonics nowadays generates a huge interest mainly for optical data transmission and increasingly also for sensing. The developments of elementary passive and active components have to reach high performance level in terms of sensitivity; modulation efficiency and power consumption to be commercialized. To get such performances, active silicon photonics modules need to be carefully studied, designed and optimized, from the electro-optical integration into the chip up to the packaging. This is especially the case for the modulator used in transmitter modules.

From the Si Electro-optical Modulator . . .: In this paper, we will first focus on RF design challenges for electro-optical Mach-Zehnder modulator (MZM) using the PN junction carrier depletion, to achieve high data rate transmission over 40 Gb/s. We will for example show how the shield coplanar waveguide can increase the RF bandwidth and also the electro-optical performances compared to the conventional coplanar one [1]. We will discuss new RF electrode architectures [2]. Parasitic effects to be minimized to design MZM in travelling wave configuration or by distributed electrodes will be pointed out.

. . . **towards the hybrid silicon photonics module:** In a second part, we will talk about integration of transmitter photonic chips in modules, with several different architectures. Each one has its figures of merits and can fulfill a specific application (e.g., rack to rack, board to board or intra-board link). Depending on the targeted application, the packaging strategy will differ, and various interconnection methods can be used, from legacy wire-bonding technology to advanced micro-bump interconnections and Through Silicon Vias (TSV) technologies, or direct Cu bonding technologies [3]. These interconnection technologies are used to connect the Photonic Integrated Circuit (PIC) to the related control electronics (EIC), and also in some advanced architecture to the host chip (switch, microprocessor, FPGA). In some cases the host chip can be co-packaged with the Photonic transceiver in the same package. Each interconnection technology has its own figure of merit in term of density, parasitic effects, data rate and manufacturing throughput. We will consider it in three particular cases:

- Standalone module: the photonic transmitter in apart from the host chip module, on the same motherboard.
- System In Package approach, the photonic transmitter and the host chip share the same BGA package.
- Photonics Interposer: the Photonic chips acts as a 2.5D interposer, the host chip and EIC are flip-chipped on the top of the PIC.

Abstract— Stimulated Brillouin Scattering (SBS) is a highly resonant acousto-optic interaction that leads to the formation of a hypersonic wave, which in turn acts as a traveling grating that converts the incident pump wave into a red-shifted Stokes wave. This can be effectively described as a third order optical nonlinearity. In this work, we investigate the impact of two-photon absorption (TPA) and the resulting free carrier absorption (FCA) on the SBS gain especially of silicon waveguides, which are one of the best candidates for the on-chip integration of SBS-based functional devices such as amplifiers and oscillators.

To this end, we formulate a set of nonlinear steady state coupled mode equations that involve effective TPA- and FCA-coefficients, which we derive as overlap integrals of the nonlinear material parameters and higher order powers of the eigenmodes' electric field distributions. As a further approximation, we assume that the Stokes wave is weak. The resulting equations are solved analytically. We find that two-photon absorption — being a third order process like SBS itself — leads to a algebraic yet monotonic evolution of the Stokes signal as a function of both the waveguide length and the pump power. The exponent is determined by the ratio of the SBS gain and the effective TPA-coefficient. In contrast, free carrier absorption results in a Stokes profile with an extremum as the pump power is varied; excessive pump powers in fact lead to net loss in the Stokes wave. From this we obtain an expression for the optimal pump power as a function of the material parameters and the waveguide length. Finally, we find that nonlinear loss has exactly the same impact on forward SBS as on backward SBS within the weak Stokes approximation.

Silicon Photonics Integrated Devices for Low Cost End-user Bidirectional Transmission in Passive Optical Networks: The FABULOUS European Project

Guido Giuliani
University of Pavia, Pavia, Italy

Abstract— We present the Silicon Photonics technologies developed within the European project "FABULOUS" aimed at the demonstration of a low cost integrated end-user device (Optical Network Unit, ONU) to be deployed in Passive Optical Networks (PON) for bidirectional downstream and upstream optical communication.

The Si-Photonics chip integrates several sub-components, namely: i) fiber-to-device polarization-splitting coupler with record coupling efficiency based on 2D-grating photonic crystal technology; ii) ring-shaped waveguide pass-band filters; iii) Semiconductor Optical Amplifier (SOA) realized by hybrid integration of III-V gain material on Si; iv) bidirectional Mach-Zehnder Modulator (MZM) to be driven by different electrical signals travelling in the two opposite directions; v) photodetectors; vi) electronic driver for the MZM integrated on the Si chip.

The combination of the above sub-components allows the ONU to communicate bidirectionally with a central node (Optical Line Terminal, OLT). The ONU is capable to receive a downstream optical signal and, simultaneously, to impress an upstream modulation to a selected un-modulated blank wavelength generated by the OLT. This scheme is compatible with the PON philosophy, where the optical fiber connecting the OLT and the ONU is passive, and with the Wavelength Division Multiplexing (WDM) configuration, where multiple wavelengths are used to enhance the transmission capacity. The filter selects a specific blank wavelength, onto which the bidirectional MZM impresses a signal modulation using the so-called Frequency Division Multiplexed Access (FDMA) format, that has a high spectral efficiency thanks to the 16-QAM code used. The bidirectional MZM, in conjunction with the polarization-splitting coupler, realizes a sort of Faraday mirror, thus making the coherent detection of the upstream signal easier. The integrated SOAs provide an optical gain that compensates for optical fiber propagation losses and instrinsic device losses.

Predictions, based on experimental results obtained from the integrated device and its hybrid version, show that a total upstream transmission capacity of 32 Gb/s per single wavelength is feasible over fiber networks with 31 dB optical loss.

Abstract— In this paper we present the design, fabrication and experimental demonstration of advanced building blocks in a thick Silicon generic photonic integration platform. The platform provides a fabrication process with waveguides of different contrast ratio, through different etch levels, and the possibility of metalization in selected areas. Combining waveguiding and metals we report on Echelle Gratings (EG) multiplexers and re ective Multimode Interference (R-MMI) couplers. Several devices were designed in the same reticle and several dies were supplied by the fabrication platform. The experimental results for the individual devices are reported, as well as a die to die comparison and statistical analysis.

Silicon Optical Routers for Photonic Networks-on-Chip

Lin Yang, Yuhao Xia, Hao Jia, Qiaoshan Chen, and Fanfan Zhang
State Key Laboratory on Integrated Optoelectronics
Institute of Semiconductors, Chinese Academy of Sciences, Beijing 100083, China

Abstract— The performance of chip multiprocessor (CMP) is determined not only by the number of the processor cores integrated on a chip, but also by the communication efficiency among them. With CMP continuously requiring more communication bandwidths, metallic-based electrical networks-on-chip (NoC) gradually becomes the bottleneck for improving the performance of CMP due to its high power consumption, limited bandwidth and long latency. Photonic NoC is considered as a potential solution to overcome the limitations of its electrical counterpart. Optical router is an essential component for photonic NoC, which is responsible for switching data from one optical link to another one.

In this paper, we will review the status of the optical routers for photonic NoC and introduce our efforts on this topic. Firstly, we will introduce several demonstrated optical routers based on microring or Mach-Zehnder optical switches. Then, we will introduce a universal method for constructing an N-port non-blocking optical router for photonic NoC. The optical router constructed by this method has minimum optical switches, in which the number of the optical switches is reduced about 50% compared to the reported optical routers based on microring optical switches and about 30% compared to the reported optical routers based on Mach-Zehnder optical switches, and therefore is more compact in footprint and more power-efficient. Finally, we will introduce the fabricated 4- and 5-port optical routers constructed by this method.

Optical Properties of 2D Materials on Silicon and Silicon Nitride Waveguides

H. K. Tsang, Z. Cheng, L. H. Liu, J. Wang, K. Xu, X. Wan, B. Q. Zhu, C. Shu, and J. B. Xu
Department of Electronic Engineering, The Chinese University of Hong Kong, Hong Kong, China

Abstract— The unique optical and electronic properties of two-dimensional (2D) materials (such as graphene, MoS_2) have attracted much research interest. The integration of 2D materials on photonic integrated circuits (PICs) can offer dramatically increased interaction length with light propagating along the plane of the 2D sheet, and can offer potential applications in nonlinear devices and photodetectors [1]. In this talk, we will review our recent study of the optical properties of 2D materials integrated silicon/silicon nitride (Si_3N_4) PICs.

Monolayer chemical vapor deposition (CVD) grown graphene can be placed on top of silicon or Si_3N_4 waveguides by wet transfer and give rise to enhanced optical absorption. The absorption is strongly polarization dependent. In a waveguide formed by 340 nm thick silicon-on-insulator (SOI), graphene introduced 7.7 dB higher losses for transverse-magnetic mode in a 150 μm long waveguide [2]. The graphene also improved the 1 dB grating bandwidth which was increased from $\sim$ 60 nm to $\sim$ 72 nm because of the reduction of grating dispersion [3]. The free carrier absorption and spectral hole burning of graphene-on-silicon waveguide were observed by using a pump-probe measurement over microsecond timescales [4]. The graphene-on-Si_3N_4 microring structure was optimized to enhance its effective absorption from 25 dB/mm to 174 dB/mm. Q factors of graphene-on-Si_3N_4 microring resonator, was measured between $\sim$ 28200 to $\sim$ 3800 depending on the graphene length, in agreement with theoretical calculations [5].

Another interesting 2D material is MoS_2. We transferred a flake of MoS_2 onto silicon waveguide. The high refractive index (RI) of MoS_2 [6] induced a significant red shift in the grating's coupling center wavelength, with which the effective RI of the material was extract to be $\sim$ 4.5. Self-phase modulation of chirped picosecond pulses were observed. The MoS_2-on-silicon (MOS) structure exhibited larger spectral broadening of the $\sim$ 60 ps gain switched pulses than the silicon waveguides. This magnitude of the Kerr coefficient of MoS_2 was estimated to about two orders of larger than that of silicon in order to account for the enhanced spectral broadening.

Femtosecond Modulations Based on Periodic Patterns of Excited Free-carriers in Semiconductors

Y. Sivan[1], **G. Ctistis**[2], **and A. P. Mosk**[2]

[1]Unit of Electro-optics Engineering, Ben-Gurion University, Israel

Abstract— We demonstrate femtosecond-scale switching and modulations of ultrashort optical pulses using transient Bragg gratings of free-carriers in a semiconductor waveguide. This is enabled by employing the fast carrier diffusion or a double (non-uniform) pump schemes. The demonstrated efficiencies are unusually high for the interaction durations employed.

Ultrafast switching is considered as one of the oldest and most important applications of nonlinear optics. Traditionally, ultrafast switching is based either on Kerr nonlinearity, which is instantaneous, but weak, or on free carrier nonlinearity, which could be much stronger, but comes at the cost of a substantially slower turn-off time [1].

Here, we demonstrate a simple scheme that enables to enjoy the best of the two worlds — to have an utrafast and strong switching, based on free-carrier generation in a semiconductor. Specifically, we describe a novel switching scheme operating on femtosecond time scales, which is based on the generation of a periodic pattern of free-carriers (FCs) which serves as a transient Bragg grating. In the first realization, we rely on diffusion to erase the initial FC pattern, hence, to remove the reflectivity of the system. In the second realization, we erase the FC pattern by launching a second pump pulse at a controlled delay. We discuss the advantages and limitations of the proposed approach and demonstrate it for modulating and switching ultrashort pulses propagating in silicon waveguides. We show reflection efficiencies of up to 50% for 100 fs pump pulses (see Fig. 1), which is an unusually high level of efficiency for such a short interaction time, a result of the use of the strong FC nonlinearity. Due to limitations of saturation and pattern effects, the scheme can be employed for switching applications requiring femtosecond features but standard repetition rates. Such applications include switching and modulations of ultrashort pulses, femtosecond spectroscopy (gating) and time-reversal of short pulses for abberation compensation [2].

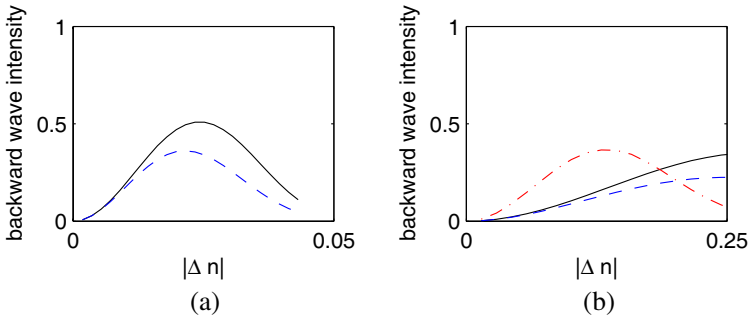

Figure 1: (a) Intensity of the backward wave for the diffusive switching scheme for $T_{rise} = 50$ fs, $T_f = 1000$ fs, $T_{mod} = 600$ fs for various lengths of switching regions. (b) The same for the write-erase technique with $T_{mod} = 50$ fs and $T_{mod} = 150$ fs.

Laser-induced Thermomechanical Processes around Metal Nanoparticles in a Transparent Medium

Alexey N. Volkov
Department of Mechanical Engineering, University of Alabama
7th Avenue, Tuscaloosa, AL 35487, USA

Abstract— Utilization of metal nanoparticles (NPs) for selective laser treatment of biological tissues is a promising approach in medicine and, in particular, in cancer treatment. The therapeutic effect is achieved by delivering NPs to cancer cells and irradiating the tissue by a laser at a wavelength which can be efficiently absorbed by NPs only. Laser heating of NPs results in the formation of thermal and pressure waves that propagate through the surrounding medium and kill cancer cells. The practical use of this methodology, however, requires a detailed understanding of thermomechanical processes induced in the surrounding medium by laser heating of NPs.

In the present work, the thermal and mechanical processes around gold NPs in water are studied numerically in the broad range of laser fluences and pulse durations. Water is assumed to be transparent to the laser radiation, so that all processes in the medium surrounding a NP are induced by the heat transfer at metal-liquid interface and thermal expansion of metal nanoparticles. Heating and thermal expansion of NPs are described by the balance equations based on the one-temperature or two-temperature thermo-elastic models. The two-temperature thermal model takes into account non-equilibrium energy exchange between the electrons and phonons in metals irradiated by ultrashort, pico- and femtosecond, laser pulses. Heat conduction as well as propagation and attenuation of the pressure waves in water are described by onedimensional Navier-Stokes equations. Compressibility of water and water vapor is taken into account, and the pressure and internal energy of water are calculated based on the semi-empirical multiphase equation of state. Thermal boundary resistance and surface tension at metal-water interface are taken into account, and the model of thermal boundary conductance is parameterized based on results of molecular dynamics simulations. Both volume and surface mechanisms of vaporization of overheated water are taken into account.

The calculations performed for the pulse duration varied from tens of femtosecond to microseconds. The limiting case of continuous wave laser heating is also considered. Transient distributions of temperature and pressure in the surrounding liquid are obtained and analyzed. Threshold values of the laser fluence which correspond to the onsets of boiling and spinodal decomposition in the liquid adjacent to the gold particle are determined as a function of particle radius and pulse duration. The effects of the finite thermal boundary resistance and surface tension at metal-liquid interface are shown to be significant in the broad range of irradiation conditions. The size of region around the absorbing particle, where the biological cells can be killed due to high pressure or high temperature, is estimated for various irradiation conditions. Selected simulation results are compared with experimental data.

Effect of Laser Field Enhancement on Collision Frequencies and Absorption during Ultra-short Laser Interactions with Dielectric Materials

T. E. Itina, **A. Rudenko**, **J.-Ph. Colombier**, **and N. S. Shcheblanov**
Laboratoire Hubert Curien, UMR CNRS 5516, Lyon University
18 rue de Prof. Benoit Lauras, Bat. F, Saint-Etienne 42000, France

Abstract— Laser-induced electronic excitation, absorption and relaxation are the key issues in ultra-short laser interactions with dielectric materials. To numerically analyze these processes, a detailed non-equilibrium model is developed [1] based on the kinetic Boltzmann equations without any appeal to the classical Drude model. The calculations are performed including all possible collisional processes. As a result, electron energy distributions are obtained allowing a better analysis of ultra-short laser interactions. The results reveal a remarkable effect of the laser-field on collision frequencies resulting in smaller free-carriers absorption than the one predicted by commonly used rate-equation models. In addition, our calculations clearly demonstrate laser intensity limits for the applicability of Keldysh's equation for the photoionization process [2]. Both electron-electron and electron-phonon relaxation are then examined, and the mean energy density of the electron sub-system is investigated as a function of laser fluence and pulse duration. Because efficient bond breaking requires energy, these calculations provide the required thresholds.

The dependency of the calculated fluence threshold on laser pulse duration is compared with the available experimental data. The obtained results also explain several recent pump-probe experiments. The developed model is useful for many laser applications including high precision in laser treatment, laser-assisted atomic probe analysis, and for the development of new powerful laser systems.

Furthermore, a finite-difference time-domain (FDTD) solution of Maxwell's equations is numerically coupled with time-dependent electron carrier density equation for dielectric material (fused silica) with a small inclusion. The process of plasma generation near the inclusion is studied and local field distribution is obtained. The generated plasma is studied and the roles of the electron collisional frequency and the irradiated wavelength are demonstrated.

Abstract— Small nanometric defects, such as color centers or impurity sites, located in dielectrics, irradiated by focused ultrashort laser pulses, can reinforce field localization and lead to inhomogeneous distribution of multiphoton nonlinear ionization and formation of nanoplasmas.

A finite-difference time-domain (FDTD) method based on Maxwell's equations coupled with time-dependent electron carrier density's equation is proposed to investigate numerically femtosecond laser irradiation of dielectrics with a small inhomogeneity. The process of plasma generation due to multiphoton absorption near small defect in fused silica is studied in details and local field distribution around the void inhomogeneity is first explained by using the Rayleigh scattering theory. Further investigation of the laser-matter interaction has shown that the generated plasma properties do not significantly depend on the size of the inhomogeneity as long as it remains considerably smaller than the irradiation wavelength. The calculation results show, however, that there are several parameters, which are crucial. Among such parameters, for instance, is collision frequency,which affects strongly both the created electron density and laser propagation. In addition, the characteristics of the generated plasma are studied as a function of the irradiated wavelength and the changes in the refractive index are explained by the Lorentz-Drudemodel with time-dependent carrier density. The differences between the results obtained by considering Keldysh theory for multiphoton ionization and by taking into account only six-photon ionization are discussed. Finally, temporal changes in behavior of scattering due to generated nanoplasma are observed and analyzed by using Mie scattering theory, which is more complete than Rayleigh one.

Femtosecond Laser Material Alteration by Means of Micro- and Nano-particles

N. Bityurin, A. Pikulin, and A. A. Smirnov
Institute of Applied Physics RAS, Nizhniy Novgorod, Russia

Abstract— We consider laser nanostructuring of a material surface by means of a colloidal particle lens array deposited on the surface. Here, the monolayer of dielectric micro- or nanospheres placed right on the surface acts as an array of near-field lenses that focus the laser radiation into the multitude of distinct spots, allowing the formation of many structures in a single stage. We consider optical properties of such layer taking into account that within this layer spherical particles do not act as independent microlenses. Due to the coupling of the spherical modes, the field near the clusters of spherical microparticles cannot be calculated by means of the superposition of Mie solutions for individual spheres. We consider opportunities offering by combing femtosecond pulses of the fundamental frequency and of the second harmonic.

We analyze the opportunities provided by the plasmonic nanoparticles inserted into the bulk of a transparent medium to modify the material by laser light irradiation. This study is provoked by the advent of photo-induced nano-composites consisting of a typical polymer matrix and metal nanoparticles located in the light-irradiated domains of the initially homogeneous material. The subsequent irradiation of these domains by femtosecond laser pulses promotes a further alteration of the material properties. We separately consider two different mechanisms of material alteration. First, we analyze a photochemical reaction initiated by the two-photon absorption of light near the plasmonic nanoparticle within the matrix. We show that the spatial distribution of the products of such a reaction changes the symmetry of the material, resulting in the appearance of anisotropy in the initially isotropic material or even in the loss of the center of symmetry. Second, we analyze the efficiency of a thermally-activated chemical reaction at the surface of a plasmonic particle and the distribution of the product of such a reaction just near the metal nanoparticle irradiated by an ultrashort laser pulse.

Advantages of Contact Arrays of Spheroidal Particles for Femtosecond-laser Micro- and Nanoprocessing of Materials

A. Pikulin, **N. Mitin**, **and N. Bityurin**
Institute of Applied Physics RAS, Nizhniy Novgorod, Russia

Abstract— Monolayers of dielectric spherical microparticles have become a convenient tool for laser alteration of material surface [1–3]. Under the irradiation by a wide laser beam, such particles act as focusing microlenses. When placed right on the surface, the arrays of microparticles provide the multitude of distinct field enhancement spots within the material, allowing for the large-area single-step material nanomodification. The ultra-short laser pulse also provides simultaneous withdrawal of the spheres from the surface.

The close-packed monolayers of spherical microlenses can be conveniently deposited onto the surface, e.g., by means of drying of the colloidal solution droplet. However, the spherical shape is not optimal for the beam focusing due to strong aberrations [4, 5]. In the case of silica or polymeric microspheres with refractive index of about 1.5, the field maximum is situated close to the surface of the sphere thus resulting in a small aspect ratio of the obtained nanostructures. In the case of the higher refractive index, the maximum is placed inside the sphere, thus rendering such particles inapplicable for the surface nanostructuring.

In this work, we study the possibility to employ spheroidal microparticles instead of the spherical ones in order to reduce the aberrations. With self-made FDTD code, we calculate the laser field intensities provided by monolayers of spheroidal particles and analyze the advantages and disadvantages of such focusing systems for surface nanomodification. In particular, we demonstrate the possibility to improve the aspect ratio of the nanostructures and increase the density of the modification spots.

Comparison of Kinetic and Continuum Models for Simulations of Laser-induced Plasma Plumes

A. N. Volkov, **G. Silverstein**, **and O. Ranjbar**
Department of Mechanical Engineering, University of Alabama
H. M. Comer Hall, 7th Avenue, Tuscaloosa, AL 35487, USA

Abstract— Plasma effects in laser-induced plume flows are known to be important for processing of various materials by high-power nanosecond pulsed lasers. In particular, the plasma plumes can efficiently absorb the incident laser radiation, thus substantially decreasing the amount of energy absorbed directly by the target, reducing the target temperature, and, finally, decreasing the amount of ablated material. Along with this major "shielding effect," the plasma plume induces a number of secondary effects like the heating and etching of the target by adjacent high-temperature plasma. These plasma-related effects substantially limit the overall efficiency of industrial laser systems and reduce the accuracy of laser machining.

The present work is aimed at the numerical modeling of laser-induced plasma plume expansion. Although a number of diverse models of plasma flow in laser plumes were proposed in the literature, these models were not compared in a unified framework. The major goal of the present work is to accurately compare the results of laser-induced plume expansions obtained with continuum and kinetic models. The continuum model solves the one-dimensional gas dynamics equations of the multi-component plume flow and incorporates both equilibrium, based on Saha-Langmuir equations, and non-equilibrium, based on kinetic rates of ionization and recombination, models of plasma. Boundary conditions at the irradiated target take into account the formation of the Knudsen layer. The kinetic model of multi-component plume flow is based on the Direct Simulation Monte Carlo (DSMC) method. This kinetic model is capable of taking into account the same plasma models as the gas-dynamic model. Both the gas-dynamic and the kinetic models are coupled with the same thermal model of the target. Boundary conditions at the target surface account for the evaporation and condensation, thermionic emission, and back heating of the target by the high-temperature plume. These models are applied to study the one-dimensional plume expansion from a copper target irradiated by nanosecond and shorter laser pulses. The gas dynamic and kinetic models are found to result in substantially different flow structures in broad ranges of laser fluence and background gas pressure.

Computer Modeling of Material Modification by Short Laser Pulses and Optically-induced Surface Acoustic Waves

Leonid V. Zhigilei[1], **Chengping Wu**[1], **Maxim V. Shugaev**[1], **and Vladimir Yu. Zaitsev**[1, 2]

Abstract— Short pulse laser irradiation can trigger a cascade of structural and phase transformations in the region of direct laser energy deposition and can also generate strong acoustic pulses (bulk and surface waves) capable of affecting key processes responsible for material modification at a substantial distance from the absorption region. Large-scale atomistic simulations are used in this work to investigate both the direct femtosecond laser material modification and the acoustically-induced surface processes. In the case of the direct laser modification of metal targets, the processes responsible for the formation of a sub-surface porous region covered by a nanocrystalline surface layer with random crystallographic orientation of nanograins and a high density of stacking faults, twins, and nanoscale twinned structural elements with five-fold symmetry will be discussed and related to the experimental observation of surface swelling and incubation effect in multi-pulse laser ablation. For the acoustic activation of surface processes, the conditions leading to the maximum enhancement of surface diffusion are analyzed and explained by nonlinear wave profile sharpening leading to efficient generation of high-frequency harmonics that directly couple to the vibrational modes of surface species. The implications of the computational predictions for the design of new techniques where the acoustic energy serves as an effective substitution for thermal activation of surface processes are discussed.

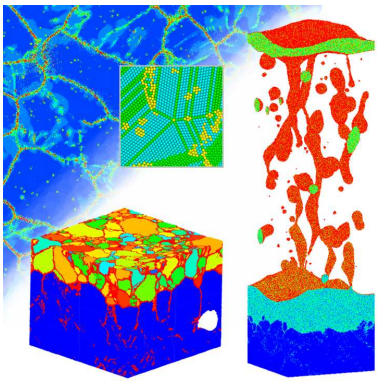

Figure 1: Illustration of some of the results of large-scale atomistic simulations of laser-induced structural modification of Ag targets irradiated by 200 fs laser pulses. The simulations predict the generation of sub-surface voids and nanocrystalline surface layer and explain the experimental observation of surface swelling at laser fluences close to the ablation threshold.

Abstract— Results of numerical and experimental studies are presented for the absorption of near-IR and visible femtosecond laser pulses focused in the bulk of fused silica and the application of the method for the creation of fiber Bragg and long-period gratings in different types of silica fibers.

Introduction: Femtosecond (fs) laser technologies making it possible to produce high-energy ultrashort pulses are increasingly used in laser processing of materials. In comparison with other well-developed methods of laser processing (cutting, ablation etc.), the key advantage of fs pulses is the possibility of local change in the refractive index of nonphotosensitive transparent materials, which allows one to create elements of integrated optics [1]. We report the results of numerical and experimental studies of nonlinear absorption of fs laser pulses focused in the bulk of fused silica and the application of the method for the creation of fiber Bragg (FBG) and long-period gratings (LPG) in different types of silica fibers.

Modelling and experiments: Laser wavelength is one of the most important characteristics that determine the process of material modification because it defines the order of multiphoton absorption. In our work, the numerical and experimental investigations of fs laser pulses absorption were carried out for the fundamental ($\lambda = 1026\,\text{nm}$) and the second ($\lambda = 513\,\text{nm}$) harmonics of Yb-doped laser. Numerical model adopted in this work comprises a nonlinear evolution equation for the envelope amplitude of the laser beam in a form of extended nonlinear Schrödinger equation (NLSE) coupled to the balance equation for the concentration electrons-hole plasma [2]. It was found that second harmonic is more efficient in terms of amount of absorbed energy which leads to lower inscription threshold, but localization of the absorbed energy is higher for IR pulses due to higher order of multiphoton process.

Inscription of LGPs was carried out in different types of single-mode fibers including standard telecom Corning SMF-28e+, Nufern 1060-XP and polarization maintaining "Panda" type Nufern FUD-3561. The applied slit beam shaping technique allowed us to enlarge the cross-section of created modification area in the core and thereby to increase the mode coupling coefficients. Relatively low level of out-of-band losses (down to 0.3 dB) and high resonant dip amplitude ($> 12\,\text{dB}$) allows one to use such gratings in filtering applications. The first- and the second-order FBGs, with the periods of 0.535 and 1.07 μm respectively, were inscribed in Corning SMF-28e+ fiber through the acrylate coating as well as in specialty fibers through the polyimide coating: high-temperature tolerant Fibercore SM1500(9/125)P fiber and pure-silica core hydrogen tolerant SM1500SC(9/125)P. Characterization of the FBGs was performed using differential interference contrast microscopy and the measurement of refractive index modulation by means of quantitative phase microscopy.

Investigation of Instabilities in Femtosecond Laser Irradiated Semiconductors Using Numerical Modeling and Dispersion Relations

Thibault J.-Y. Derrien
HiLASE Centre, Institute of Physics, Academy of Science of the Czech Republic
Za Radnicí 828/5, Dolní Břežany 25241, Czech Republic

Abstract— Illumination of semiconducting and transparent materials by a femtosecond laser pulse leads to transient excitation of electrons from the valence band to the conduction band during the laser pulse action [1]. As the front part of the pulse locally excites carriers and transiently modifies the properties of matter, the tail of the laser pulse interacts with an inhomogeneously excited plasma [2, 3]. As a result, modulation effects can be stimulated, leading to the development of instabilities in the laser-excited region of the solid [4–6]. This study presents preliminary theoretical works aiming at understanding the excitation of possible electrodynamic instabilities in this context. To reach this aim, two complementary approaches are proposed.

First approach is a 2D time-dependent numerical modeling of the processes induced by a femtosecond laser pulse focused on the silicon surface which was developed based on a finite element method. The core of the modeling is a two-temperature model [3] taking into account the transient excitation of the electron-hole pairs by laser irradiation which is solved together with the wave equation for the electromagnetic field of the laser pulse of a Gaussian temporal and spatial shape. It has been found that, when reaching the critical density of the electron-hole plasma, a spatial modulation is generated in the excitation region, where the gradients of electron density and energy are large.

To understand the origin of the modulation of the electron-hole plasma density arising as a result of highly non-linear interaction, a perturbative study is performed for the case of a laser-irradiated system. The results reveal two oscillatory modes of the electron-hole plasma. While the first mode exhibits a near-wavelength spatial modulation, the second mode is found to be linked to the electron-hole plasma temperature, exhibiting a spatial period of ∼200 nm. Both modes are found to be highly dependent on the laser wavelength and the band structure of the material.

[2]Institute of Thermophysics SB RAS, Novosibirsk, Russia
[3]Applied Laser Technology, Ruhr-University Bochum, Bochum 44801, Germany

Abstract— In this work a simplified 2D model has been developed to analyze the temperature relaxation of dielectric materials after excitation by femtosecond laser pulses at 800 nm wavelength in the regimes of formation of laser-induced periodic surface structures (LIPSS). The model assumes that laser absorption is modulated upon laser action as a result of partial scattering of the incident electromagnetic wave by surface roughness. The model is based on the rate equation for free electron generation dynamics and the heat flow equations for electron and lattice subsystems. Modeling has been performed for fused silica as an example. Peculiarities of modulated temperature profile evolution are analyzed. The effects of nanoscaled melting/softening and heat and defect accumulation are discussed.

Electromagnetic Models and Applications in Remote Sensing

Study of Orientational Effects in Magnetic Induction Tomography (MIT) Using a Weakly Coupled Finite Elements (FE) Solver

Wuliang Yin and Anthony Peyton
School of Electrical and Electronic Engineering, University of Manchester
Sackville Street Building, Manchester M13 9PL, United Kingdom

Abstract— Non symmetrical objects show strong orientational effect in a MIT Sensor. In this paper, we developed a fast magnetic induction FEM solver in the thick skin regime. This solver delivers higher accuracy with reduced computation load. Using this solver, we investigated the rotational effects of an object in MIT. A potential use of MIT for object recognition, which exploits the new solver, is also investigated.

A Formulation for Predicting the Asymptotical Magnetic Polarization Tensors for Complex-shaped Samples Using the Boundary Element Method

M. Y. Lu, W. Yin, and A. J. Peyton
School of Electrical and Electronic Engineering, University of Manchester, Manchester M13 9PL, UK

Abstract— The magnetic polarization tensor is a frequency-dependent, rotation-invariant and object-specific property of a metallic object. This paper presents an approach to compute the magnetic polarization tensor of a metallic object based on the Boundary Element Method (BEM) which treats the object as a perfect electrical conductor (PEC) and therefore is able to predict the limiting cases where very high frequency and/or high conductivity is assumed. A uniform magnetic field is applied to an object and the scattered field at a certain distance is obtained in the simulations. The magnetic tensor can then be deduced from the scattered field. The simulated results agree well with an analytical solution for spheres and with measured results for a number of cylinders at limiting cases. An explicit formulation is deduced for the magnetic polarization tensor.

Retrieval of Land Surface Temperature from Landsat 8 Thermal Infrared Sensor in Heihe River Basin

Xiaoying Ouyang
State Key Laboratory of Remote Sensing Science
Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences, Beijing 100101, China

Abstract— One of the important land surface products derived from Landsat is the land surface temperature (LST). The Thermal Infrared Sensor (TIRS) onboard Landsat 8 collects two thermal bands with appropriate response spectral distribution in the atmospheric window between 10–12 µm (833–1000 cm^{-1}) at a spatial resolution of 100 m: B10, 10.6–11.2 µm (890–945 cm^{-1}) and B11, 11.5–12.5 µm (800–870 cm^{-1}). This advance sensor could give the LST data for global change analysis due to its highly technical advancements in both spectral and spatial resolution in thermal infrared regions.

A split-window (SW) algorithm to obtain satellite-derived LST of semi-arid areas from freely available and easily accessible data of the latest Landsat 8/TIRS is first developed. So far, great efforts have been made in estimating LST using SW method from either geostationary or polar-orbiting thermal infrared data. The SW method estimates LST by correcting for atmospheric effects based on the different absorption in two adjacent infrared bands [1–4]. Wan and Dozier (1996) proposed a generalized split-window (GSW) method and applied to top-of-atmospheric (TOA) radiance observed by AVHRR and MODIS SW channels respectively to retrieve LST. The retrieval parameters can be given by interpolation on a set of multi-dimensional look-up tables (LUT) [1]. The accuracy in atmospheric water vapor content is vital for obtaining suitable coefficients in Wan and Dozier's SW method in different ranges of atmospheric humidity condition. Method using radiance observations in thermal infrared bands, say the Split-Window Covariance-Variance Ratio (SWCVR) method [5, 6] is adapted to the Landsat 8/TIRS sensor for water vapor content retrieval in this study. In situ LST data for the period from mid-June to mid-September 2012 were acquired from automatic meteorological stations (AMS) that are part of Heihe Watershed Allied Telemetry Experimental Research (HiWATER) project. TIRS-based LSTs are compared with in situ measurements at 16 AMS sites with land cover types of vegetable, maize and orchards. The standard deviation (STD), root mean square error (RMSE), and correlation coefficient (R) of TIRS/LST vs. the in situ measurements are 2.45 K, 2.78 K, and 0.67, respectively, whereas those for the MODIS 1 km LST product vs. the in situ measurements are 4.07 K, 2.98 K, and 0.79, respectively. The spatial pattern of the TIRS/LST over the study area in the Heihe River Basin generally agreed well with the MODIS 1 km LST product and contained more detailed spatial textures.

Model Initialization and Inversion for Geophysical Retrieval Based on Time Series Optimization of AMSR-E X-band Data

Steven Chan, Eni Njoku, and Mariko Bürgin
Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA 91109, USA

Abstract— The zeroth-order radiative transfer model, also known as the *tau-omega* model, has been used extensively for decades in passive remote sensing of soil moisture. In order to apply the model successfully to obtain soil moisture estimates, the model must first be initialized with known model coefficients, along with other ancillary data inputs. Although the values of these coefficients are generally available at smaller spatial scales applicable to studies at point or field scale, their values and geographical variability are usually not known at larger spatial scales applicable to many recent satellite missions (AMSR2, SMOS, Aquarius, and SMAP) whose objectives include frequent global mapping of soil moisture for hydroclimatological and hydrometerological applications.

In this presentation, a time series optimization (TSO) approach will be proposed to address the ambiguity associated with the initialization of these model coefficients, and the subsequent uncertainty in geophysical retrieval. In this approach, satellite-based brightness temperature (TB) measurements at a given geolocation from successive overpasses are used as observations to construct the cost function $\varphi(\mathbf{x})$ to be optimized, where $\mathbf{x}$ is a multi-dimensional vector that contains model coefficients as well as geophysical parameters. By iterative optimization on $\varphi(\cdot)$ formed from successive TB observations accumulated over a certain period, it is possible to obtain an optimal $\mathbf{x_o}$ that minimizes $\varphi(\cdot)$ in a least-squares sense. As this procedure repeats, the TSO results in two-dimensional mapping of model coefficients and geophysical parameters. Because the same computation can be repeated for the next time window, this approach also sheds insights into the seasonality of model coefficients and geophysical retrieval.

An annual record of the X-band TB data acquired by the Advanced Scanning Microwave Radiometer EOS (AMSR-E) onboard the NASA Aqua satellite will be used to illustrate the principles and results of this approach. The TSO-based soil moisture estimate will be discussed. In addition, estimates using other common soil moisture retrieval techniques will be presented as a comparison to highlight the differences in spatial pattern among these methods. Finally, the prospect of extending this approach to other satellites and hence the creation of a long-term consistent soil moisture record will be discussed.

Effect of the Rock/Water/Air Interaction on the Complex Dielectric Permittivity and Electromagnetic Waves Attenuation in Water-saturated Sandstones

P. P. Bobrov, A. S. Lapina, and A. V. Repin
Omsk State Pedagogical University, Omsk, Russia

Abstract— We have described how the complex relative permittivity (CRP) of water-saturated rocks depends on textural and interfacial effects. We used an experimental wideband frequency domain method for the CRP measurements of a porous medium at the frequency 10 kHz–1 GHz [1].

In the literature, for example in [2], the properties of elastic waves in the water-saturated sandstones, particularly the dispersion and attenuation, were described in details, but the properties of electromagnetic waves were described insufficiently. It is known that the real part of CRP of completely saturated sandstones depends on the porosity and it remains almost constant in the frequency range of 1 MHz to 1 GHz. At frequencies below 1 MHz observed abrupt increase due to the relaxation of the double layer at the rock-water interface.

It is usually assumed that reduction of water content in the rock reduces the real part of CRP. We measured CRP water-saturated powders of the quartz granules and hard sandstones with a porosity from 7% to 40%, and showed that at the frequencies 0.1–10 MHz the real part of CRP increases with decreasing of water content to 60–90% of the total porosity. In this case the conductivity drops sharply. The CRP frequency dependence is similar to the dielectric relaxation, described by the models of Debye or Cole-Cole.

A possible reason for this phenomenon is the interlayer polarization of the air-water boundary. Relaxation time weakly depends on the overall porosity, but greatly increases with the increasing of the pore size. In this case, the relaxation domain shifts down at frequency. In connection with an increase of the real part of CRP and conductivity decrease, the attenuation of the electromagnetic wave in relaxation domain decreases. The thickness of the skin layer at water-saturation of 70–80% in 1.5–2 times higher than at the water-saturation of 50%.

The Electrical Characteristics of the Rocks with Different Texture

P. P. Bobrov, A. S. Yashchenko, O. V. Rodionova, A. V. Repin, and A. S. Lapina
Omsk State Pedagogical University, Russia

Abstract— In the methods using ultra wideband electromagnetic pulses, as well as for dielectric logging data interpretation while oil searching the complex relative permittivity (CRP) over a wide frequency range are required [1].

The species CRP measurement indicates that the dielectric properties are the complex functions of particle size, clay content, saturating the fluid and its components.

To determine the influence of these parameters we have measured the frequency characteristics of the CRP of artificial mixtures that have different textures and saturating fluid. The mixtures consisted of spherical quartz grains of various sizes, river sand, bentonite of 3 types or kaolin clay in different proportions. They were saturated with liquid: distilled water, oil or saline. The measurements were made using a vector network analyzer in the frequency range from 10 MHz to 8.5 GHz. Samples were placed in a cell that can be connected as a coaxial line segment and a cylindrical capacitor. The surface area was calculated for each sample.

For the analysis of the spectra of CRP the relaxation time was chosen. It was determined by the model of Cole-Cole. It is shown that the relaxation time increases with a decrease in the specific surface area of granule mix with all types of bentonite. The same relationship is observed in mixtures of kaolin and bentonite with sand at low water content.

In the samples having the same specific surface area and the same fluid saturant but containing different concentrations dissolved the relaxation time decreases with the increasing of the salt content.

The CRP spectra of the mixtures with the same surface area emulsion saturated with diesel fuel — water were also investigated. Simulations have shown that as the proportion of oil in the emulsion decreases the relaxation time decreases too.

Abstract— Typically, the three growth phases of a rice plant are vegetative, reproductive, and ripening. The growth duration is determined by changes in the length of the vegetative phase. Accordingly, radar response at different stages that present different scattering mechanisms, either single mechanism or mixture, is of vital interest. In terms of scattering mechanisms, seedling and tillering in vegetative phase present surface scattering, and often water body or wet ground, while in stem elongation stage, vegetation crown appears, scattering may be from volume together with surface depending on the radar probing wavelength. In reproductive phase, the rice plant approaches to full-grown. From heading to flowering, the scattered signal levels may change. Finally, in ripening phase, from gain milking to mature, the wetness of the ground underneath changes as the rice filed undergoes practice of inundation and drainage. The rice plant height, leave area index, and stem density, among other parameters, vary from reproductive to ripening phases, although the land-cover may just look like a vegetation canopy as whole. All possible scattering mechanisms may present but weight in differently to total returns. After harvest, the bare soil presence prompts the surface scattering as the dominant scatterers.

In all, it can be seen that the complex process of rice growth makes an electromagnetic wave modeling of it difficult, if not possible. In this paper, a three layer scattering model based on radiative transfer theory by Karam and Fung [1], originally proposed to characterize backscattering from vegetation canopy, is modified for rice plant and their growth phases. A rice plant is electromagnetically modeled as cluster of rice plant components, a bunch. In particular, antenna array concept is adopted into the three-layer scattering model to account for the intra-clusters interactions between quasi-periodic bunches subtended by the antenna footprint. The performance of the proposed method is validated by comparison with continuous ground-based measurements for a complete cycle of rice growth [2], in which in-situ ground truths were collected as well and used as the model inputs. Result shows that excellent agreement of backscattering coefficients for various growth phases between model predictions and measured data is obtained. Dependence and sensitivity of radar scattering on various radiometric and geometric parameters, including water content, leaf size, curvature, and stem height and so on, will be discussed and reported.

An Inverse Model for Sea Ice Thickness Retrieval Using Simulated Annealing

Y. J. Lee, **K. C. Yeong**, **and H. T. Ewe**
Universiti Tunku Abdul Rahman, Malaysia

Abstract— An inverse model named the Radiative Transfer Inverse Scattering Model (RTISM) for the retrieval of sea ice thickness using Radiative Transfer Theory (RTT) had previously been developed by the authors. The model incorporates the use of the Dense Medium Phase and Amplitude Correction Theory (DMPACT) for better accuracy in the radar backscatter calculations and the application of the Levenberg-Marquardt Algorithm (LMA) to predict the sea ice thickness from the radar backscatter data. While the model has been successful in its attempts to predict the sea ice thickness from radar backscatter data, it has limitations in extending its applications to other sea ice parameters. In this paper, the study of using Simulated Annealing (SA) as an alternative solution for the LMA in the RTISM is presented. SA is appealing as a viable option to replace the LMA due to several reasons. It is a global optimizer and reduces the likelihood of being trapped in a local extremum, thus improving convergence. In addition, SA eliminates the cumbersome recalculation of the Jacobian matrices of the problem function for different applications, as required by LMA. Thus, the use of SA generalizes the inverse model and allows for more room to extend its applications. A comparison between the performances of both optimizers implemented in the RTISM shall be explored in terms of the execution time and accuracy in predicting the sea ice thickness.

Adaptive Boundary Approach for EMF Exposure Assessment in Broadband Measurements

Dragan Kljajic, **Nikola Djuric**, **Karolina Kasas-Lazetic**, **and Danka Antic**

Trg D. Obradovica 6, Novi Sad 21000, Serbia

Abstract— Recently proposed boundary approach for exposure assessment of humans to electromagnetic field (EMF), regarding continuous broadband monitoring, offers determination of daily upper and lower exposure boundaries. This means that the range with potential exposure of the general population, as well as occupational one, can be located in real time. As an advancement of this method, our paper presents a new approach based on adaptation of exposure boundaries in order to reduce the difference between them and this will increase the precision of the assessment. Frequency spectrum analysis has been applied, determining the appropriate reference levels, at particular in-situ location, for the boundary approach improvement. The results of performed in-situ test measurement of high-frequency electric field strength show attainment in reduction of boundaries difference of 36.25%, consequently resulting with increased precision of the daily exposure assessment for the broadband EMF monitoring.

Introduction: The two most commonly applied approaches for the insitu measurements of EMF level are frequency selective and broadband approaches. For requirements of the longterm continuous EMF level monitoring in the environment and obtaining of real-time EMF level fluctuations, the broadband measuring approach seems to be a more appropriate solution, because it results with single value of the overall and cumulative EMF strength, unlike frequency selective approach, which simultaneously offers results for each separate frequency in particular frequency range.

Unfortunately, due to the lack of information on EMF sources operating frequencies, the utilization of the broadband measuring approach leads to the difficulties in performing exposure assessment, since it is not known which of reference levels has to be applied for a comparison.

The Boundary Exposure Assessment Approach: The proposed boundary approach suggests comparison of the obtained measured values with the lowest and highest reference levels in the field probe frequency range. Applying such an approach, the upper and lower boundaries of exposure have been determined. In the case of high-frequency electric field measurements, the boundaries are calculated via following expressions:

$$\mathrm{GER}_{\mathrm{low}} = \left(\frac{E_m}{E_{ref\,\max}}\right)^2 \quad \text{and} \quad \mathrm{GER}_{\mathrm{up}} = \left(\frac{E_m}{E_{ref\,\min}}\right)^2, \tag{1}$$

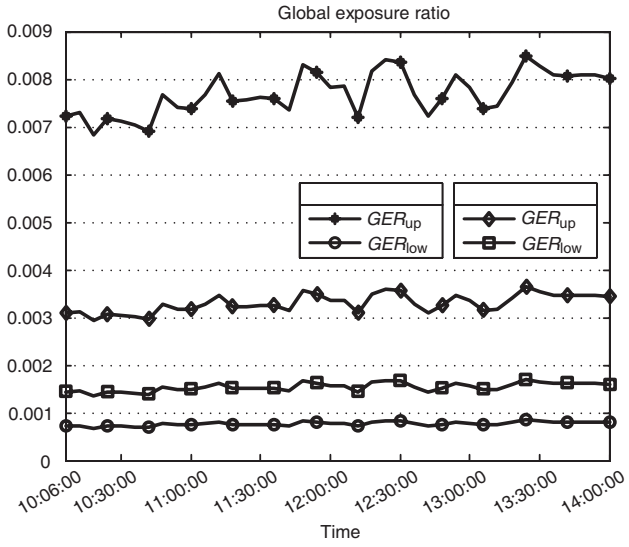

Figure 1: Adaptation of exposure boundaries.

where E_m is the measured electric field strength, while the $E_{ref\,\min}$ and $E_{ref\,\max}$ are minimum and maximum electric field reference levels, defined by corresponding legislation acts.

Combining this approach and the results of continuous in-situ EMF broadband monitoring, the daily boundaries can be obtained, showing fluctuation of the potential exposure over a long period of time.

The Adaptive Boundary Approach: Calculation of exposure boundaries results with certain difference between them. Therefore, this paper focuses on reduction of that difference through the appropriate adaptation of exposure boundaries. The main idea is based on the utilization of frequency selective in-situ measurement combined with broadband EMF monitoring.

The frequency spectrum scanning is applied to determine the frequencies on which EMF sources emits over particular in-situ location. Consequently, it is possible to narrow the frequency range over which the new minimum and maximum reference level should be selected for the exposure boundaries. The performed test measurement brings the reduction of the difference between exposure boundaries, as presented in Fig. 1.

The results show that, involving a frequency selective measurement, a reduction in boundaries difference of 36.25% is attained, resulting with much clearer insight of the human exposure to EMFs at particular in-situ location.

Conclusion: The performed analysis shows that having information on frequency spectrum and EMF sources in the vicinity of in-situ location, it is possible to adapt proposed exposure boundaries and reduce the difference between them.

It can be concluded that such adaptive boundary approach could offer clearer overview of exposure of human population to EMF and increase the precision of the daily exposure assessment on the chosen in-situ location.

Topographic Effect on the Canopy Reflectance

[2]Joint Center for Global Change Studies (JCGCS), Beijing 100875, China

Abstract— Many researches indicate that the topographic factors have strong influence on forest canopy reflectance. However, the quantatively effects of canopy reflectance by topographic is difficulty to be evaluated. For this purpose, the topographic effects on sloping forest reflectance are quantitatively evaluated based on GOST model and the observed remotely-sensed images. The following objectives are addressed: 1) the topographical effects on the sloping canopy reflectance; 2) the topographical effects on the multi-angle view canopy reflectance; and 3) the topographical effects on the reflectance with different canopy structures. The major findings are summarized as follows: First, the topographic factors (slope and aspect) have great impacts on sloping canopy reflectance. A case study shows that the modeled topographic index for reflectance ([bidirectional reflectance distribution of a sloping forest-bidirectional reflectance distribution of a flat forest]/bidirectional reflectance distribution of a flat forest), which is the relative error in modeled canopy reflectance by ignoring the topographic effects, can reach up to 138%, while the maximum observed topographic index for reflectance from a Landsat image is 99%. Therefore, the forest reflectance models considering the topographic factors are recommended for canopy reflectance simulation and canopy parameters retrieval. Second, model simulations show that topography has differents effects on the sloping canopy reflectance in different view directions. These effects should be considered in analyzing multi-angle images. Third, topographic factors have different impacts on sloping canopy reflectance of different canopy structures. Canopy structure should also be considered in topographic correction on reflectance images because topographic factors alone is insufficient for correcting all variations of reflectance with slope and view angle.

A Study of Scattering of Scatterers Using Equivalence Principle Algorithm

Chan-Fai Lum[1], **Fu Xin**[2], **Hong-Tat Ewe**[1], **and Li-Jun Jiang**[2]

[1]Universiti Tunku Abdul Rahman, Malaysia
[2]University of Hong Kong, China

Abstract— For theoretical models used in microwave remote sensing of earth terrain, it is quite common to represent the medium as a random discrete medium where the medium can be modelled as layers of scatterers of basic shapes embedded in the host medium and bounded by upper and lower rough surfaces. By solving the wave propagation and scattering in the medium through Radiative Transfer (RT) theory, the scattering returns from the medium can be obtained. Traditionally, analytical expression of scattering from these scatterers of basic shapes is derived and computed with simplification based on basic assumptions. However, it is generally found from ground truth measurement that the actual shapes of those scatterers are much more complex and irregular. Although it is difficult to simulate the scattering from this wide range of scatterers of different sizes, orientation and shapes, it is possible to model the medium better by representing the scatterers with the major types of scatterers of particular shapes, though the shapes may not be of basic geometrical shapes like spheres. In this study, it is proposed to use the Equivalence Principle Algorithm (EPA) method under the approach of computational electromagnetics to perform the calculation of scattering from these scatterers and incorporate this for the simulation of radar scattering returns from Radiative Transfer (RT) formulation. With this approach, the theoretical model developed can be extended to cover scattering from scatterers which are not easily represented by basic geometrical shapes. Comparison of the simulation based on Mie scattering and EPA will be presented with theoretical analysis for better application of this method in medium such as snow or sea ice. The model prediction is also compared with satellite SAR data with physical parameters input from ground truth measurement conducted in Antarctica.

Abstract— IR absorption spectroscopy is widely used as a simple and reliable technique for both detection and identification of hazardous and greenhouse gases. Various mid-IR (2.5–10 μm wavelength) methods that work at the highly sensitive fundamental vibration bands, such as Fourier transform IR (FT-IR) spectroscopy that detect gases through spectroscopic signatures, are available commercially. However, most commercial mid-IR spectrometers are large, expensive, and heavy tabletop instruments. On the other hand, near-infrared (NIR $\sim$ 0.6–2.5 μm wavelength) optoelectronic devices are miniaturized, low cost, and highly reliable. The biggest challenge is that most gases do not have fundamental vibration bands at NIR regions, and hence it has relatively low detection sensitivity.

To resolve this challenge, we develop an ultra-short NIR fiber-optic gas sensor by depositing a thin layer of metal-organic framework (MOF) on the core of multimode fibers. MOF is a new class of highly porous crystalline material consisting of metal ions and bridging organic ligands linked together by coordination bonds. Due to its high surface area, chemical and physical tailorability and tunable nanostructured cavities, it can be used for gas sensing by effectively concentrating various gases from the ambient environment. The fiber-optic gas sensor was fabricated by growing nanoporous MOF materials on the core surface of an etched optical fiber. First, standard buffered oxide etchant was used to etch away the cladding of a fluorine-doped silica cladded/silica core multimode fiber (MMF) (Thorlabs AFS 105/125Y). The etched length is about 8 cm. To increase the interaction between the evanescent field and the surrounding gas molecules, the core of the fiber was etched to approximately 75 μm. Second, the etched MMF was cleaned thoroughly, followed by O_2 plasma treatment (50 w) for 20 minutes. Finally, a 100 nm thick MOF was grown on the surface of the etched core by stepwise layer-by-layer (LBL) method. The fiber-optic sensor was then placed inside a gas cell connecting with CO_2 flowing system. Gas sensing experiment was performed by scanning the wavelength from 1571.5 nm to 1573.5 nm. The detection limit is 500 ppm with overall real-time response of only 40 s. Such ultra-short fiber-optic gas sensors with rapid response time can be used for greenhouse gas detection and environmental protection.

Development of a Six-dof Fiber Bragg Grating Force-torque Sensor for Minimally Invasive Robotic Surgery

Cheol Kim, Chan-Hee Lee, and Seong-Min Yun
Department of Mechanical Engineering, Kyungpook National University
80 Daehak-Ro, Book-Gu, Daegu 702-701, South Korea

Abstract— Minimally invasive robotic surgery is recently attracting much attention, because it can alleviate patients' pain, bleeding, and long-term recovery, etc.. If the robotic surgery end has a haptic device equipped with a 6-dof force sensor, surgeons can easily control their operating grasping forces. In an effort to develop a 6-dof optical sensing device with a FBG (Fiber Bragg Grating) sensor which is applicable to detect forces acting on the end-effectors of a minimally invasive surgical robot, a new design analysis method has been developed. The sensing device attached to an end-effector consists of a cylindrical frame structure (Fig. 1) and a FBG optical fiber surrounding the frame diagonally. As the frame deforms subjected to forces and moments, the attached FBG fiber with 2000 micro-strain of pretension also elongates or contracts. Deformations of the frame was calculated by the finite element method subjected to x-, y-, and z-direction forces and three moments about x, y, and z axes, respectively. Displacements of the FBG fiber regarding to six load-types could be then extracted from frame deformation data and converted to changes in wavelength on the basis of an equation of optical fiber reflected wavelength and FBG strain. Using the developed method, various wave lengths were calculated as three forces changed from 0 to 10 N and three moments varied 0 N-mm to 500 N-mm. To validate accuracy of the analytic design method, a system of the 6-dof FBG sensor with a frame was fabricated and tested under the loads used for analyses. The changes in wavelength were measured by an optical spectrum analyzer in the experiment. Analytical and experimental results showed a good correlation with 4% error. The sensitivities of the theoretical and analytical models were very similar.

Abstract— Making optical fiber sensor components technology have chemical-etching, fused-tapering, laser ablation etc., Most of used the hydrogen flame to made the tapered fiber. In this experiment, is used the hydrogen flame to made the taper fiber at the flat-clad fiber, shown in Fig. 1. The diameter is around 20 µm, then the fiber was connected to superluminescent diodes and optical spectrum analyzer, Fig. 2 is the experimental set-up, we found the taper flat-clad fiber has interference, shown in Fig. 3, and further explore.

Abstract— In this work, we demonstrate using a single mode fiber (SMF-28) end-spliced with a hollow optical fiber (HOF) composition broadband high sensitivity micro fiber Michelson interferometers (FMI) possess a fiber spherical lens can test outside refraction index (RI). The output end of the HOF is fused by arc to form a spherical lens, shown in Fig. 1, for efficiently collecting reflection lights from external moving materials under test. This broadband high sensitivity micro-FMI with extinction ratio of 25 dB over 1250–1650 nm wavelength and the reflected cladding modes can rise to beat signals, shown in Fig. 2. The transmission spectra of using this experimental set-up (Fig. 3) to test different external environment RI, the Fig. 4 shows the transmission spectra in the difference RI of 1.456, 1.54 and 1.6. When refraction index increase the extinction ratio will gradually decreased. Therefore, sensing external environment refractive index for using this micro fiber Michelson interferometers is feasible.

Surface Plasmon Resonance Excitation in Metal-clad Single-mode Optical Fiber through the Tunneling of Fundamental Mode Across the Fiber Cladding

Yuri N. Kulchin[1], **Oleg B. Vitrik**[1,2], **and Anton V. Dyshlyuk**[1,2]

[1]Institute of Automation and Control Processes, FEB, RAS, Russia

Abstract— We present a novel approach to the excitation of surface plasmon resonance (SPR) in a single mode optical fiber with metal-coated optical cladding for precision refractometery and biosensing applications. As a rule fiber-optic SPR-refractometers built around single-mode fibers require removal of a part of optical cladding so that the metal layer could be deposited in close proximity of the fiber core to make it possible for the fundamental mode to couple to surface plasmons [1, 2]. The proposed method uses a bent fiber with a reduced normalized frequency to enable the fundamental mode to tunnel across the cladding and excite surface plasmons in the metal film applied to the outer surface of the cladding. Such an approach eliminates the need for mechanical or chemical modification of the fiber thus simplifying the fabrication procedure and increasing the robustness and longevity of the sensitive element.

The schematic of the waveguide under study is shown in Fig. 1(a). It consists of straight input and output sections and a bent metal-clad central section. We used numerical modeling based on eigenmode expansion method to simulate the propagation of light through the studied waveguide. It was shown that by choosing a proper combination of normalized frequency, bend radius, and metal film thickness one can achieve strong coupling between the fundamental mode guided by the fiber core, and symmetric surface plasmon mode supported by the metal layer applied to the fiber cladding. This brings about a narrow dip in the transmission spectrum of the waveguide whose resonant wavelength has a strong and nearly linear dependence on the refractive index of the surrounding medium n_3, which enables precision refractometric measurements with spectral sensitivity and resolution estimated at 70 µm/refractive index unit and $3 \cdot 10^{-7}$, respectively.

Abstract— Fiber sensors had been widely used in many different places, the traditional fiber Michelson interferometer is non-integrated. In this work, we demonstrate a high-sensitivity micro-Michelson interferometer (MMI) using a single mode fiber end-spliced with a short hollow-core fiber end-fused by arc to measure a tiny variation of topography. The experimental set-up as shows in Fig. 1, the topography using a gold tape and a silver tape to made topography. Thickness of gold tape and silver tape are 70 μm and 37 μm, respectively. The depth on the gold tape is equivalent to the lower topography. Non-cleaved place on the gold tape is equivalent to the higher topography. Fig. 2 shown the spectrum respond of the MMI is correspondence to the high and low topography.

Micro Fiber Accelerometer Based on Multibeam Michelson Interferometer

Yu-Lin Tseng[1], **Jhih-He Jhang**[1], **and Nan-Kuang Chen**[1, 2]

[1]Department of Electro-Optical Engineering, National United University, Miaoli, Taiwan
[2]Optoelectronics Research Center, National United University, Miaoli, Taiwan

Abstract— We use a High-sensitivity broadband micro-Michelson-interferometer to measure acceleration. Use a single mode fiber (SMF) end-spliced with a short hollow-core fiber (HOF) end- fused by arc to measure a sway of spring piece. Tunable laser is launched into the optical fiber and fixed spring piece on the fixture. The distance of optical fiber to spring piece is around 16.14 nm. Then, make the optical fiber and spring piece together become a devise, shown in Fig. 1. Push the devise going quickly and make it stop suddenly. At this time, we can see spring piece sway violently to weakly and then stop, shown in Fig. 2. When light passes through an optical fiber to the spring piece, the light will be reflected back from the surface of spring piece and get spectrum from Oscilloscope. By calculating, we can get acceleration from sway of spring piece.

Session 3A7a
SC3: Non-reciprocal and Topological Features in Photonic Systems

Generating Non-reciprocal Phases in Photonic Systems

Benjamin J. Eggleton[1] and Enbang Li[2]

[1]CUDOS, University of Sydney, NSW, Australia
[2]University of Wollongong, NSW, Australia

Abstract— Photonic topological insulators support unidirectional protected modes and enable light to flow around imperfections with perfect transmission. Generating non-reciprocal phases in photonic systems is vital in realizing photonic topological insulation. In this talk, methodologies and techniques for experimentally generating non-reciprocal phases will be discussed.

Topological Photonics Quasicrystals

Miguel A. Bandres[1], **Mikael C. Rechtsman**[1], **and Mordechai Segev**[2]

[1]Physics Department and Solid State Institute, Technion, Haifa 32000, Israel
[2]Department of Physics, The Pennsylvania State University, University Park, PA 16802, USA

Abstract— Topological insulators are materials that insulate in their bulk, but allow extremely robust flow of current on their surfaces [1]. In two dimensions, they possess one-way edge currents that that are immune to scattering and imperfections. Recently, the ongoing theoretical effort to realize topological insulation and protection in optics [2–8] culminated in the first experimental observation of photonic topological insulators in optics [9], as demonstrated in an honeycomb array of evanescently coupled helical waveguides. This effect was also demonstrated in a silicon-chip platform using a lattice of coupled ring resonators [10]. Introducing topological protection into photonics not only brings technology closer to employing the unique properties of topological phases in real applications but also provides an entirely new platform for probing and understanding topological protection.

Quasicrystals are unique structures with long-range order but no periodicity [11]. They constitute an intermediate phase between crystals and disordered media. Quasicrystal transport is extremely rich, this is evidenced by the surprising regime of disorder-enhanced transport in a photonics quasicrystal [12], and the direct connection between 1D quasi-crystalline band structures and topological physics [13].

Here we show that it is possible to have a topological phase in two-dimensional quasicrystals without zero magnetic field. This topological quasicrystal exhibits gapless one-way edge states that scale with the systems perimeter, contrary to the general states of a quasycristal system which are critical, characterized by a power law decay. We show that the spectrum exhibits a rich structure of topological minigaps whose gapless edge states only form by increasing the system size due to their long penetration depths into the bulk. This is a new phenomenon in which the quasicrystal topological structure emerges as a function of the system size, in contrary to periodic systems where the topological phase can be completely characterized using its unit cell. We demonstrate the existence of this topological phase both by using a topological index (Bott index) and also by studying the dynamics (unidirectional transport) of the gapless edge states. Our specific model is a Penrose lattice of helical optical waveguides, a photonic quasicrystal; however we expect this new topological quasicrystal phase to be universal.

Abstract— Recently, there has been a surge of interest in investigating topological edge states, with synthetic gauge fields, in various photonic systems. In particular, topological robustness of photonic transport was quantitatively confirmed both in the microwave [1] and telecom domains [2], using synthetic 2D structures. Moreover, topological photonic edge states have been imaged in two concurrent experiments [3, 4]. Edge states are char- acterized by a topologically invariant integer, the winding number. However, measurements of the winding number have so far remained elusive in photonic systems. Here, we report first measurement of the winding number of photonic edge states. We implement the integer quantum Hall model in a photonic system: a two dimensional square lattice of ring resonators with a uniform synthetic magnetic field in the bulk and a tunable gauge field coupled only to the lattice edge. By selectively tuning the gauge flux coupled to the edge, we show that the edge states resonances in the transmission spectra of the device undergo a spectral ow. In particular, for a gauge ux of 2π, the edge state resonances move by their winding number. This experiment provides a new approach for direct measurement of topological invariants, independent of the microscopic details, and thus could be extended to probe topological orders in other photonic and atomic systems.

Realizing One-way Negative Refraction in Magneto-optical Photonic Crystal by Both Parity and Time-reversal Symmetry Breaking

Yan-Feng Chen[1], **Cheng He**[1], **Yin Poo**[2], **and Rui-Xin Wu**[2]

Abstract— One-way propagation of optical wave is highly desired due to its applications as photonic devices, whereas negative refraction have attracted much attention since it companies such novel effects as super-lensing and subwavelength resolution potential. With recent studies on one-way optical propagation, how to realize one-way negative refraction or even one-way cloaking attracts much attention, which has particular importance in security and military applications. Up to now all realized negative refraction are reciprocal. Very recently some theoretical studies predict the nonreciprocal refraction can exist in PCs with symmetry breaking however, they need further experimental verification. In this work, we theoretically and experimentally demonstrate one-way negative/positive refraction based on a two-dimensional composite magneto-optical photonic crystal (MPC), which is fabricated by alumina and ferrite square rods. Biased by magnetic field, the ferrite element breaks the time-reversal (T) symmetry. In the meantime, the heterostructure of the MPC makes the parity (P) symmetry broken. The two broken symmetries induce the MPC has distinguished refractions under a pair of counter-incidence angles (+ and −). The EM wave can transport through the MPC at one incidence angle but be forbidden totally at the opposite angle, forming a one-way refraction. In addition, such one-way refraction could be either positive or negative, which depends on the incidence angle and operating frequency. Further, corresponding experimental demonstrations are given and the results are in good agreement with theoretical predictions. These interesting properties would offer promising applications in optoelectronic devices such as optical isolator, and provide a practical way toward one-way focusing and one-way cloak.

Chiral Interaction of Light and Matter in Confined Geometries

A. Rauschenbeutel
Vienna Center for Quantum Science and Technology, Institute of Atomic and Subatomic Physics
Vienna University of Technology, Wien, Austria

Abstract— When light is strongly transversally confined, significant local polarization components that point in the direction of propagation arise. In contrast to paraxial light fields, the corresponding intrinsic angular momentum of the light field is position-dependent — an effect referred to as spin-orbit interaction of light. Remarkably, the light's spin can even be perpendicular to the propagation direction. The interaction of emitters with such light fields leads to new and surprising effects. For example, when coupling gold nanoparticles or atoms to the evanescent field surrounding a silica nanophotonic waveguide, the intrinsic mirror symmetry of the particles' emission is broken. This allowed us to realize chiral nanophotonic interfaces in which the emission direction of light into the waveguide is controlled by the polarization of the excitation light [1] or by the internal state of the atoms [2], respectively. Moreover, we employ this chiral interaction to demonstrate nonreciprocal transmission of light at the single-photon level through a silica nanofiber [3].

Abstract— The recent development of topological insulator states for photons [1–3] has led to an exciting new field of "topological photonics," which has as a central goal the development of extremely robust photonic devices [4]. Topological insulator physics has been studied extensively in condensed matter [5] and cold atoms [6], but photonics facilitates introducing non-Hermitian effects through the engineering of optical gain and loss. In this talk, we will present two results demonstrating non-Hermitian topological systems for the first time, as described below. Our systems are realized in an array of laser-written waveguides. Losses in the waveguides are engineered by oscillating waveguide trajectories (Fig. 1(b)). Although in the experiment there are only passive components, this maps directly onto the problem with gain and loss (modulo an overall exponential decay).

(1) The first experiment concerns a one-dimensional dimer model (lattice part S in Fig. 1(b)) in which the non-Hermitian character of the system can be used to extract topological information purely from the bulk dynamics of the system [7]. Since the diffraction of light through the waveguides maps to the Schrödinger equation, its topological character carries over into the optical domain. We show that, as predicted in [7], the 'mean displacement' $\langle \Delta m \rangle$ of the optical wavepacket on the Bsites undergoes a transition as a function of the 'dimerization' $[d_1 - d_1]/2$ of the lattice (Fig. 1(a)). This transition measures the 'winding number' of the lattice, a topological number that must be either zero or one in our case.

(2) The second is the proposal of the first non-Hermitian, PT-symmetric topological system, and its experimental realization in the 'passive-PT' framework. It had been previously thought that PT-symmetric topological states were impossible [8]. Here we provide an example of such a state. The model comprises a topological defect state in a one-dimensional system (shown in Fig. 1(b)). Due to the global PT symmetry, both the bulk and defect states have real eigenvalues. The defect state is observed in Fig. 1(c).

In conclusion, these two experiments constitute the first realization of non-Hermitian topological states in any system in nature.

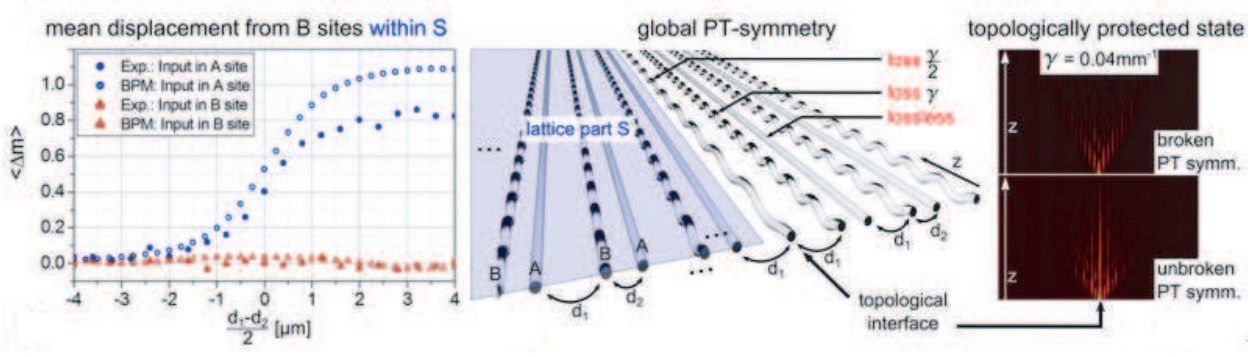

Figure 1: (a) Simulation and experiment showing the topological transition in the non-Hermitian dimer model; (b) schematic showing the experimental setup with global PT symmetry; (c) experiment showing no topological state (above), and with topological state (below).

Unidirectional Spontaneous Emission in Waveguides with Tailored Photonic Spin-orbit Coupling

Søren Stobbe and Peter Lodahl
Niels Bohr Institute, University of Copenhagen, Blegdamsvej 17, DK-2100 Copenhagen, Denmark

Abstract— We review the recent experimental progress on using the spin-orbit interaction of light to construct deterministic light-matter interfaces. We show that photonic-crystal waveguides with particular symmetries exhibit a pronounced photonic spin-orbit coupling, and quantum emitters placed inside such media exhibit highly directional emission. The direction depends on the orientation of the dipole moment of the emitters and we experimentally demonstrate a directionality of 90% of single photons emitted from a quantum dot into a single propagating mode.

When an excited quantum emitter decays by spontaneous emission, light is normally emitted in all directions. By embedding the emitter in photonic nanostructures, the emission can be funnelled into specific optical modes [1]. Using photonic-crystal waveguides, nearly all spontaneous emission is emitted in the propagating modes (propagating in opposite directions) of the waveguide and so far a coupling efficiency of 98.4% has been demonstrated experimentally [2]. Photonic-crystal waveguides are therefore amongst the most promising platforms for deterministic quantum gates with optical photons.

Photonic-crystal waveguides offer an exceptional exility in their design and fabrication, and novel functionalities may be implemented by imposing a particular glide-plane symmetry of the crystal. Here we are concerned with structures optimized for creating large regions with a local circular polarization. In this case the internal quantum state of an embedded emitter is directly mapped onto a single propagation direction due to the photonic spin-orbit interaction [3]. This interaction is inherent to Maxwell's equations but has only been studied rather recently because it vanishes in the paraxial approximation, which is often a good approximation for laser beams but breaks down in photonic nanostructures due to the strong transverse mode confinement. The link between polarization and direction constitutes a deterministic chiral light-matter interface, which may be probed by embedding quantum dots with circularly polarized excitonic states [4, 5].

Surface Impedance and Bulk Zak Phase Correspondence in Two Dimensional Photonic Crystals

Meng Xiao[1], **Xueqin Huang**[1], **Zhihong Hang**[2], **Z. Q. Zhang**[1], **and C. T. Chan**[1]

Abstract— Surface impedance is an important concept in classical wave systems. It tells how a wave reacts when encountering an interface, say between the vacuum and a dielectric photonic crystal (PC). We find that the surface impedance of a truncated PC is related to the geometric property (Zak phase) of the bulk band of this PC. This surface bulk correspondence plays a crucial role in understanding the formation of interface states between PCs. While the existence of interface states can be obtained with the surface impedance, this correspondence uncovers the underlying physics which explains the robustness of the interface state through the Zak phases of reduced 1D bulk bands. We give two examples to illustrate the significance of this surface bulk correspondence.

The first example is about interface states between two PCs consisting of square array of dielectric cylinders in the vacuum. The low frequency response of the PC can be described with the monopole and dipole excitations of the dielectric cylinder. When the parameters of the cylinders are carefully chosen, there exists an accidental degeneracy point between the monopole mode and the dipole mode at the Brillouin zone center. We show that if the parameters of two PCs are both near this accidental degeneracy point, we can always find at least one interface state at the boundary. This peculiar feature can be explained with the surface bulk correspondence.

The other example is about the interface state between two PCs with mutually inverted structure sharing a common gap above the lowest band. We show that the interface state exists as long as the PCs possess a mirror symmetry on average along the direction of the interface. The robustness of the interface state stems from the difference of the Zak phases of the lowest bulk bands across the boundary. Zak phase is related to the distribution of the Wannier function and that of the lowest band tends to concentrate on the high dielectric component of the PC. Hence the Zak phases of the lowest bulk bands are different for PCs with inverted structure. According to the surface bulk correspondence, the surface impedance of the gaps above the lowest band are also different and thus interface state exists in the common gap region above the lowest band.

Single Molecules Coherently Coupled to a Dielectric Nanoguide

V. Sandoghdar
Max Planck Institute for the Science of Light (MPL) and Friedrich Alexander University
Erlangen-Nürnberg, Erlangen 91058, Germany

Abstract— An efficient interface between photons and a controlled number of individual quantum emitters would allow one to study fundamental many-body effects relying on cooperative phenomena and polaritonic excitations. Several years ago, we demonstrated the first long-distance coupling of two individual molecules via tight focusing [1]. In this talk I will report on a new experimental system that allows the coupling of a mesoscopic ensemble of molecules. The core of our setup consists of a glass capillary with a subwavelength and high refractive index core that is doped with dye molecules. The highly confined mode of such a nanoguide can allow coupling efficiencies up to 18%. By combining high-resolution microscopy with extinction, fluorescence excitation and resonance fluorescence spectroscopy, we demonstrate the versatility of this geometry for reaching high optical densities while maintaining a low background and addressability of each single emitter. I will present our published experimental results [2], the prospects of our approach, as well as the ongoing efforts for achieving higher coupling efficiencies in a chip-compatible geometry. Furthermore, I show how efficient coupling of propagating photons to a single molecule can make it possible to observe four-wave mixing of continuous-wave laser beams via a single molecule [3].

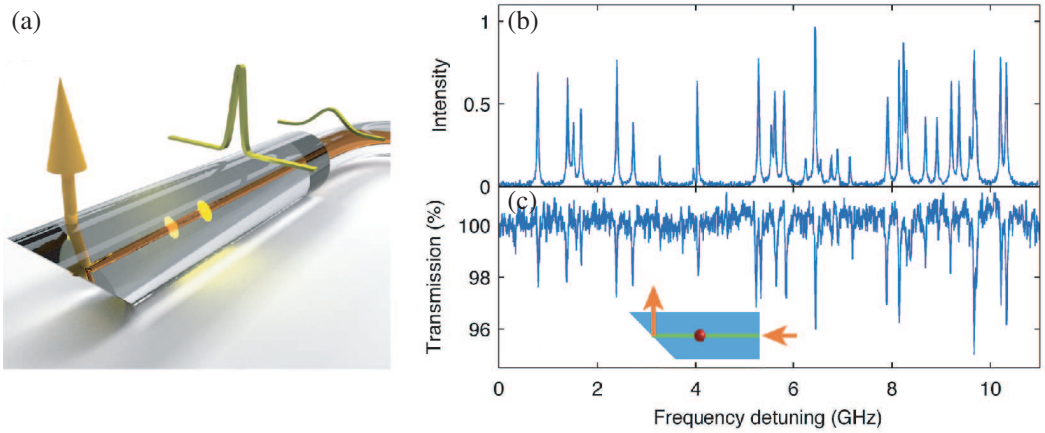

Figure 1: (a) Visualization of the sample geometry including the nano-capillary butt-coupled to a conventional single mode fiber. (b) Transmission spectra of the nanofiber showing the stokes-shifted fluorescence and (c) the extinction of the resonant light.

Using Dressed-state Resonance Fluorescence from a Single (In,Ga)As/GaAs Quantum Dot for Alkali Atomic Vapor Spectroscopy

S. M. Ulrich[1], **R. Löw**[2], **and P. Michler**[1]

[1]Institut für Halbleiteroptik und Funktionelle Grenzflächen
Universität Stuttgart, Allmandring 3, Stuttgart 70569, Germany
[2]5. Physikalisches Institut, Universität Stuttgart, Pfaffenwaldring 57, Stuttgart 70569, Germany

Abstract— Hybrid quantum systems combining semiconductor quantum dots (QDs) and atomic vapors promise interesting applications in quantum information technology. Recent research in this field has explored the resonant coupling between single GaAs QDs and Rubidium gas to generate, e.g., frequency-stabilized non-classical emission ($\sim$ 780 nm) as well as slow light for qubit storage/retrieval operations [1, 2].

As an alternative hybrid approach, we use a cw laser-driven single (In,Ga)As/GaAs QD (4 K) in the "dressed state" resonance fluorescence (RF) regime to address the $D1$ transitions of atomic Caesium (Cs) vapor (300 K) [3]. QD-atom resonance is achieved by tuning the frequency of the dressing laser close to the QD ground state $v \sim 335.116$ THz (894.592 nm) and shifting the narrow-band center and side channels of the QD Mollow triplet. Using this laser frequency controlled QD probe light for absorption measurements allows to precisely identify all four Cs hyperfine-split transitions. Therefore, narrow-band (In,Ga)As/GaAs QD RF is demonstrated as suitable to optically address individual channels of the $D1$ quadruplet without magnetic field or electric field tuning. Further ongoing experiments will be discussed in the talk.

Nonlinear Optics with Coupled Polariton Modes

S. R. K. Rodriguez, **A. Amo**, **I. Sagnes**, **E. Galopin**, **A. Lemaître**, **and J. Bloch**
Laboratoire de Photonique et de Nanostructures, LPN/CNRS
Route de Nozay, Marcoussis 91460, France

Abstract— Extreme optical nonlinearities emerge when photons are spatially confined and rendered mutually interacting. Semiconductor optical microcavities are promising solid-state systems wherein these two conditions can be simultaneously fulfilled. Photons in a microcavity can couple strongly to excitons in semiconductor quantum wells, giving rise to composite light-matter quasi-particles known as polaritons. The excitonic constituent confers polaritons giant interaction strengths, while the photonic constituent enables micron-scale confinement of polaritons followed by photon emission. Hence, polaritons constitute an excellent system for studying light-matter interactions under the influence of tunable coupling, driving, nonlinearity, and dissipation. In addition to single-mode nonlinearities, coupled polariton modes exhibit rich nonlinear dynamics and steady-states due to the interplay between nonlinear interactions and linear coupling. Here, we will present recent experimental results on coupled semiconductor micropillars exhibiting such strongly nonlinear optical dynamics and steady-states.

Our group has demonstrated several hallmark features of nonlinear Josephson oscillations in a photonic system [1]. The system studied consists of two tunnel-coupled semiconductor micropillars. The dynamics was characterized by measuring the population imbalance and phase difference between polaritons in adjacent pillars under pulsed excitation. In the linear regime (low pump power), polaritons oscillate between the two pillars — Rabi oscillations. For increased pumping, the oscillations become nonlinear. For even higher pumping, polaritons are trapped by the intensity-induced nonlinearity in the pumped pillar. This fascinating phenomenon, known as macroscopic self-trapping, was observed for the first time in a photonic system in Ref. [1].

Recently, we have studied the steady-states of coupled polariton modes under resonant excitation [2]. In particular, we have observed how the symmetries of the hybrid modes formed by the tunnel coupling between the two cavities can be broken, and restored, as the pump power increases. Distinct nonlinear thresholds enable us to abruptly increase the emitted intensity by one of the two coupled cavities or both. As we will show, these effects are associated with optical multistability and a pronounced hysteresis spanning several orders of magnitude in pump power. These results illustrate new ways to achieve all-optical nonlinear switching, and offer intriguing prospects for accessing the quantum regime with polaritons. In particular, non-classical states of light seem within reach with state-of-the-art polariton systems. Such extremely nonlinear optical cavities hold great promise for the realization of polariton blockade, photon fermionization, and quantum phase transitions beyond the Bose-Hubbard model.

Abstract— In a semiconductor quantum dots, the coulomb interaction between carriers results in a strong anharmonicity of the energy levels. This non-linearity is widely used to generate single photons on demand. It has also been recently explored to implement single photon routers. Both these applications requires to implement a highly efficient single photon-single quantum dot interface, so as to collect every photon emitted by the quantum dot or, symmetrically, so that every photon sent on the device interacts with the quantum dot. In this talk, we will present our recent progresses along this research line.

By deterministically coupling a single quantum dot to the optical mode of a micropillar cavity, we implement a highly efficient single quantum dot-single photon interface. We demonstrate the fabrication of ultrabright sources of indistinguishable single photons with a record brightness of 79% collected photon per pulse [1]. Under non-resonant excitation, we demonstrate indistinguishability of successively emitted photons in the 70- to 90% range. With electrically controlled structures [2], strictly resonant excitation can also be achieved. Under a p-pulse excitation, a near unity indistinguishability is observed. The quantum interference of photons emitted by two remote devices is finally shown to be greatly enhanced by the acceleration of spontaneous emission [3].

Symmetrically, we show that such devices can be used to demonstrate optical non-linearities at the level of only few incident photons [4]. When a single spin is inserted in the quantum dot, the polarization of a photon sent on the device can be rotated by $\pm 6^\circ$ depending on the single spin state [5].

Abstract— We show experimentally a 4-fold reduction of the intensity required to achieve sub-diffraction resolution in a stimulated-emission-depletion microscope, in good agreement with theory. This shows that the theoretical prediction of a 100-fold intensity-reduction is achievable.

The limit that diffraction puts on imaging was considered as the most fundamental problem in wave physics. This limit was broken in the early 2000s in the context of fluorescence microscopy, eventually resulting in the awarding of the Nobel Prize in Chemistry, 2014. One of the prominent super-resolution technique is stimulated-emission-depletion (STED) nanoscopy, which offers superb resolution along with fast acquisition times. The STED nanoscope, however, suffers from the need for high intensities required for efficient depletion. Here, we show that using metal nanoparticles (NPs) improves the performance of STED nanoscopes [1]. Compared with a standard STED nanoscope, we show theoretically a resolution improvement by more than an order of magnitude, or equivalently, depletion intensity reductions by more than 2 orders of magnitude; these come along with a strong photostabilization due reduction of photobleaching. We show that such performance improvement can be attained without excessive heating, making it useful for live-cell studies.

We demonstrate the technique experimentally by comparing the resolution attained by imaging dye-doped silica nanoparticles with or without a thin shell of gold [2]. We observe that an optimum resolution, limited by the particle sizes, can be reached for the NPs for a power of the STED beam 4 times smaller than for the bare cores, see Figure below, in good agreement with the theoretical calculations. We show that the experimental obstacles encountered all have very satisfactory solutions. Accordingly, we expect to reach the theoretical predictions once the measurements will be repeated with particles of optimal geometries. Our experimental demonstration opens the way to improvement of existing STED nanoscopes and assisting the development of low-power, low-cost nanoscopes. This has the potential to increase the availability of STED nanoscopes and lead to an expansion of our understanding of nanoscale biological phenomena.

The Wedding of Bioelectromagnetic and Biochemistry: Bridging a Molecule and Its Own Electromagnetic Information

Alberto Foletti[1, 2], **Mario Ledda**[1], **Settimio Grimaldi**[1], **and Antonella Lisi**[1]

[1]Institute of Translational Pharmacology, National Research Council-CNR, Rome, Italy
[2]Clinical Biophysics Research Group, Lugano, Switzerland

Abstract— Previously we showed an interesting effectiveness of the electromagnetic information delivery of a specific source molecule in mimicking its specific biological effect [1, 2]. Nevertheless the effect was quite lower than the original positive control. Therefore we decide to assess a possible synergism between a reduced dose of a molecule and its own electromagnetic information in order to increase the efficacy of this procedure trying to disclose new possible avenues in translational pharmacology [3] following suggestion from other works reporting synergistic effect between molecules and extremely low frequency electromagnetic fields [4, 5]. A reduced dose of retinoic acid, corresponding to a tenth of the usual, was delivered together with its own electromagnetic information to LAN-5 neuroblatoma cells. The signals from retinoic acid molecules was transferred to the cell culture medium employing as for our previous reports a commercial available electro medical device (Vegaselect 719). The effect on cell differentiation was significantly higher, and statistically significant, than the one obtained by the electromagnetic information delivery procedure when performed alone. A positive and effective synergism between a reduced drug dose and its own electromagnetic information seems to emerge as a promising and useful perspective in translational pharmacology outlining future applications in new drug delivery protocols allowing to reduce the amount of drug's doses especially in the elderly and in the increasing number of patients with multiple comorbidities. Bioelectromagnetic and biochemistry should, therefore, be considered on the way of a promising wedding instead of a permanently independent life. Future researches should either optimize the protocols of preparation of these potentially new drugs, either assess the lifespan of their biological effect in order to translate them into effective clinical application at the bedside through Biolectromagnetic medicine [6].

Oversensing and Undersensing of Implantable Cardiac Medical Devices Exposed to EMI

I. L. Spano, **A. Serpi**, **M. Tomasi**, **I. Marongiu**, **and G. Gatto**
Department of Electrical and Electronic Engineering, University of Cagliari, Italy

Abstract— In the last decade, the development of new technologies and the increased use of Radio Frequency (RF) sources make Electromagnetic Interference (EMI) a growing issue. In fact, when an electronic device is exposed to RF signals, they may prevent it to operate correctly, causing malfunctions. EMI issues are particularly critical for Implantable Cardiac Medical Device (ICMDs), which are generally employed for people whose spontaneous heartbeat is not good enough to ensure normal living conditions. Nowadays, ICMDs are implanted even from a very young age, thus it is no longer unusual for people wearing an ICMD to be highly exposed to EMI, such as in factories.

In this context, EMI immunity of ICMDs against RF signals is a growing issue, particularly electromagnetic interactions between ICMDs and intentional and unintentional RF sources (e.g., cell phones, safety systems, magnetic resonance, radiation, X-rays, etc.) may impair ICMD sensing performances. Consequently, the device may interpret spurious signals as threatening arrhythmias, starting unsuitable pacing activities or providing an improper defibrillation shock. Despite the use of appropriate filtering systems and/or recognition algorithms, misunderstandings can still occur, leading to undersensing or oversensing, as shown in Fig. 1. Particularly, undersensing prevents ICMD to detect the heartbeat, whereas oversensing makes ICMD sensitive to spurious signals.

In this paper, the problems of oversensing and undersensing due to EMI are addressed referring to two different types of ICMDs, i.e., a pacemaker (PMK) and an Implantable Cardioverter Defibrillator (ICD). This is done by means of a novel experimental testing procedure, which is developed in order to reveal EMC susceptibility of the device under test. Experiments have been carried out within an RF anechoic chamber, which guarantees a proper EMI injection, shielding against external EMI sources at the same time. In particular, an equivalent EMI source is employed, i.e. a Bilog antenna generates an RF signal (80% AM modulation), the frequency of which has been chosen in accordance with ANSI/AAMI ISO 14117: standard 2012. In fact, this last provides specific frequency ranges for EMC testing of ICMDs. As a result, different ICMD behaviours have been revealed in absence/presence of EMI, as highlighted in Fig. 1. Much more results will be enclosed in the final version of the paper, as well as a detailed description of the proposed procedure.

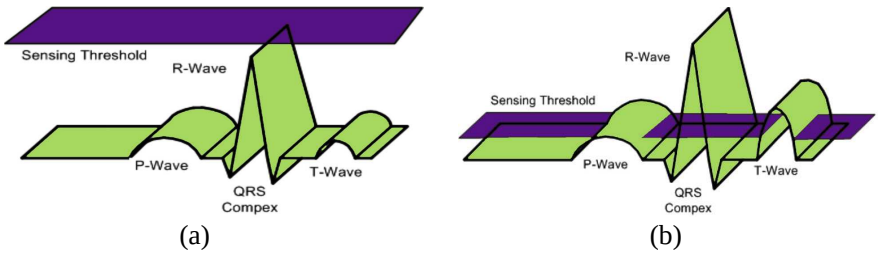

Figure 1: (a) Undersensing and (b) oversensing: heartbeat (green waves) and sensing thresholds (purple).

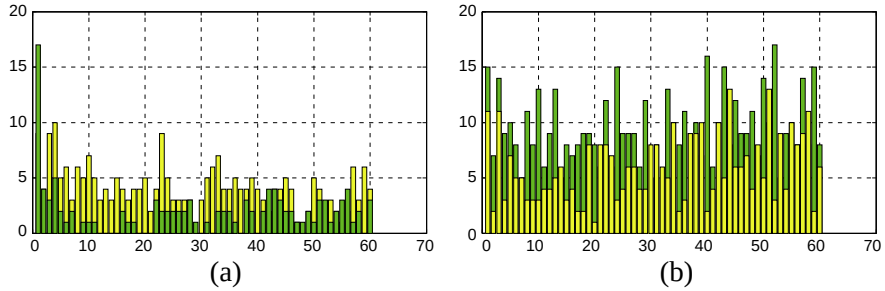

Figure 2: Pacing occurrences for (a) PMK and (b) ICD over about fifty one-minute tests, with and without EMI (yellow and green respectively).

Biomagnetic Fields of Propagating Electric Activity in Functional Syncytia Measured Using Amorphous Metal Magnetic Sensor

Shinsuke Nakayama[1] **and Tsuyoshi Uchiyama**[2]

[1]Graduate School of Medicine, Nagoya University, Japan
[2]Graduate School of Engineering, Nagoya University, Japan

Abstract— Electric current propagates in excitable cellular organizations so as to achieve their functions. In the heart, pacemaker potentials are amplified and forwarded from the atrium to ventricle muscle, thus synchronizing heart beats. Also, in the gut, coordinated motions, such as peristalsis and segmentations, require electric activities to organize smooth muscle segments. Magnetic detection would provide a non-invasive and aseptic estimate of their functional states.

In this study, we performed real-time measurements of biomagnetic fields in the musculatures of functional syncytium, using a gradio-type magneto sensor. Smooth muscles were isolated from gastrointestinal and urinary systems of guinea-pigs. Also, right ventricular muscle along with the right atrium was isolated from the heart of mice. In the gradio-magneto sensor, the performance of differentiation was improved by using a single amorphous metal wire with a pair of transducer coils, which produced well-balanced induction potentials. The distance between the sample and the wire was $\sim 1\,\mathrm{mm}$.

When musculature samples were incubated in a physiological extracellular solution at 32–35°C, spontaneous magnetic waves of up to several nT were observed. The frequency and the time course of biomagnetic waves reflected the cellular tissue-dependent excitability. For instance, in stomach samples only several magnetic waves occurred in a minute, while in cardiac samples magnetic transients occurred at 1–2 cycles/s at the beginning of recording. Since the thickness of ventricular musculature was $< 1\,\mathrm{mm}$ in mice, it is considered that our sensor would be able to measure magnetic activity in cardiac muscle sheets of regenerative medicine, if available.

Performance Evaluation of Dipole versus Modified Bow-Tie in Annular Phased Array Applicators

P. Takook, **H. D. Trefná**, **A. Fhager**, **and M. Persson**
Chalmers University of Technology, Sweden

Abstract— The main goal of the hyperthermia treatment is to heat up tumors to temperatures above 42°C while keeping healthy tissues at normal temperatures. To reach this goal, accurate hyperthermia treatment planning is necessary. This demands finding the optimal excitation amplitudes and phases of the antenna applicator to heat the tumor.

In this paper we utilized the 3D time reversal focusing method for hyperthermia treatment planning application [1]. The method which is based on the constructive wave interference at the tumor site, is implemented. The implementation used the finite-difference time-domain (FDTD) to solve Maxwell's equations. In a previous study conducted by the authors, the effect of different parameters as the input settings of 3D method for optimal heating of tumor models was shown in a head-and-neck phantom [2]. Among those, the antenna model is one the most influential parameters.

This paper aims to study the effect of a simplified antenna model in hyperthermia treatment of different tumor types and positions. The antenna used in this study is a modified version of wide-band Bow-Tie antenna [3]. To simplify the architecture of the 3D model, the Bow-Tie antenna models were replaced by half-wave dipole antennas. To evaluate the performance of the simplified model, treatment planning outcome of Bow-Tie antenna applicator were compared with that of the half-wave dipole antenna applicator. The efficacy of these two antennas in heating the tumors were then evaluated in terms of average power absorption ratio (aPA), remaining tissue maximum index (RTMi) [1] and target coverage$_{25\%}$ [4].

Two spherical tumors were positioned in the center and the side of a homogeneous phantom with radius 80 mm. The performance measures were then computed for each simulation. An irregular shaped tumor in a non-homogeneous head-and-neck phantom of similar size was studied afterwards.

The results of the simulations for the spherical tumors, demonstrated that for a centrally located tumor with radius of 10 mm (where distance of tumor center to the phantom surface is $d = 80$), array of Bow-Tie antennas presented 3.3% higher aPA, 1% higher $TC_{25\%}$ and 3.9% lower RTMi compared to array of dipoles. When tumor was located closer to the phantom surface, $d = 60$, all quality indicators were approximately the same for Bow-Tie and dipole. For the irregular shaped tumor in the laryngeal region which was even closer to the phantom surface, $d = 50$, dipole antennas showed considerably higher aPA and $TC_{25\%}$ and lower RTMi values compared to the Bow-Tie. The aPA = 47, $TC_{25\%} = 84\%$ and RTMi = 0.3 for dipole and aPA =25, $TC_{25\%} = 78\%$ and RTMi = 0.64 for Bow-Tie respectively. This confirmed authors previous study, in which for the same laryngeal tumor the treatment outcome from dipole antennas modeled in 3D code was better than Bow-Tie in CST [2]. Figure 1 shows the power absorption distribution radiated by Bow-Ties and dipoles in a 10-antenna applicator along the transverse plane of the laryngeal tumor.

Hyperthermia treatment quality indicators are correlated with the size of tumor and its relative position to other non-homogeneities. However, the results demonstrated that only based on the

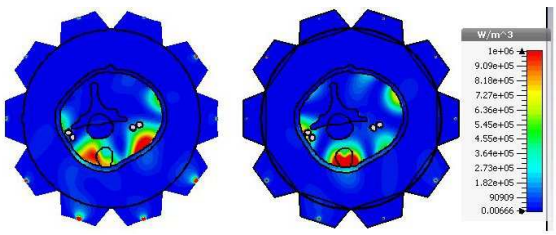

Figure 1: (a) Power absorption distribution radiated by Bow-Tie and (b) dipole in a laryngeal tumor, shown along the transverse plane.

relative distance between center of the tumor and the phantom surface, it can decided which antenna type leads to a better treatment outcome. For example, more tumor coverage can be achieved by Bow-Tie antennas for a tumor in tongue region, centrally located in a head-and-neck phantom.

Further studies are necessary to reach higher treatment quality for all tumor positions, e.g., by combination of different treatment plannings and hot-spot reduction techniques.

RF-photonic 2D/3D Integrated Circuits for Arbitrary Waveform Generation and Detection in Temporal, Spectral, and Spatial Domains

S. J. Ben Yoo
Department of Electrical and Computer Engineering, University of California, Davis, USA

Abstract— We will discuss 2D and 3D photonic integrated systems designed for coherent synthesis, processing, and detection of optical waves in time, space, and frequency domains. In particular, we will discuss a new class of RF-photonic devices based on 3D ultrafast laser inscription methods. The talk will be in three parts addressing applications in future communication, computing, and imaging systems including chip-scale LIDAR, satellite communication, and data systems. The 3D photonic integrated circuit (PIC) platform exploits direct inscribing of arbitrarily shaped waveguides using femtosecond lasers. In one example, such a 3D PIC allows arbitrary beam forming for spatial division multiplexing using orbital angular momentum states. We will further discuss 2D integrated photonic technologies based on InP, silicon, and silica material platforms. Examples at UC Davis include > THz coherent optical transmitters and receivers on a monolithically integrated InP platform, silicon photonic RF-photonic lattice filters, and orbital-angular-momentum (OAM) MUX/DEMUXes. Dynamic optical arbitrary waveform generation and measurement (OAWG and OAWM) technologies enable > THz scale coherent optical transmission systems with arbitrary modulation formats and bandwidth. Integrated 3D OAM devices can realize arbitrary spatial beam forming. Finally, we will address future prospects of the new 2D/3D RF-photonic integration circuits towards realizing future communication, computing, and imaging systems.

Software-defined Integrated Microwave Photonics for Radio Access Networks

Daniel Pérez, Ivana Gasulla, and José Capmany
ITEAM Research Institute, Universitat Politecnica de Valencia, Spain

Abstract— Microwave Photonic (MWP) systems are usually at the heart of analog signal processing engines that are placed in between the signal acquisition devices and front-end digital signal processors (DSPs) to accommodate the signal formats to the constraints imposed by the DSP limited sampling rates. This entails the realization of a wide variety of functionalities. Typical space, weight and power (SWAP) figures for commercial MWP systems are around 0.04–0.2 m^2 in size, 1.5–10 kg in weight and 15–20 W in power consumption, making them unsuitable for mass production and widespread use required by the next generation and emerging applications. Integrated photonics has the potential to change the power scaling laws of high bandwidth systems through proper architectural choices that combine photonics with electronics to optimize performance, power, footprint, and cost. In particular, analog photonics has a qualitatively different behavior compared to digital electronics since the energy per analog task is dominated by the steady-state bias power and does not increase significantly as the bandwidth increases.

Integrated Microwave Photonics (IMWP) [xx] that aims at the incorporation of MWP components/subsystems in monolithic or hybrid photonic circuits is instrumental to achieve the aforementioned evolution objectives. The activity in IMWP has been almost exclusively focused towards the so-called Application Specific Photonic Integrated Circuits (ASPICs) where a particular circuit and chip configuration is designed to optimally perform a particular MWP functionality. As a result, there are almost as many technologies as applications and, due to this considerable fragmentation, the market for many of these application-specific technologies is too small to justify their further development into low-cost industrial mass-volume manufacturing processes.A radically different approach that we propose in this paper is to design a software defined universal MWP signal processor architecture that can be integrated on a chip and is capable of performing all the main functionalities by suitable programming of its control signals. This is inspired by the flexibility of software-radio [16] and digital signal processors, where a common hardware is shared by multiple functionalities through a software-defined approach (or programmability), leading to significant cost reduction in the hardware fabrication. In the paper we propose a general configuration of this processor, discuss its application as a reconfigurable front-end subsystem in centralized radio access networks (CRANs) and its possible implementation in the different available material platforms.

Application of Multicore Fibers to Microwave Photonics

Ivana Gasulla and Sergi Garcia
ITEAM Research Institute, Universitat Politecnica de Valencia, Spain

Abstract— The exploitation of the last available degree of freedom for optical multiplexing -space- has been recently touted as a solution to the upcoming capacity bottleneck in Digital Communications [1]. The future optical network can benefit from Space-Division Multiplexing (SDM) by establishing independent light paths in a single optical fiber via multicore fibers or few-mode fibers. This paper presents the novel extension of this concept to the areas of analogue photonics and radio-over-fiber in order to create a new paradigm in the field of Microwave Photonics (MWP).

Microwave photonics is currently being used in many information and communication scenarios, including satellite communications, converged fiber-wireless communication networks, distributed antenna sensing systems, signal processing, medical imaging systems and optical coherence tomography [2]. Most of the MWP solutions applied to these scenarios rely on a core optical component, *the true time delay line*, which is typically implemented using discrete optoelectronic or fiber-based devices, including switched and dispersive single-core fibers, photonic crystal structures and active semiconductor waveguides.

We propose to exploit the inherent parallelism of SDM to implement a sampled true time delay line featuring, not only a reduction of size, weight and power consumption, but also unique processing capabilities beyond the current state of the art in terms of system stability, flexibility, versatility and record bandwidth. More specifically, we envision the application of heterogeneous multicore fibers, which are composed of a set of non-identical cores, to provide in a single optical fiber a broadband true time delay line featuring 2 dimensional tunability thanks to the simultaneous use of space and optical wavelength diversities. While keeping comparable propagation characteristics in all the cores of heterogeneous multicore fibers is important in digital communications, tunable true time delay lines for MWP require to design each single core so that it presents a different group delay and a different chromatic dispersion behavior.

We will also show how this SDM-based true time delay line can be applied to different MWP applications, such as tunable microwave signal filtering, optical beamforming networks for phased-array antennas, arbitrary waveform generation, optoelectronic oscillators and radio-over-fiber distribution in converged fiber-wireless access networks.

Electro-optic Dual-comb Interferometry

Vicente Duran[1], **Santiago Tainta**[2], **and Victor Torres-Company**[1]

[1]Department of Microtechnology and Nanoscience
Chalmers University of Technology, 41296 Gothenburg, Sweden
[2]Department of Electrical Engineering, Universidad Pública de Navarra, 31006 Pamplona, Spain

Abstract— Dual-comb interferometry is a multiheterodyne technique based on two phase-locked frequency comb sources. This technique permits to measure the complex spectral response of a sample under test at ultrafast speeds because it avoids using any mechanically moving parts. Dual-comb interferometry has impacted a wide range of fields, including spectroscopy, ranging or Raman microscopy.

In this contribution, we present our results on dual-comb interferometry implemented with electro-optic combs. These coherent light sources operate at repetition rates $> 10\,\mathrm{GHz}$, which allows for realizing dual-comb interferometry at speeds in the $\sim$MHz range. The fundamental tradeoffs between number of lines, detection speed and number of bits are exemplified with pulse shaping experiments.

Ultrahigh-speed Photonically-enabled Compressive Microwave Spectrum Sensing

Mark A. Foster
Department of Electrical and Computer Engineering
Johns Hopkins University, Baltimore, Maryland 21218, USA

Abstract— With its multitude of uses in communications and sensing, the radio spectrum is a highly regulated and finite resource. At present the radio spectrum is tightly and statically allocated This static allocation model is necessary to ensure that primary users have unimpeded access free of interference from other users. However, the modern proliferation of wireless electronics is placing pressure on this 100 year old model. Modern electronic devices will increasingly rely on high-bandwidth wireless communications for internet connectivity as well as inter-device communications. Furthermore, while the radio spectrum is tightly allocated, recent investigations indicate that usage at any spatiotemporal location is generally sparse with a limited number of active channels, scattered across an extremely broad bandwidth. This observation indicates that a cognitive radio system that can efficiently and rapidly sense spectral usage could adapt to exploit these temporary spectral opportunities and thus make more efficient use of the finite radio spectrum resource. However, efficiently detecting spectrum usage across an extremely wide bandwidth remains a primary challenge for any such system. Here we will discuss our recent work on a microwave photonic compressive sampling system for extremely wideband microwave spectrum sensing. Our approach employs chirp processing of ultrafast laser pulses to achieve all-optical high-rate compressed sensing measurement. Pseudorandom binary sequence (PRBS) patterns are modulated onto time-stretched optical pulses, encoding them onto the optical spectra at a rate of one unique pattern per laser pulse. The pulses are then partially-compressed, increasing the system's effective sampling rate well beyond the electronic limits. The partially-compressed patterned pulses are then modulated again with the microwave signal under test and fully compressed to perform optical integration of the PRBS to microwave signal inner product before output photodetection and digitization. Using this approach, we have successfully acquired multi-tone sparse microwave spectra with instantaneous bandwidths beyond 15 GHz utilizing both an electronic sampling rate two-orders of magnitude lower than the Nyquist rate and also less than 1% of the measurements traditionally required for Nyquist sampling. Thus this approach allows for a significant reduction in the hardware resources needed for wideband spectrum sensing while maintaining rapid and continuous spectral awareness.

Session 3A9
Density Functional Theory and Its Applications to Nanomaterials

Thermally-assisted-occupation Density Functional Theory (TAO-DFT)

Jeng-Da Chai
Department of Physics, National Taiwan University, Taipei 10617, Taiwan

Abstract— In this talk, I will briefly describe the formulation of our recently proposed thermally-assisted-occupation density functional theory (TAO-DFT) [1] and the density functional approximations to TAO-DFT [2]. In contrast to Kohn-Sham DFT, TAO-DFT is a DFT with fractional orbital occupations given by the Fermi-Dirac distribution (controlled by a fictitious temperature), for the study of large ground-state systems with strong static correlation effects. Relative to TAO-LDA (i.e., the local density approximation to TAO-DFT), TAO-GGAs (i.e., the generalized-gradient approximations to TAO-DFT) are significantly superior for a wide range of applications, such as thermochemistry, kinetics, and reaction energies. For noncovalent interactions, TAO-GGAs with empirical dispersion corrections are shown to yield excellent performance. Due to their computational efficiency for systems with strong static correlation effects, TAO-LDA and TAO-GGAs are applied to study the electronic properties of acenes with different number of linearly fused benzene rings (up to 100), which is very challenging for conventional electronic structure methods. Some interesting results will be presented in this talk.

Ensemble Formalism of the Orbital-free Density Functional Theory

Á. Nagy
Department of Theoretical Physics, University of Debrecen, Debrecen, Hungary

Abstract— There are two ways to perform density functional calculations: solving the Kohn-Sham equations or the Euler equation. Nowadays mainly the Kohn-Sham equations are utilized. This scheme has the disadvantage that there are several equations for systems with a lot of electrons. The Euler equation, on the other hand, is a single equation, independently on the number of electrons of the system under study. Naturally, the solution of a single equation instead of several Kohn-Sham equations leads to a huge simplification. That explains the growing interest in orbital-free methods. The reason for the fact that the orbital-free scheme is not so popular lies in the lack of accurate approximation for the kinetic energy functional. Here, a way avoiding the kinetic energy functional problem is presented.

Ensembles are constructed in the ground-state non-interacting density functional theory [1–4]. Ensemble Euler equation is derived from the ground-state non-interacting Euler equation. It can be formulated as a one-particle Sccrödinger-like equation for the square root of the ensemble density. The potential in this equation is the sum of the original Kohn-Sham potential plus the ensemble Pauli potential. The latter satisfies a first-order differential equation. The true electron density can be easily obtained from the ensemble electron density. The properties of the ensemble electron density will be presented.

Plasmon Excitations in Na Nanoparticles and Graphene Studied by Time-dependent Density Functional Calculations

Guang-Yu Guo
Department of Physics, National Taiwan University, Taipei 10617, Taiwan

Abstract— Plasmon, a collective type of electronic excitations generally featured by metallic systems, has been an old topic in physics. However, the prominent outlook of plasmonics for various applications in nanotechnology has stimulated its intense studies in recent years. Previous theoretical and experimental investigations on plasmons in metal nanostructures have mainly been focused on the Mie surface plasmons, as opposed to volume plasmons which cannot be optically excited in extended bulk metals. However, volume plasmons in small metal nanoclusters and graphene nanoflakes have been theoretically and experimentally shown to be significant. Furthermore, in nanoscale size regime, quantum plasmons could have distinct behaviors that are different from classical plasmons.

In this talk, I will report our recent quantum mechanical calculations of plasmon excitations in quantum-sized neutral Na clusters [1] and also in graphene [2]. Our theoretical calculations are based on linear-response time-dependent density functional theory. In particular, the optical absorption spectrum, density response function and static polarizability of the Na clusters are evaluated [1]. The π- and $\pi + \sigma$-plasmon dispersions in graphene are calculated and compared with electron energy loss spectroscopy [2].

First-principles Simulation of Real-time Electronic Dynamics on Surfaces of Materials

Rulin Wang[1, 2], **Dong Hou**[1], **and Xiao Zheng**[1]

[1]Hefei National Laboratory for Physical Sciences at the Microscale
University of Science and Technology of China, Hefei, Anhui 230026, China
[2]Beijing Computational Science Research Center, No. 3 He-Qing Road, Beijing 100084, China

Abstract— Understanding the electronic dynamics on material surfaces or at interfaces of adsorbate-surface systems is crucially important to a variety of applications in physics and chemistry, such as photovoltaic conversion, heterogeneous catalysis, and scanning tunneling microscopy. However, theoretically it is very challenging to simulate the electronic dynamics at material surfaces/interfaces at atomic level. One major difficulty is that the conventional first-principles methods, particularly those based on the time-dependent density-functional theory (TDDFT), were developed mainly for isolated or periodic systems, while the surface of bulk material has an open boundary and is thus beyond the realm of conventional TDDFT methods [1, 2].

To overcome the above difficulty, we develop a practical TDDFT approach for systems with open boundaries [3]. Our novel TDDFT approach is based on a combined Padé and Lorentzian decomposition scheme for resolving the energetic structure and memory content of bulk material environment. A hierarchy of equations of motion is constructed, which accurately characterizes the real-time electronic response to local potential perturbations at material surfaces/interfaces. The new practical approach for open systems thus greatly extends the applicability of TDDFT.

The accuracy and practicality of our novel TDDFT approach is exemplified by simulations on two prototypical systems: (1) the dynamic relaxation of an excess electron on the two-dimensional surface of a graphene monolayer, and (2) the real-time electron transfer at the interface of a molecule-graphene complex. Both the transient and long-time asymptotic dynamics are examined. The numerical results clearly affirm the correctness and usefulness of our open-system TDDFT approach. The simulations also provide important insights into the characteristic features of temporal electron evolution and dissipation on surfaces of bulk materials.

Application of Density Functional Theory Combined with Lippmann-Schwinger Equation to Thermoelectric Properties in Atomic/Molecular Junctions from First Principles

Yu-Chang Chen[1, 2]

[1]Department of Electrophysic, National Chiao Tung University, Hsinchu, Taiwan
[2]National Center of Theoretical Science, National Chiao Tung University, Hsinch, Taiwan

Abstract— Thermoelectric nanojunctions for use in the development of new forms of energy-conversion devices at the nanoscale have attracted rapidly growing attention. Thermoelectric nanojunctions consist of a nano-structured object sandwiched between source-drain electrodes. As the Seebeck coefficients are relevant not only to the magnitude but also to the slope of density of states (DOSs), it is of key importance to investigate the details of electronic structures in thermoelectric nanojunctions. Electronic structures offered by sized reduction thereby provide new opportunities and challenges for exploring new forms of nanoscale renewable energy system. Due to the relatively small sizes of junctions, the nature of electron transport are characterized by coherent wave functions. To calculate the wave functions in atomic/molecular junctions, density-functional theory (DFT) combined with Lippmann-Schwinger equation (LS) is applied to investigate non-equilibrium electron transport and thermoelectric properties. Firstly, we will briefly present an introduction for DFT+LS theory for nanoscale junctions formed by atoms/molecules sandwiched between bimetallic electrodes. We then focus on how we apply LS+DFT to investigate the Seebeck coefficients in atomic/molecular junctions from first-principles approaches. To gain further insight into the quantum transport of electrons and energy under nonequilibrium conditions, we investigate effects of electron-vibration interactions on the Seebeck coefficient and the figure of merit ZT. We also propose several atomic-scale thermoelectric devices, such as nano-refrigerators, power generators, and self-powered atomistic transistor.

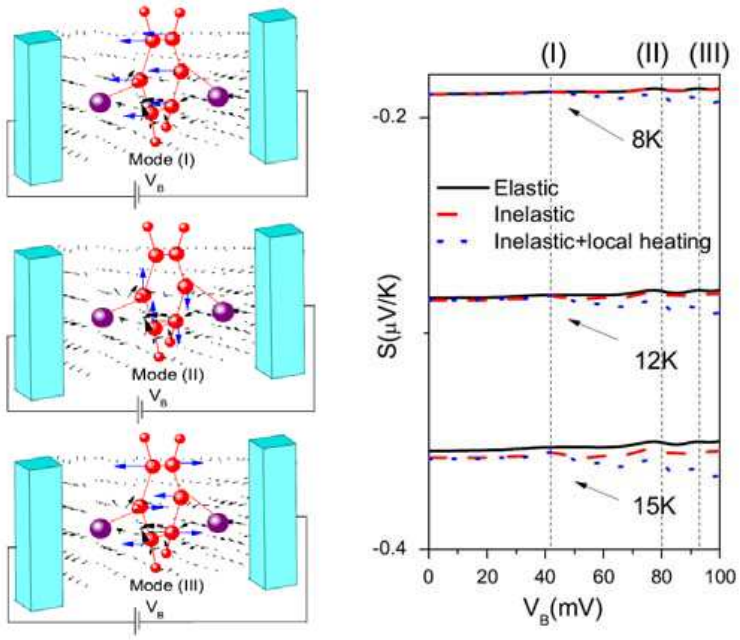

Figure 1: Inelastic Seebeck coefficients due to electron-vibration interactions.

Exchange-correlation Functionals from the Strongly-interacting Limit of DFT

Francesc Malet Giralt[1], **A. Mirtschink**[1], **C. B. Mendl**[2], **J. Cremon**[3], **S. M. Reimann**[3], **and P. Gori-Giorgi**[1]

[3]Mathematical Physics, Lund University, Sweden

Abstract— The strongly-interacting limit of the Hohenberg-Kohn functional is represented by a reference system that is the opposite counterpart of the non-interacting Kohn-Sham one. The properties of this strictly-correlated-electrons system can be used to build an exchange-correlation potential that is able to describe strongly-correlated effects without introducing any artificial symmetry breaking. We show applications of this method on semiconductor 1D quantum wires and 2D quantum dots.

Spin-polarized Transport through Single-molecule Magnetic Junctions

Chao-Cheng Kaun
Acad Sinica, Res. Ctr. Appl. Sci., Taipei 11529, Taiwan

Abstract— We investigate spin-polarized (SP) electronic transport properties and hybrid states of a single manganese phthalocyanine (MnPc) molecule adsorbed on a Co nanoisland, with the SP scanning tunneling microscopy measurements and the first-principles calculations. Our analyses show that the MnPc molecule can pin the Co surface state to the Fermi level, forming hybrid stationary spin resonance states which, with an antiparallel-magnetization tip, give a resonant SP conductance peak. Our calculations further reveal that as the tip approaches the molecule, electronic and magnetic couplings in the junction are tuned as the Zener indirect exchange coupling becomes prominent, which switches the conduction carriers from s to d electrons and leads to the tailored magnetic moments and magnetoresistance.

Theoretical Investigations on Band Gaps of Extended Systems

T. Tsuneda
Fuel Cell Nanomaterials Center, University of Yamanashi, Japan

Abstract— The difference between fundamental and optical band gaps is presented by comparing the excitation energies and corresponding orbital energy gaps of extended systems. In solid state physics, optical band gaps are significant to investigate the electric conductivity of semiconductors. These have often been evaluated as HOMO-LUMO gaps in band structure calculations by neglecting excitonic effects, which are electron-hole interactions through Coulomb-exchange-correlation integral kernels called Landau interactions. To figure out the excitonic effects, we compared the time-dependent Kohn-Sham (TDKS) excitation energies and corresponding orbital energy gaps of extended systems: all-trans polyacetylenes, linear oligoacenes, symmetric graphenes, and fullerenes. Calculated results showed that the difference is significant when long-range exchange interactions are properly involved, though long-range exchange interactions should be incorporated to obtain accurate charge transfer excitation energies [1, 2]. We also performed spin-flip (SF) TDKS calculations [3] to make clear the effects of double excitations. As a result, we found that double excitations become significant especially in long oligoacenes and large fullerenes, though the SF-TDKS method is found to considerably underestimate the excitation energies for the excitations from HOMO.

The Effect of Nitrogen-doping and Mechanical Strain on the Enhanced Visible Light Absorption of Anatase TiO_2

Chin-Lung Kuo
Department of Materials Science and Engineering
National Taiwan University, Taipei, Taiwan

Abstract— Atomic-level control and determination of the electronic band gaps of the semiconductor-based photocatalysts such as TiO_2 is of great importance for their applications in the challenging photo-electrochemical water splitting reactions using sunlight. Due to the relatively large band gap of TiO_2, only a small portion of the solar spectrum in the UV light region can be absorbed to excite electrons from the valence band top region to the conduction band edge of TiO_2 to generate photocurrents for use in photocatalytic reactions. Therefore, many research efforts have been made to extend the absorption edge of TiO_2 to the visible light part of the solar spectrum to increase its photocatalytic efficiency under sunlight. Currently, one main strategy to achieve this goal is to dope TiO_2 with various transition metals or non-metal elements to effectively narrow down the electronic band gap of TiO_2. In particular, N-doped TiO_2 has recently become one of the most popular and widely investigated systems in the field of photocatalysis since Asahi et al.'s experiment in 2001. Nevertheless, the physical origins of the enhanced visible-light absorption of the N-doped TiO_2 remain unclear to date and many critical issues are still under intensive debate.

In the first part of my talk, I will briefly introduce our recent work on studying the effect of nitrogen doping on the enhanced visible-light absorption of anatase TiO_2. Regarding this aspect, we have performed first principles calculations in conjunction with our newly developed method to investigate the long-term controversy regarding the effect of nitrogen doping on the electronic and optical properties of TiO_2. Our main focus here is to reveal whether the enhanced optical property is primarily attributed to the band gap narrowing of TiO_2 or that is simply induced by the excitation of the localized states within the electronic band gap. Moreover, we are also interested in finding out if there is any other possible origin for the redshift-like behavior of the light absorption edge, such as the O vacancy and H impurities in the TiO_2 bond network. In the second part of this talk, I will present our previous work on modulating the electronic properties of anatase TiO_2 via imposing a uniaxial/biaxial strain. Based on first principles calculations, we have explored the effects of mechanical strains on the electronic band gaps, VBM/CBM positions, and the effective masses of holes and electrons in anatase TiO_2. Our calculations showed that the effective masses of charge carriers and the band gap of TiO_2 can be effectively modulated by imposing mechanical strains along certain directions. This result also suggests that epitaxial growth of TiO_2 on some selected substrates/processing conditions could be a promising route toward enhancing the charge carrier mobility and the visible light absorption in anatase TiO_2.

Simulating Nuclear Quantum Effects on the Fly with DFT

Jian Liu
Institute of Theoretical and Computational Chemistry
College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, China

Abstract— The norm-mode analysis is useful for near-harmonic systems but does a poor job when nuclear quantum effects become significant for anharmonic molecular systems. We have recently combined quantum dynamics and thermodynamics methods (path integral Liouville dynamics and path integral molecular dynamics) on the fly with DFT and TD-DFT to study several types of spectra (such as IR, Raman, electronic absorption, fluorescence spectra) of molecules in gas phase and in solution. The traditional approaches — employing the norm-mode analysis around the optical structure and/or *ab initio* molecular dynamics are often inadequate for describing these spectra in a consistent way. Comparison to experimental data reveals that nuclear quantum effects can sometimes be important in these spectra.

Application of Graphene Dopants to Anodes of Dye-sensitized Solar Cells

Yu-Chao Wang and Chun-Pei Cho
Department of Applied Materials and Optoelectronic Engineering, National Chi Nan University, Taiwan

Abstract— Graphene oxide could be successfully reduced to graphene using autoclave, and this has been demonstrated by the results of Raman, XRD and XPS analyses. Graphene was doped into TiO_2 electrode, which was applied to DSSC to improve device performance. It has been discovered that appropriate graphene doping could enhance dye adsorption and absorption of visible light. The optimum ratio of graphene doping in TiO_2 was $0.005:1$. Furthermore, it was demonstrated that three-layer graphene-doped TiO_2 covered on FTO conductive substrates would be better than two- or one-layer graphene-doped TiO_2 and could achieve an optimum DSSC performance. Graphene was favorable for dispersion of TiO_2 nanoparticles and reduction of electrolyte by the dye, leading to improved electron transfer at the interface and decreased probability of electron-hole recombination. The path and time of electron transport were thereby reduced. Nevertheless, excessive graphene doping resulted in non-uniform dispersion of TiO_2 nanoparticles and reduced specific surface area and amount of dye adsorption. This could cause lower photocurrent density and DSSC performance. In this study, the most optimized ratio of graphene doping in TiO_2 has been ascertained.

Microwave Tomography Technique for Concrete Diagnosis

Z. Meng
Fukuoka Univercity, Japan

Abstract— Concrete is a very fantastic construction material and concrete buildings occupy over than 30% of whole buildings of office, hotel, and facilities for education and employee welfare. However, concrete can be damaged by fire, aggregate expansion, sea water effects, bacterial corrosion, calcium leaching, physical and chemical damage, and many incidents, such as falling concrete, happen all over the world. Because some of the degradation could also occur unseen in concrete, techniques for concrete diagnosis are needed in construction industry. Radiography is one of well-known non-destructive inspection techniques with very high precision, but human health risk is involved and applicable location is limited. On the other hand, Reinforced Concrete Radar is developed for concrete diagnosis. The device radiates electromagnetic waves to a target and receives the waves scattered by surface of the target as well as reinforcing steel bars, cavities, or other objects in the target body. However, in practice it is difficult to comprehend and interpret the scattering waveforms shown on screen of the device directly.

Microwave tomography is a hopeful technique for concrete diagnosis. The distributions of permittivity ε, magnetic permeability μ and conductivity σ of a concrete body are computer-reconstructed by making use of measured data of scattering waves. For example, a cost-function

$$Cost(\varepsilon,\mu,\sigma)=\frac{\|\mathbf{E}_{\text{measured}}-\mathbf{E}_{\text{estimated}}(\varepsilon,\mu,\sigma)\|}{\|\mathbf{E}_{\text{measured}}\|}$$

is introduced, where the $\mathbf{E}_{\text{measured}}$ is measured scattering wave by a receiver, and $\mathbf{E}_{\text{estimated}}(\varepsilon,\mu,\sigma)$ is the scattering wave estimated by using wave scattering analysis technique, such as FDTD method, and then ε, μ and σ are estimated by minimizing the $Cost$. Unlike common case of inverse scattering problems, usually a target of concrete diagnosis cannot be separated from concrete structure body and taken into a radio wave dark room for measurement. This is why it is so important in microwave tomography technique for concrete diagnosis how to determine the area of scattering analysis and use measured data of scattering wave effectively.

In this paper, "Successive Estimation Technique" is introduced for concrete diagnosis, which is an iteration method reconstructs the target part by part automaticly. Intuitive tomography images of concrete targets are shown in numerical experiments.

DC Impedance Tomography in Anisotropic Media

Abstract— Many rocks and layered/fractured sequences have a clearly expressed electrical anisotropy although it is rare in practice to incorporate anisotropy into low frequency impedance tomography to reconstruct the resistivity structure of the subsurface. Most DC electric inversions are based on the assumption of medium isotropy. In this study we develop a 2.5D anisotropic impedance tomography algorithm using a novel Gaussian quadrature grid forward modeling approach, valid for arbitrary surface topography and the most general class of medium anisotropy. We perform a series of 2.5D synthetic inversion experiments for various electrode configurations and 2D models (tilted transversely isotropic solids) to recover the spatial variations of the longitudinal and transverse resistivities as well as the tilt angles of the local the plane of isotropy. We examine and compare the image reconstructions obtained using the correct anisotropic inversion code to those obtained using the false but widely used isotropic assumption. Superior reconstruction in terms of reduced data misfit, true anomaly shape and position, and anisotropic parameters were obtained when the correct anisotropic assumption was employed for medium to high coefficients of anisotropy. However, for low anisotropy coefficient values the isotropic assumption produced slightly better-quality results because the problem is better determined with fewer unknown parameters to recover. When an incorrect isotropic inversion is performed on medium to high level anisotropic data the images are dominated by patterns of banded artefacts and high data misfits. Various pole-pole, pole-dipole and dipole-dipole data sets were investigated and the inversion images compared against the true model. Eigen spectra analysis of the pseudo Hessian matrix was performed along with computation of the model relative resolution matrix to determine and contrast in a quantitative sense the information content and goodness of the results. We also present a data selection strategy based on high sensitivity measurements which drastically reduces the number of data to be inverted but still produces comparable results to that of the comprehensive data set. Inversion was carried out using transversely isotropic model parameters described in two different co-ordinate frames for the resistivity tensor viz. Cartesian versus natural or eigen frame. The Cartesian frame provided a more stable inversion product. This can be simply explained from inspection of the differing sensitivities for the two model descriptions.

Non-contact Measurements of Power-line Currents Using the External Magnetic Field

F. Ghasemifard, M. Johansson, and M. Norgren
KTH Royal Institute of Technology, Sweden

Abstract— With the on-going development into more complex and controllable power grids, monitoring of voltages and currents at different locations in the grids becomes of increasing importance. In a non-contact measurement setup the voltages and currents are determined indirectly by measuring the extraneous electric and magnetic fields. This study concerns the inverse source problem of determining the currents in a parallel conductor structure, e.g., a power line or a bus bar, from the magnetic field, measured in a finite number of points. The method we have developed is capable of handling disturbance field from external sources, by modelling the external field as an expansion into spherical harmonics. Hence, the field in the different measurement points becomes a linear combination of the expansion coefficients and the currents to be determined. For situations with a finitely conducting ground below the currents, a model of the conductivity in the ground can also be included into the method. For a given level of Gaussian measurement noise, the theoretically attainable standard deviation in the reconstructed currents is quantified using the Cramer-Rao bounds (CRB). It turns out that a direct inversion of the linear system yields results exceeding the CRB with about two orders of magnitude; a consequence of the illposedness of the problem. To remedy this, we have employed Tikhonov regularization, where the regularization parameter is determined using the L-curve criterion, which results in reconstructions about one order above the CRB. Our numerical results show that with a signal to noise ratio of 30 dB, the currents can be reconstructed with accuracy better than five percent. Interestingly, when applying regularization, the incorporation of the model of the ground does not significantly improve the results, which indicate that the spherical harmonic expansion is in practice sufficient; in practice one does not need to know the ground conductivity.

Auto-focused Imaging of a Moving Target Using an Ultra-wideband Array Radar

T. Sakamoto[1], **T. Sato**[2], **P. Aubry**[3], **and A. Yarovoy**[3]

[1]University of Hyogo, Japan
[2]Kyoto University, Japan
[3]Delft University of Technology, The Netherlands

Abstract— Recent terrorist threats necessitate the development of new measures for the prevention of future attacks, especially in public places such as airports. One such measure is the adoption of ultra-wideband radar body scanners. Many commercial body scanners employ a mechanical scanning antenna array, and passengers are asked to remain stationary for a period of seconds during measurement. For a moving target, however, the resultant image is blurred, which prevents quick and convenient passenger screening.

To prevent such blurriness, the motion of the target must be compensated for. However, it is not an easy task to estimate this motion because the antenna scans while the target is moving at an unknown speed. In addition, the target shape is unknown, which makes the reflection point sweeping on the target surface unpredictable. The conventional Doppler-based speed estimation is thus not valid in such a case.

This paper demonstrates the imaging of moving targets using a scanning one-dimensional array ultra-wideband radar system. We apply a fast radar imaging algorithm, referred to as revised range point migration, to quickly obtain multiple images for various target speeds assumed. We then select one of the images according to a certain criterion. The size of the image focus cannot be adopted for the criterion because the image of a finite-sized target such as a human body does not necessarily focus on a small area. Therefore, we exploit prior knowledge about human bodies to estimate the target speed accurately, and realize auto-focused radar imaging of a moving target. A measurement using a mannequin on a moving platform is conducted to demonstrate the effectiveness of the proposed approach.

Gradient-based Inverse Scattering Approach Using Only Total Electric Field Data

Toshifumi Moriyama, **Toshiyuki Tanaka**, **and Takashi Takenaka**
Graduate School of Engineering, Nagasaki University
1-14 Bunkyo-machi, Nagasaki 852-8521, Japan

Abstract— We consider image reconstruction of an object imbedded in a homogeneous medium. The object is successively illuminated by fields generated from several primary sources. The data of the total field as the sum of incident and scattered fields is collected on an observation surface for each illumination. By using these total field data, inverse scattering reconstructs the image of the object. Most inverse scattering methods assume a priori information on incident field generated by a transmitting antenna. In near-field measurement situations, incorporation of antenna modeling into numerical simulation of scattering by the object is preferable to take account of incident field accurately. In our previous work [1], we have proposed an inverse scattering approach which uses only total electric field data on an observation surface and does not assume the incident field information. This results in reduction of the calculation complexity. We set up an interior boundary value problem in which the solution is the same as that of the original scattering problem in the region Ω interior to the observation surface S enclosing the object. The boundary value is given by the tangential components of total electric field of the original scattering problem on the surface S. The data of the total electric field on S is collected till the time $t = T$ when the electromagnetic fields disappear almost entirely in the interior region Ω. Then, the electromagnetic field $\mathbf{u}(\mathbf{r}, t)$ of the equivalent boundary value problem is also null after $t = T$. If the material in the interior region is different from that of the original problem, the field $\mathbf{u}(\mathbf{r}, t)$ of the boundary value problem does not become null at $t = T$. Therefore, the value of $\mathbf{u}(\mathbf{r}, t)$ at $t = T$ can be used as an indicator of misfit between an estimated and the original objects. The inverse scattering problem considered here is cast as an optimization problem where the cost functional consisting of the stored energy in the interior region Ω at $t = T$.

It was demonstrated that the proposed method can estimate the locations and sizes of homogeneous scatterers in the region of interest by using a genetic algorithm (GA) as an optimization tool to minimize the cost functional [1]. Since GA cannot deal with many unknowns, it is difficult to reconstruct the electrical parameter's distributions of inhomogeneous object. In this paper, we apply a gradient-based optimization method to the proposed inversion method instead of GA and examine a reconstruction of inhomogeneous object. Numerical examples show the effectiveness of the method.

The Hollow Detection in the Concrete Wall Using 2D-FBTS Method from Real Data

Toshiyuki Tanaka, **Yuki Tanaka**, **Toshifumi Moriyama**, **and Takashi Takenaka**
Department of Electrical and Electronic Engineering, Graduate School of Engineering
Nagasaki University, Nagasaki 852-8521, Japan

Abstract— Concrete radar is used the detection of a rebar or a hollow in concrete structure. The existence of a rebar or a hollow is found easily using concrete radar. But we don't estimate the size, the position and the electric constant of the object. To estimate these values inverse scattering analysis is required. One of them is Forward-Backward-Time-Stepping Method (FBTS method). According to FBTS method, the distributions of the electric parameter of unknown objects are clarified.

In this paper, the imaging of concrete wall from real data is discussed. The reconstruction of concrete wall is performed by comparison between measured data and estimated field calculated by FDTD. Three-dimensional analysis is necessary to reproduce observation data by numerical analysis exactly. However, 2D-FDTD is used approximately to make computation time short. A transmitter and a receiver are arranged at both side of concrete wall respectively. Dielectric loading Vivaldi antennas are used for a transmitter and a receiver. In 2D-FDTD, as the shape of antenna can be not incorporated, it is incorporated in program as directivity function. Also, the directivity function is decided by the amplitude of electric field that was observed with a homogeneous concrete wall. Furthermore, the incident current source is decided so that the observation wave shape propagating the homogeneous concrete wall becomes the third derivative shape of Gaussian function with center frequency 2 GHz. The thickness of the concrete wall to explore is 10 cm, and a cylindrical hollow of 5 cm in diameter exists in the concrete wall. As the number of transmitting point and receiving point is 5 respectively, the number of the total data is 25. It is shown to have succeeded in the reconstruction of a cylindrical hollow from measured data by using 2D-FBTS method which incorporated antenna's directivity.

Exploiting a Sparsity Enhanced Microwave Imaging Approach for Non-destructive Evaluation

M. Bevacqua[1], **L. Crocco**[2], **L. Di Donato**[3], **and T. Isernia**[1]

[1]DIIES, University 'Mediterranea' of Reggio Calabria, Italy
[2]IREA, CNR, Naples, Italy
[3]DIEEI, University of Catania, Catania, Italy

Abstract— Compressive Sensing [1, 2] (CS) has recently become a relevant paradigm in the signal processing and recovery community, due to the possibility of overcoming the Nyquist criterion or to achieve "superresolution" in a number of recovery (and imaging) problems. CS theory is based on the concept of "sparsity" of the unknown function, i.e., on the possibility of representing the unknown by means of a limited number of nonzero coefficients with respect to a given basis. Then, CS theory guarantees an accurate reconstruction of the unknown, even if the number of data is much lower than the overall number of coefficients.

In inverse scattering problem the number of available data is limited, but in many applications it is possible to assume that the unknown function is sparse. As such, the CS theory could improve the accuracy of inversion techniques and/or drive the design of simpler and cheaper measurement set-ups. In this respect, non-destructive evaluation (NDE) via microwave imaging is a particularly relevant case, since localized anomalies are sought for in the imaging problem and the reduction of the complexity of the hardware is an important goal. Unfortunately, a fundamental difficulty exists, since CS theory is well developed for the case of linear problems, while inverse scattering is generally cast through a non-linear (ill-posed) problem. Again this is especially true in NDE, where often the target is an air gap (hosted in an electrically dense medium) and possibly more damages may occur and have to be revealed.

In this contribution we present a new inversion approach [3–5], which allows an effective application of CS theory for microwave imaging without neglecting the underlying no-linear nature of the problem.

Near-subsurface Imaging with a Single Frequency Scanner

C. Eyraud[1], **A. Litman**[1], **H. Tortel**[1], **M. Sobrero**[1], **and F. Daout**[2]

[1]Aix-Marseille Université, CNRS, Centrale Marseille, Institut Fresnel UMR 7249, Marseille 13013, France
[2]IUT/UFR SITEC Ville d'Avray, 50 rue de Svre, Ville d'Avray 92410, France

Abstract— Probing the near-subsurface is a very challenging problem. The usual methods consist in prob- ing the soil with temporal techniques, i.e., directly with a temporal pulse or with a synthetic pulse using a step-frequency acquisition. These techniques are widely exploited since several years, but they may present some limitations. Indeed, the main advantage of these approaches — the possibility to remove the contribution of the interface — fails for near-surface probing when the target echo is in the temporal ambiguity with the interface echo. Moreover natural soil consists of heterogeneous media having different types of dispersion relationships with respect to the frequency.

Within that framework, we thus propose an original approach, where we analyze the capabilities of a mono-frequency/multistatic setup for imaging shallowly buried targets. We have shown the possibility to perform such an imaging in a previous study working with equivalent media — composed by foams charged with carbon particles. Our study is now conducted with a realistic embedding medium composed of silica sand. In the present contribution, we moreover focus on the available information which can be acquired in such configuration and propose some strategies to gather the maximum amount of it. The measured fields are post-processed with an efficient method which takes benefit from the spectral bandwidth properties of the scattered field. The calculated fields are performed with a home-made Finite Element Method software. Efforts are put to precisely modelize the real configuration. In particular, an accurate method for modeling the antennas behavior using a balanced set of elementary sources has been developed. Imaging results of the near-subsurface from numerical and experimental fields are then fulfill with the E-DORT method — an extension of the DORT method to elongated targets. This qualitative and fast imaging procedure, which exploits the spectral properties of the multistatic scattering matrix, has been adapted to the present stratified configuration. The resulting images will be presented at the conference.

Microwave Imaging of Dispersive Scatterers Using Vectorial Lagrange Multipliers

T. G. Papadopoulos[1], **T. I. Kosmanis**[2], **and I. T. Rekanos**[1]

[1]School of Electrical and Computer Engineering, Aristotle University of Thessaloniki, Greece
[2]Department of Automotive Engineering
Alexander Technological Educational Institute of Thessaloniki, Greece

Abstract— A time-domain microwave imaging method is proposed for the reconstruction of the spatial distribution of the electromagnetic properties of dispersive scatterers. The method is based on the minimization of a cost function, which describes the discrepancy between measured and estimated scattered field data. The Maxwell's curl equations satisfied by the electromagnetic field are introduced in the augmented cost function, as equality constraints, via vectorial Lagrange multipliers. By means of the calculus of variations and the stationarity condition, it is shown that the vectorial Lagrange multipliers are the solution of the adjoint scattering problem subjected to the Sommerfeld's radiation condition. Moreover, the Fréchet derivatives of the cost function with respect to the distributions of the scatterer properties are derived analytically. It should be mentioned that their evaluation involves the solution of the adjoint scattering problem. As a result, the Fréchet derivatives obtained can be utilized by any gradient-based optimization technique that updates the estimated scatterer properties iteratively. Also, it is possible to apply any time-domain computational electromagnetics method to compute the estimated scattered field data (direct scattering problem solution) as well as the vectorial Lagrange multipliers (adjoint scattering problem solution). In this study, two cases of dispersive scatterers have been investigated. The first case concerns Debye scatterers where the spatial distributions of the electromagnetic properties of the medium, namely the relaxation time, the static and the optical permittivity, are reconstructed simultaneously. In the second case, the method is applied to the reconstruction of the resonant frequency, the damping factor, the static and the optical permittivity of Lorentz dispersive media. The implementation of the proposed microwave imaging method has been based on the finite-difference time-domain method and the Polak-Ribière conjugate gradient optimization algorithm.

Analysis of Radiation from X-band Slotted-waveguide Antenna Arrays Using the Parallel DDA-FE-BI-MLFMA

Xu-Min Sun, **Ming-Lin Yang**, **and Xin-Qing Sheng**
Center for Electromagnetic Simulation, School of Information Science and Technology
Beijing Institute of Technology, Beijing 100081, China

Abstract— The slotted-waveguide array antennas are widely used in real-life applications because of their small size, light weight, compact structure, high efficiency, and low side lobe characteristics. Due to their importance, various methods have been developed to compute the radiation from slotted waveguide antennas, such as the variational approach in terms of equivalent network, the method of moments (MoM), the finite-difference time-domain (FDTD) method, the finite element method (FEM) and the hybrid finite element-boundary integral (FE-BI) method. However, previous researches only study on radiation by a single slot in a waveguide, 1-D slotted-waveguide arrays or small 2-D slotted-waveguide arrays in a planar surface. Full-wave analysis for radiation from a 3-D X-band slotted-waveguide antenna array still faces great challenges due to the electrically large size, large amounts of tiny slots in the narrow wall of each waveguide and mutual coupling between two close slotted-waveguides through the inner interior the exterior free space of the waveguide.

We adopted in this paper, the finite element-boundary integral-multilevel fast multipole algorithm (FE-BI-MLFMA) for fast and accurate computation of radiation from large slotted-waveguide antenna arrays. To simplify the calculation, for each single slotted-waveguide, a short and infinitesimally thin current probe is used as the front-end excitation. A perfectly matched layer (PML) is used to terminate end of the waveguide port and absorb the reflected wave from the antenna without any spurious reflection to make each slotted-waveguide antenna work in the travelling wave mode. In a slotted-waveguide antenna array, each slotted-waveguide antenna can be generally considered as a single sub-domain. Hence the domain decomposition algorithm (DDA) can be applied to reduce computation resource and achieve a higher efficiency. To validate the presented method for characteristic study of radiation from slotted-waveguide antenna arrays, numerical results of radiation patterns for a slotted-waveguide array antenna are presented together with the results from the commercial software CST. Good agreement can be observed between the computed results by our DDA-FE-BI-MLFMA and the CST. To show capability of the proposed parallel DDA-FE-BI-MLFMA, a large X-banded slotted-waveguide antenna array contains eighteen waveguides with Taylor amplitude and inverse phase excitation is designed and its radiation patterns are studied with the DDA-FE-BI-MLFMA.

Scattering of a Gaussian Beam by an Ellipsoidal Particle with Vectorial Complex Ray Model

K. F. Ren
CORIA — UMR 6614, Normandie Université, CNRS, Université et INSA de Rouen
675 Av. de l'Université, BP 12, 76801 Saint Etienne du Rouvray, France

Abstract— The numerical prediction of the scattering properties of electromagnetic waves or light by objects of complex shape and of size much larger than the wave length has being always a great challenge in both the filed of electromagnetic computation or light interaction with particles. Among a large number of theories, models and algorithms the methods based on the ray models seem the the most appropriate. But their precision is not often satisfactory because the wave properties (phase, divergence/convergence...) are not or not properly taken into account.

In the model developed by the author — Vectorial Complex Rays Model (VCRM) [1, 2], the aforementioned wave properties are counted correctly by introducing the wave front curvature as a generic property of rays. So VCRM improves considerably the precision of ray models. It has been validated by comparison with two rigorous methods: Lorenz-Mie theory for spherical particle and the Multilevel Fast Multipole Algorithm (MLFMA) [3] for the ellipsoidal particles. It is already used to the prediction of the scattering diagrams of the plane wave by large ellipsoidal particles [4] and the elliptical infinite cylinders [5]. It has also been applied to the scattering of a two dimensional Gaussian beam by an elliptical infinite cylinder at normal incidence. In this communication, the VCRM will be further extended to the scattering of a Gaussian beam by an ellipsoidal particle.

The amplitude, the phase and the wave front curvature of the incident Gaussian beam are considered in the model, but the diffraction has not yet taken into account. The developed code has been compared with the rigorous Generalized Lorenz-Mie Theory (GLMT) and we found that the agreement is perfect when the particle is on or near an incident Gaussian beam of waist radius smaller the particle radius accept in a very narrow forward direction angle. This is due to the diffraction effect to be considered in VCRM. Typical scattering diagrams will be exemplified in the presentation to show the new phenomena of scattering when an ellipsoidal particles is illuminated by a beam.

Sesquicentennial Year of Maxwell's Equations and Computational Electromagnetics

W. C. Chew
Department of Electrical and Computer Engineering
University of Illinois, Urbana-Champaign, USA

Abstract— This year is the sesquicentennial year of Maxwell's equations. Electromagnetics and Maxwell's equations have been instrumental in the conception of many electrical engineering and optical technologies. It the beginning, it was telegraphy, and rotating machineries. Over the years, Maxwell's equations have given rise to wireless communications, antennas, radar, masers, optics, and photonics.

An amazing feature of Maxwell's equations is that they are valid from subatomic length scale to galactic length scale. Therefore, they are valid over a vast frequency range where the wavelength could be very long as well as being very short. Furthermore, they are also valid in classical electromagnetics as well as in quantum electromagnetics. The validity of electromagnetic theory has been tested at many different length scales. It has been tested to a few parts in a billion. As a result, electromagnetic theory has impacted a whole sleuth of technologies in electrical engineering, optics, photonics, as well as in material science.

Because of the highly predictive value of Maxwell's equations, there is always a quest for their accurate solutions. Various methods to solve Maxwell's equations have been developed since the dawn of their discovery. With the advent of computers, the need for more accurate and robust solutions does not diminish, but indeed increases.

In this presentation, we will present the history of different solution methods in electromagnetic theory, ranging from analytic methods, to approximate methods, to numerical methods, namely, the computational electromagnetics methods. We will discuss some issues associated with computational electromagnetics in solving Maxwell's equations and their enduring legacy. We will also discuss future directions in this area.

Scattering of a Cylindrical Wave by the End-face of an Ordered Waveguide System

Akira Komiyama
Osaka Electro-Communication University, Hatsu-cho Neyagawa-shi 572-8530, Japan

Abstract— A periodic grating scatters an incident plane wave only in discrete directions and the scattered wave is expressed as a sum of diffracted plane waves. At low grazing angle limit of incidence high order diffracted waves disappear and only the zero order diffracted wave with a diffraction amplitude of -1 remains. Nakayama has pointed out that the zero order diffracted wave cancels the incident wave and a dark shadow takes place [1]. On the basis of a shadow hypothesis a diffraction theory has been proposed by Nakayama [2]. In there the scattering factor has been introduced as an essential quantity and an integral representation of Green's function in terms of the scattering factor has been presented. So far, however, the execution of the integration is not reported.

An image fiber is composed of a large number of cores embedded in a single cladding, which is used to transmit directly an optical image. By illuminating the end-face of an image fiber with a laser beam a diffraction pattern reflecting the arrangement of cores can be simply observed. We can see experimentally that the diffraction pattern does not almost depend on the polarization of the laser beam. From a theoretical interest in the problem the scattering of a plane wave by the end-face of a waveguide system composed of a large number of cores has been analytically treated by the perturbation method [3]. The method is applicable to an infinite waveguide system.

In this paper the scattering of a cylindrical wave by the end-face of a two-dimensional ordered waveguide system composed of an infinite number of cores is analytically treated by the perturbation method and the behaviour of the scattered wave near the end-face is clarified.

Computation of Spheroidal Micro-organisms Cross Sections Using the Aperiodic Fourier Modal Method

M. Abboud[1,2], **G. Granet**[1,2], **K. Edee**[1,2], **J. F. Cornet**[1,2], **and J. Dauchet**[1,2]

Abstract— It is well known that our society is facing numerous ecological challenges. Cultivation of photosynthetic micro-organisms within controlled environments such as photobioreactor processes is recognized today as a serious alternative to contribute to the CO_2 capture and to produce bio-diesel and bio-hydrogen.

In order to optimize convertion of light energy into chemical energy within the process of photosynthesis, we have to predict the light scattering properties, such as the absorption, scattering and extinction cross sections as well as the scattering diagrams [5].

Based on the rigorous solution of Maxwell's equations, Mie [4] has studied the scattering properties of the spherical particles when it is illuminated by a plane wave.

However, most micro-organisms are not spherical and differ by their size and shape parameters. Their scattering properties are significantly different from those of spherical scatterers. A better approximation of micro-organisms is to consider them as spheroidal particles. In order to deal with general shapes, the true geometry is replaced by a staircase approximation which allows to solve the corresponding scattering problem with the Fourier Modal Method (FMM) [6].

In this communication, we investigate light scattering properties of spheroidal particles with various sizes and complex refractive indexes. Our results are successfully compared with those obtained by Asano [1–3].

A Couple of Topics in Numerical Analysis of Diffraction by a Metal Grating Using Yasuura's Method of Modal Expansion

T. Matsuda[1], **X. Xu**[2], **and Y. Okuno**[3]

Abstract— In solving the problem of scattering or diffraction on a computer, we often encounter small issues. Assuming a numerical solution process of grating problems by Yasuura's method of modal expansion [1–7], we pick up a few of such issues or topics that require us to take some action. The issues taken up here are:

(1) Choice of modal functions: In the method we define an approximate solution in terms of a finite linear-combination of modal functions. We state our opinion on the choice of the set of modal functions because the effectiveness of the method depends strongly on the choice.
(2) Modification of the functions in approximation process: We fit the approximate solution to the boundary condition in the sense of least-squares. Because the grating problems are pseudo-periodic, we need to modify each function that appears to be periodic.
(3) Behavior of the Jacobian matrix: We employ the orthogonal decomposition of the Jacobian in solving the least-squares problem and the behavior of the matrix is important. We observe the behavior and add some comments.
(4) Refractive index of a metal: The index of a metal is of a great interest in application to plasmonics. Here we show a couple of examples of plasmon resonance absorption predicted by our computer program using four different values of gold index.

Although most of the topics taken here might have been discussed elsewhere, we should consider these old topics together with many similar subjects again now to make good use of them. This is because such matters, sometimes, are inadequately forgotten in today's progressed computer environment.

Dispersion Characteristic Analysis of Open Cylindrical Waveguide and Its Metalic Closed Model

P. Kelebekler[1] and N. Yener[2]

[1]Technical Education Faculty, Kocaeli University, Turkey
[2]Biomedical Engineering Department, Technology Faculty, Kocaeli University, Turkey

Abstract— In the study, complex dispersion characteristics of cylindrical plasma column open waveguide are obtained from method of moment by modeling the open waveguide with cylindrical plasma column loaded closed waveguide. The complex dispersion curves obtained from the exact solution and the MoM are presented correspondingly in the same figure.

Plasma called fourth state of matter is an ionized state of matter, which exists in universe and can be obtained artificially in the earth. Plasma medium is an anisotropic medium. But it is typically tackled under special conditions which transform anisotropic medium into isotropic medium. Thus supplies simplification in solutions. One of these simplifications is that the radian electron cyclotron frequency (ω_c) is taken zero, which is called plasma column with zero magnetic field in the literature. In our study, isotropic plasma medium with frequency depended permittivity, $\tilde{\varepsilon} = \varepsilon_0(1 - \frac{\omega_p^2}{\omega^2}) = \varepsilon_0\varepsilon_p$ is investigated by using the simplification. Where, ω is the angular frequency, ω_p is the radian electron plasma frequency and ε_0 is free space permittivity. The parametric values of the structure used for numerical computations are that plasma column radius (a) is 10 mm, azimuthal variation (m) is one and normalized plasma frequency (ω_p a/c) is 0.25.

In the study, the MoM based on the generalized telegraphist's equations is fundamental method. For the sake of analysis, cylindrical plasma column is enclosed with a metallic cylindrical frame, because the method gives in the most general solution cluster of closed waveguide structures. The method was used especially to obtain propagating modes for dielectric open waveguides in the literature.

The propagation constant of complex modes has real and imaginary part at the same time. Complex Dispersion curves generally indicate wide spectrum of dispersion characteristics involving forward waves, backward waves, damped waves and complex waves. The complex dispersion characteristics were presented in different studies for different structures as cylindrical dielectric rod loaded closed waveguide or two-lawyer circular shielding waveguide. In these studies, the common feature for complex modes is that they rise at frequency point in which the dispersion curve changes direction. In the view of this feature, the complex modes for the structure are investigated numerically in the neighborhood of these points from exact solution by using fsolve function in MATLAB. Besides, the studies which report the complex modes and complex dispersion curves of open waveguides are rather restricted in the literature. Consequently, major contribution of our study is that the complex dispersion curves of cylindrical plasma column open waveguide obtained from exact solution and also its closed waveguide model using the MoM are presented. Additionally, it is indicated by computing with different ratio of plasma column and metallic frame, that radius of waveguide metallic frame is getting wider, solutions obtained from the method is approaching the exact solutions in different figures.

Rigorous Coupled-wave Analysis of Plane-wave Scattering from Defected Lamellar Grating in Conical Mounting

Koki Watanabe
Fukuoka Institute of Technology, Japan

Abstract— Lamellar gratings are widely used for spectrographs, monochromators, laser tuning, integrated optics etc.. However, the fabrication of lamellar grating with nanometer scale has the potential to cause various defects, and the specification of defects influence on the diffraction efficiency is very important. On the other hand, the defects are artificially generated to change the physical properties of periodic structures. The principle of defects implementation is used in photonics crystals.

This paper proposes a spectral-domain approach to the electromagnetic scattering problem of defected lamellar grating in conical mounting. The fields in imperfectly periodic structures have continuous spectra in the wavenumber space, and the main problem of the spectral-domain approach is wavenumber sampling. The present approach introduces the pseudo-periodic Fourier transform (PPFT) [1]. The PPFT makes it possible to consider the scheme only inside the Brillouin zone because the transformed fields have a periodic property in terms of the transform parameter related to the wavenumber. Also, the transformed fields are pseudo-periodic in terms of the spatial parameters, and the conventional approaches to the periodic structures become possible to be applied for the scattering problem of imperfectly periodic structures. The present formulation is based on the rigorous coupled-wave analysis [2, 3] with the help of pseudo-periodic Fourier transform.

Three Dimensional Electromagnetic Simulations of Complex Scenes with FDTD Based Hybridization Method

J. Vincent[1], **P. Borderies**[2], **V. Gobin**[2], **and J.-R. Poirier**[1]

[1]Research Group in Electromagnetism, LAPLACE, Toulouse, France
[2]Electromagnetism and Radar Department, ONERA, Toulouse, France

Abstract— In this paper, we investigate the effects of multiple natural environments located in the far-field of a vertical electric current element at low frequencies. A three dimensional Finite-Difference in Time-Domaine based hybridization technique is used to compute the electromagnetic field around complex kind of environments remotely located from the radiating source.

Introduction: A recent study [1] shows the effects of natural environments in the near-field of low frequency antennas. The Finite-Difference in Time-Domain (FDTD) method was used to carry out these investigations. However FDTD is difficult to apply in large 3D areas because of the huge amounts of computational resources. A FDTD based hybridization technique was created in order to avoid these numerical problems and validated in [2]. The aim of this paper is to show the effects of natural environments on the surface wave propagation using the hybridization technique.

Computation of Natural Environments with 3D FDTD: Among the main existing natural environments, five scenes are proposed: a forest, a hill, a valley, a lake and a groundwater. Theses elements are created taking into account the cartesian grid used by the FDTD.

It has been shown that a forest can be represented by a dielectric slab for a frequency up to 100 MHz [3]. The values of the relative permittivity ε_r is 1.065 and the conductivity σ is $10^{-3}\,\mathrm{S{\cdot}m^{-1}}$. Dielectric blocs are stacked on each other in order to create a hill with an average slop and its dielectric constants are the same as the ground. The groundwater and the lake are freshwater reserves, the value of the relative permittivity ε_r is 80 and the conductivity σ is $5 \cdot 10^{-2}\,\mathrm{S{\cdot}m^{-1}}$.

Effects of Natural Environments in the Far-field: The current element emits at the frequency $f_0 = 100\,\mathrm{kHz}$ and the natural elements are located at 24 km $(8 \cdot \lambda_0)$ from the source. The hybridization technique provides 3D electromagnetic field mapping with and without the environment. Both are compared in order to determine the positive and negative effects on surface wave propagation.

Conclusion: This study shows the effects of multiple environments on the propagation of eletric field using a FDTD based hybridization technique. The effects of a lossy earth, including obstacles such as hills and forested areas are observed.

An Efficient Sinc-Collocation Domain Decomposition Method for Optical Waveguides Analysis

A. A. El-Mohsen[1], **A. M. Heikal**[1,2], **and S. S. A. Obayya**[1]

[1]Centre for Photonics and Smart Materials, Zewail City of Science and Technology Sheikh Zayed District
6th of October City, Giza, Egypt
[2]Department of Electronics and Communication Engineering
Mansoura University, Mansoura 35516, Egypt

Abstract— Since their development to solve differential equations boundary value problems [1], sinc numerical methods have attracted much attention. This is due to their incredible exponential rate of convergence $O(e^{-\gamma\sqrt{n}})$, γ is a positive constant. Along with domain decomposition methods, sinc numerical schemes can be developed to deal with problems which have discontinuous refractive index profiles. In this paper, a novel numerical scheme based on the sinc-collocation method is proposed for waveguides analysis. The domain of interest is decomposed into inner finite domains and outer semi-infinite domains. Patching domain decomposition is applied where the physical boundary conditions are matched at interfaces.For the finite domains, a much more convergence rate is achieved by using a double exponential transformation [2].

Mathematical Formulations: The wave equations used in each subdomain for H_x or H_y are as follows:

$$\nabla^2 H_\tau + k_0^2\left(n^2 - n_{eff}^2\right) H_\tau = 0, \quad \tau = x, y, \tag{1}$$

where $n_{eff} = \beta/k_0$ is the mode effective index, and β is the propagation constant. The field components H_x and H_y are expanded in each subdomain k as follows:

$$H_\tau^{(k)} = \sum_{i=-M}^{N}\sum_{j=-M}^{N} c_{ij}^{(\tau)} S_i^{(k)} S_i^{(k)}, \tag{2}$$

$$S_i^{(k)}(\tau) = \frac{\sin\left[(\pi/h_\tau)\left(\phi_\tau^{(k)} - jh_\tau\right)\right]}{(\pi/h_\tau)\left(\phi_\tau^{(k)} - jh_\tau\right)} \tag{3}$$

where $\phi_\tau^{(k)}$ is a suitable conformal map for each subdomain k.

Numerical Results: A standard rib waveguide structure whose cross section is shown in Fig. 1 will be analyzed. The rib width, W, is 2.0 µm, the rib height, $H = 1.1$ µm, and the outer slab depth, $D = 0.2$ m, and the operating wavelength is 1.55 µm. The refractive indices of the guiding, n_c, and substrate, n_s, regions are 3.44 and 3.34, respectively. The values of the effective index for fundamental quasi-TE and quasi-TM modes are 3.38876 and 3.8756 which accord well with the multi-domain spectral collocation method [3].

Research on Ka Rough Ocean Surface Channel Modeling Based on Stochastic Processes

Xiaodong Cao[1], **Xiaojun Wang**[1, 2], **and Tao Jiang**[1]

[1]College of Information and Communication Engineering, Harbin Engineering University, China
[2] Electrical and Computer Engineering Department, National University of Singapore, Singapore

Abstract— It is presented in this paper that a channel modeling technique based on GTD and stochastic bridge, which may boost the usage of low elevation angle Ka or higher frequency satellite down-link radio propagation prediction and estimation. First, it is introduced a random rough ocean surface modeling method under typical ocean states which is the foundation and the first step for electromagnetic simulation of telecommunication channel. Second, a huge data ocean surface reflection, scattering and diffraction based on GTD algorithm are calculated by high performance computer to provide a large number of samples for channel modeling. Third, a multipath channel model is set up to describe the statistical properties of received signal waveform which is modified by rough ocean surface. Last, all the steps are summed up and discussed to show the benefits of the presented modeling technique.

WLAN Based Indoor Locating Systems Enhanced by Ultrasonic Sensors; Hybrid Indoor Locater Systems (HILoS)

Selcuk Helhel, **Atalay Kocakusak**, **Yalcın Albayrak**, **and Sukru Özen**
Department of Electrical and Electronics Engineering, Engineering Faculty
Akdeniz University, Antalya 07058, Turkey

Abstract— In building location system requirements are growing very rapidly, since location information is a critical knowledge, for marketing and rehabilitation campuses as well as security applications. Instead GPS systems yield the highest location precision at outdoors; they are not available in indoor environments. Cellular based indoor location system is another possibility [1], and they proposed a method that uses accelerometer instead of mobile phone itself, but this solution is operator dependent and very expensive. Studies [2–4] present in the literature using Wi-Fi systems are examples of those indoor locating studies. Campos et al. [2] presented a system for multi-floor indoor positioning considering architectural aspects. They proposed a Data Correlation Method combined with neural network applications on them. They compared measured RSS levels by applying natural data clustering method and data correlation method.

Experimental results and literature tell us that While WiFi based systems get weak in case of close distance to transmitters, ultrasonic sensors respond much better in acceptable precise then the WiFi systems in that region. Similar way, they get worse by increasing distance. By the way, this paper focuses on enhanced indoor locating systems by ultrasonic sensors that offered system is called as Hybrid Indoor Locator.

New Intuitive Metrics for Diversity Performance Evaluation of Multi-element Antenna Systems

Vasileios C. Papamichael[1] and Petros Karadimas[2]

[1]Department of Electrical Engineering, Technological Educational Institute of Western Greece and Wireless Systems Performance (WiSPer), Patras 26441, Greece
[2]Department of Computer Science and Technology, University of Bedfordshire, Luton LU1 3JU, UK

Abstract— The mitigation of multipath fading is an issue of primary importance in wireless communications systems. Multi-element antenna (MEA) systems combat fading through diversity combining which potentially increases the received power. The performance evaluation of MEA system is quantified by the diversity gain (DG).

Until now, there have been proposed different metrics for the DG with the most important being the diversity antenna gain (DAG) [1], the effective diversity gain (EDG) [2] and the actual diversity gain (ADG) [3]. They are derived by comparing the cumulative distribution function (CDF) of the received signal-to-noise ratio (SNR) of the MEA and a reference antenna at a specific outage probability level (usually 1% outage probability level). Their only difference lies on the choice of that reference antenna. The DAG is based on comparing the MEA with an isotropic, dual polarized reference antenna and is thus a metric of universal applicability when deriving DG. The EDG arises by comparing the MEA with one of its single elements having 100% efficiency and the ADG by comparing the MEA with an arbitrarily selected antenna.

As the CDF just presents probabilities of specific SNR levels, DAG, EDG and ADG do not account for DG provided by a MEA system when only deep fades take place in one or more of the diversity branches. DG in such cases would be a better indicator of how effectively the MEA system combats fading. Thus, in this paper, three new intuitive metrics focusing on deep fade cases are proposed. The first is called *fading mitigation gain (FMG)* and accounts for the DAG when at least one of the diversity branches of the MEA system has *20 dB* less SNR with respect to the average received by the reference antenna SNR. It is thus a random variable. The second is called *reliability percentage (RP)* and accounts for the percentage of the cases when the MEA system has greater received SNR compared with that of the reference antenna. The third is called generalized *diversity antenna gain (GDAG)* and arises after weighting the two DAGs, i.e., the DAG (weighted by *RP*) when the MEA received SNR is greater than that of the reference antenna and the DAG (weighted by *1-RP*) when is lower. The MEA systems and propagation environments are jointly modeled by using the stochastic approach presented in [4].

A Practical Approach to Measuring Propagation Channel in the Spherical Vector Wave Domain

Y. Miao[1], **A. A. Glazunov**[2], **K. Haneda**[3], **and J. Takada**[1]

[3]Aalto University, Finland

Abstract— This paper proposes a practical approach to measuring the propagation channel in the spherical vector wave domain. By using the spherical vector wave expansion, the propagation channel can be modeled as a mode-to-mode mapping matrix or **M**-matrix. This matrix provides a compact representation of the spatial and polarimetric properties of the propagation environment without influences of the transmit or receive antennas at link ends. In addition, this mode-to-mode mapping matrix can be used in conjunction with other antennas to estimate their performances in the same propagation environment. Hence, the importance of achieving an accurate estimation of the mode-to-mode mapping matrix **M**.

In the proposed approach of estimating the mapping matrix, a virtual spherical array realized by the rotated and translated Dielectric Resonant Antenna (DRA) is used. The array size, the element spacing and location are chosen so that all the dominant spherical vector waves within the spatial bandwidth of the antenna's minimum circumscribing sphere are excited to provide a well-conditioned matrix pseudo-inverse. With the virtual spherical DRA array at both ends in a propagation environment, the radio channel transfer function denoted as $\mathbf{H}_{\mathrm{sph}}$ can be simulated or measured. From the $\mathbf{H}_{\mathrm{sph}}$, and the excitation and weighting coefficients of the virtual spherical DRA array, an estimation of the mode-to-mode mapping matrix **M** of the propagation channel can be obtained directly.

The proposed approach is evaluated by both simulations and measurements. The measurements, were conduced i) in an anechoic chamber scenario with a single line-of-sight path, ii) in a multi-path indoor scenario (a relatively empty office). For all the measurement scenarios, a reference measurement was also performed with a patch antenna located at the center of the virtual spherical array. The channel transfer function of the reference measurement is used to evaluated the synthesized channel transfer function by recombining the estimated **M** with the patch antenna.

Challenges of Radio Propagation Measurements for 5G Systems

S. Salous
School of Engineering and Computing Sciences, Durham University, UK

Abstract— Future wireless communication systems are expected to operate in the higher frequency bands due to the availability of high contiguous spectrum on the order of GHz. This provides the required bandwidths for transmission of high data rates commensurate with real time applications such as high definition TV and immersive user experiences. However, the higher frequency bands between 30–90 GHz have a number of propagation issues such as high path loss, depolarisation, and scattering; hence to be to be limited to line of sight applications to ranges on the order of 200–300 m. Essential to the design of 5G systems is the characterisation of the wireless channel in these bands. In this paper an overview of the challenges of designing and conducting radio propagation measurements in the mm wave band are outlined and the architecture of a multi-band channel sounder that covers several bands between 30–90 GHz is presented. The sounder has been used in the 60 GHz band to carry out dual antenna measurements indoor and outdoor. Results of measurements in the 60 GHz band are presented in terms of rms delay spread and path loss.

Double Broadband Balun Structure Using CRLH TL for Differential Excitation of Dual-polarized Self-grounded Bow-tie Antenna

Sadegh Mansouri[1], **John Kvarnstrand**[2], **Andrés Alayon Glazunov**[1], **Jian Yang**[1], **and Per-Simon Kildal**[1]

Abstract— Using multiple port antennas at both the transmitter and the receiver sides of a communications link has been shown to improve the wireless communication system performance in terms of capacity and also reliability for given fixed system bandwidth and transmitted power [1]. These so-called Multiple Input Multiple Output (MIMO) systems are at the core of 4G, 5G and beyond wireless standards. In that respect, communication over orthogonally polarized wireless channels will be essential to achieve the anticipated performance. The antenna design for base stations is therefore of paramount significance. Besides, multi-port dual polarized wideband antennas can be used in many other applications. For example, in the Over-The-Air (OTA) testing of autonomous cars in a Random-Line- Of-Sight (RLOS) testing environment, a dual polarized uniform linear array antenna has been proposed [2].

One promising candidate for the array antenna element in such applications is the 4-port self-grounded bow-tie antenna shown in Fig. 1(a) [3]. However, in order to achieve the dual polarized performance by differentially exciting two ports of the bowtie antenna, we need to incorporate two baluns together with the antenna design. These baluns should satisfy the required bandwidth constraint (1.6–3 GHz) and they also should have a compact structure in order to maintain a low profile. Despite the wideband characteristics of microstrip baluns they do not meet our compactness requirement.

Therefore, in this paper we propose a broadband compact lumped element balun that meets the above requirements of bandwidth and compactness. As the starting point for our design we employ the fractal shaped CRLH TL balun presented in [4] modified to the frequency band of interest. This balun comprises one +90 branch and three −90 branches to provide the 180 degree phase difference at the output. The simulated results show an amplitude imbalance less than 1 dB and phase imbalance less than 10 degrees over the bandwidth of 1.6–3 GHz. Then to validate the performance, the two designed baluns are integrated with the bow-tie antenna in such a way that could totally fit at the back of the antenna as shown in Fig. 1(b). The performance of the whole structure is also evaluated. Return loss remains below −10 dB for the whole structure. And at last, the farfield pattern of the antenna in ideal differential excitation is compared to the case with using baluns. The results shows good agreement and gain degradation only about 0.5 dB in worst case.

Capacity Analysis for On-body Communications in an Indoor Environment

C. Oliveira and L. M. Correia
Instituto Superior Técnico/INOV-INESC University of Lisbon, Lisbon, Portugal

Abstract— Body Area Networks (BANs) [1] will be strategic actors of the next generation of wireless systems beyond the fourth generation, supporting the world of everything for connected devices and objects. This work focuses on on-body communications, i.e., both transmitter and receiver antennas are attached to or located very near the body of a BAN user, most of the channel being on its surface. Potential scenarios include monitoring of biological signals in healthcare care units, as well as elderly people monitoring in home environments. The data collected by the wearable sensors can be used either in the network itself or forwarded to any appropriated external one (e.g., emergency service). A novel model is proposed using a smart and cooperative configuration of the wearable nodes, i.e., using clusters of nodes and combining multiple independent paths to behave like multi-antennas systems (i.e., Virtual MIMO). The aim is to enhance the reliability of communications and to overcome the effects of deep fading, which can be critical for some applications (e.g., life support decisions). Different metrics are proposed for the selection of the best wearable nodes, namely, the relative MIMO capacity gain (ratio between the MIMO capacity and the maximum throughput from the SISO branches), and the configuration score (relative capacity of a selected 2×2 configuration in relation to the maximum theoretical capacity of a particular BAN). This approach is supported by a channel model that considers the received signal composed of an on-body component (obtained from full wave simulations [2]) and of several multipath components present in the environment (obtained from a geometrically based statistical channel model adapted to BANs [3]). The model includes realistic body dynamics (taken from motion capture analysis), as described in [4]. Results are presented for the possible usage scenario of a female walking in an indoor complex propagation environment, and wearing a network of nine on-body sensors, organised in a 2×2 configuration (e.g., 2 data sensors transmitting hearing information to a sink composed by 2 nearby nodes). The case studies of the data sensors on the head (front and back), on the ears or on the arms, while the sink is on the front of the body (e.g., belt) are analysed. In case of the head-belt connection the signals are balanced, but, being highly correlated due to the short distances and similar propagation conditions and relative MIMO gains are small (1.57). If the data sensors are moved to the ears, higher relative MIMO gains are achieved (1.81). The trend of the average capacity over time when the sensors are on the arms exhibits higher fluctuations when compared to the placements on the head/ears, corresponding to the arms swinging, leading to an average gain of 1.73. Nevertheless, the performance of the selected virtual MIMO case studies (with relative MIMO capacity gains ranging in [1.57, 1.81]) is always enhanced when compared to the best SISO scenario, even for line-of-sight branches. The selection of the optimum placements should be done according to the specific system under study. The best performance for the analysed case studies corresponds to the sensors on the ears, reaching a configuration score of 0.76.

Spatial Probability of Detection Distribution as a Performance Measure of ZF Massive MIMO

A. Alayon Glazunov and Per-Simon Kildal
Department of Signals and Systems, Chalmers University of Technology, Sweden

Abstract— In this paper we investigate the impact of the spatial user distribution on the down-link Zero-Forcing (ZF) algorithm applied to the output signals from a dual-polarized Massive MIMO antenna array with Na antenna elements. Each element of the array antenna consists of four elementary Huygens sources that are differentially excited to form two orthogonally polarized beams. It is assumed that the Massive MIMO antenna array operates in Random Line-Of-Sight (RLOS). RLOS, here means that (i) there is a single LOS path connecting the user equipment with the base station and that (ii) the orientation of the user equipment antenna is assumed to be random. The antenna array is assumed to be wall-mounted on the facade of a building. A uniform distribution of Nu users on a circular sector in front of the array antenna is considered in order to emulate users at various distances to the base station as well as various angular separations. We present simulation results in terms of the spatial coverage given by the Probability of Detection [1] corresponding to the resulting polarisation and beamforming gain of 2-bitstream per user throughput and the corresponding coverage 2D radiation pattern of the $2N_a \times 2N_u$ multiuser Massive MIMO scenario. We also investigate wether there is an optimal antenna arrangement and size that maximize the multiplexing gain over a given coverage area based on the distribution of the Probability of Detection.

Research on Random Wireless Channel of Radio Indicator for Mariners

Tao Jiang[1], **Xiaodong Cao**[1], **Xiaojun Wang**[1, 2]

[1]College of Information and Communication Engineering, Harbin Engineering University, China
[2]Electrical and Computer Engineering Department, National University of Singapore, Singapore

Abstract— It is presented a random wireless channel model of marine emergence radio indicator in this paper, which describe the performance of telecommunications in difference typical ocean states. First, it is introduced a random rough ocean surface modeling method under typical ocean states which is the foundation for simulation of LOS and NLOS telecommunication channel. Second, massive data is calculated by running simulation code which is necessary for statistical analysis of linking properties. Last, the telecommunication performance is predicted by signal to noise ratio vs bit rate error in situation of typical ocean states and elevation angles which may provide key information for the design of next generation of marine indicators.

Feasibility Study of Emulating Extended Spatial Channel Models in a Multi-probe MIMO OTA Antenna Test Setup

Md Suzan Miah, **Afroza Khatun**, **and Katsuyuki Haneda**
Department of Radio Science and Engineering, School of Electrical Engineering
Aalto University, P. O. Box 13000, Aalto FI-00076, Finland

Abstract— Multiple input multiple output (MIMO) techniques, which use multiple antennas in both sides of the radio communication system, have been a promising method to support the increased demand for higher data rate transmission. However, the performance of MIMO systems depends not only on the antenna performance but also on the propagation environment. Hence, for accurate MIMO performance testing of terminal devices, it needs to consider both the multiple terminal antennas as well as the propagation environment. Over-the-air (OTA) testing is widely used for single-input single-output (SISO) performance testing, and its extension to the MIMO device testing has been actively investigated.

Standardization works for MIMO OTA testing have been intensively coordinated by CTIA and 3GPP, where several different MIMO OTA test methods have been proposed [1]. One mandatory requirement of any MIMO OTA test methods is to emulate an electromagnetic environment, which resembles the scenario where the terminal operates. Geometry-based channel models such as the Spatial Channel Model (SCM), its extension (SCME), WINNER II or IMT-Advance constitute a good means to describe the propagation environment, which is translated into the electromagnetic environment in the OTA testing. The use of such well-defined channel model in MIMO OTA testing makes the test methods well justified.

One of the proposed techniques in the standardization of the OTA testing is a multi-probe anechoic chamber based MIMO OTA testing, which can emulate the electromagnetic environment defined by a channel model in a controllable manner. To emulate the spatial and temporal characteristics of the channel, two channel emulation techniques have been reported in the literature [2]; one is the plane wave synthesis (PWS) and another is prefading signal technique (PFS). In this paper, we address the PWS technique based on the spherical wave theory in order to prove its consistency with other MIMO OTA testing techniques such as the PFS.

The purpose of the paper is to validate the PWS technique for emulating the electromagnetic environment in a multi-probe based MIMO OTA test system. We use the SCME as the reference channel model, for which the validation of the PWS technique has not been reported. The validation of the channel emulation is performed in terms of power delay profile, temporal correlation, spatial correlation, cross-polarization and channel capacity. Our results facilitate analyzing consistency of the performance of the PWS technique with other MIMO OTA techniques such as the PFS. The validation results are to be presented in the manuscript.

Random Optical Media for Third Generation Photovoltaics

Hernán Míguez
Institute of Materials Science of Seville, Spanish National Research Council, University of Seville
C/Américo Vespucio 49, Sevilla 41092, Spain

Abstract— In this keynote, different light trapping strategies based on the use of optical materials to enhance the light harvesting efficiency of third generation photovoltaic devices, such as dye sensitized and perovskite solar cells, will be discussed. Focus will be put on methods based on the inclusion of diffuse scattering particles randomly arranged, and a comparison to approaches based on ordered nanostructures, such as photonic crystals or surface texturing, will be provided. Near optical field effects in metal particles embedded in the photoanode will also be reported. Our work provides a theoretical framework in which the response of solar cells containing optical materials by design can be rationalized. The different synthetic routes to implement them in actual devices will be shown and their effect on the photovoltaic performance will be discussed, as well as the interplay with the tuneable semitransparency or color of the device, of interest for building-integrated photovoltaic devices.

Innovative Materials and Methods for Disorder Photonics

Álvaro Blanco and Cefe López
Instituto de Ciencia de Materiales de Madrid-ICMM (CSIC)
Sor Juana Inés de la Cruz 3, Madri 28049d, Spain

Abstract— Understanding the interaction of light with active and passive photonic structures creates challenges for new materials and preparation methods. In a self-assembly approach this concerns both structures and guest components. We prepare disordered templates by new dry methods and synthesise emitting materials both from semiconductor and dyes. The latter are efficient sources that can enter multifunctional systems and in pairs permit to engineer emission by exploiting FRET processes.

Creating structured materials from the bottom up is a widely used method owing to the easy and inexpensive techniques it involves. Self-assembly entails allowing or inducing small particles to arrange themselves into photonic structures like photonic crystals and photonic glasses. Non-spherical particles are less prone to control but still offer great possibilities always related to disorder.

Novel techniques dispensing with the liquid are nowadays being explored [1]. In this way we demonstrate monodisperse disordered structures in minutes and without the hassle associated with colloidal sedimentation.

Templating is used to infiltrate materials into the preformed structures. A good example is ZnO that permits to build both Bloch-mode and random lasers. Organic dyes have been mostly used impregnating preassembled colloidal structures. In such cases the use of FRET coupling between dyes can expand their potential as laser sources. An interesting case is when both dyes are contained inside the beads [2]. This requires a careful selection of the dyes paying attention to both their emission properties and their chemistry for a good match of their energy transfer properties.

Finally an example of multifunctional [3] material is exemplified in the preparation of elastomeric materials where a scattering medium is dispersed along with a gain material so as a shape memory functionality is accompanied by control over lasing.

Abstract— Transverse Anderson localization (TAL) is the trapping of waves due a disordered potential which is invariant along propagation direction, cancelling the effects of diffraction. We recently demonstrate that it is possible to exploit optical nonlinearity and adaptive optics to tailor light inside disordered optical fibers supporting TAL.

Recent experimental results stimulated a large body of theoretical work dealing with the role of self- focusing and defocusing in the evolution of the disorder induced localizations [1]. There is a relevant debate about the fact that nonlinearity may enhance, or hamper, this linear trapping mechanism, and there are many open research directions, as for example, considering quadratic nonlinearities. Indeed, the interplay between disorder and a nonlinear response is expected to alter the commonly accepted scenario about the absence of diffusion and transport in the Anderson regime, when all of the states are exponentially localized. Particularly intriguing is the role of spatial nonlocality. Indeed, if disorder induces exponential localizations and reduces the interactions of distant modes, nonlocality (i.e., a nonlinear perturbation that extends far beyond the region of interaction) is expected to create some action at a distance dependent on power. In recent papers, we demonstrate the effects of nonlinearity in disordered optical fibers supporting TAL [2, 3]. We notice two different striking phenomena: disorder induced self focusing [4] and mode migration [5] (see Fig. 1). In a nutshell exploiting nonlinearity and nonlocality it is possible to control light modes by tuning intensity in distant control beams that modify the refractive index landscape.

Moreover we performed adaptive focusing experiments [6] in disordered optical fibers. in the transverse Anderson localization regime [7]. By wavefront shaping and optimization, we observe the generation of a propagation-invariant beam, where light is trapped transversally by disorder,

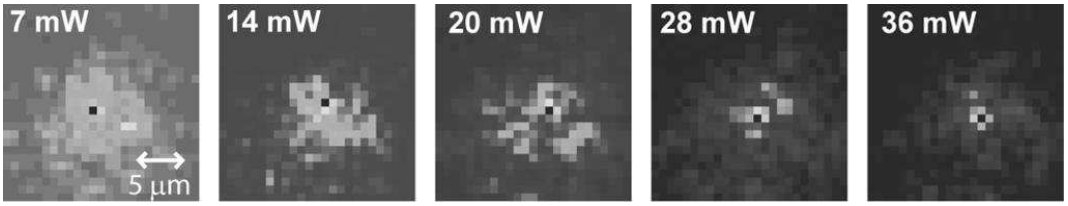

Figure 1: Visualized mode self focusing. The images represent of a localized state whose extension shrinks by increasing light intensity (value of the intensity indicated in the figures).

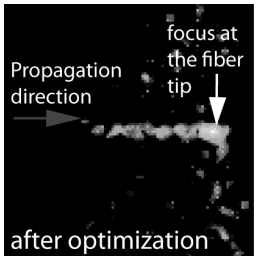

Figure 2: Side view of the fiber tip. The focus at the fiber tip shows a tail on the left, which is a signature of the localized states cooperating the adaptive focusing.

and show that localized states can be excited by extended speckled beams. We demonstrate that disordered fibers allow a more efficient focusing action with respect to standard fibers. This enhancement is due both to the cooperative action of localized states with adaptive focusing, and to the effects of localization which inhibits light paths far from the target (see Fig. 2).

Disorder in Nature: Optimisation of Light Scattering in Beetles

Matteo Burresi[1], **Lorenzo Cortese**[1], **Diederik S. Wiersma**[1], **and Silvia Vignolini**[2]

[1]European Laboratory for Non-linear Spectroscopy (LENS), Sesto Fiorentino (FI), Italy
[2]Department of Chemistry, University of Cambridge, Cambridge, UK

Abstract— In nature, an amazing range of optical strategies exists that is optimised by at least 500 million years of evolution. Animal displays are often assembled of mainly two basic materials, chitin/keratin and melanin, in various parts of animal bodies that often result in intriguing optical effects ranging from matte to iridescent colours, and from black to extremely white. These structural colours arise from complex nanostructures such as ordered and quasi-ordered photonic crystals and random assemblies.

While the most dazzling displays are due to ordered photonic structures with a strong selective reflection of single colours, whiteness arises from diffuse and broadband reflection of light and is less explored. Whiteness is typically achieved through optical scattering in randomly structured media. A white surface appearance generally requires a relatively thick system comprising randomly positioned high refractive-index scattering centres, in strong contrast to structural colour where the colour is due to coherent scattering.

Here we demonstrate how the exceptionally bright white appearance of *Cyphochilus* and *Lepidiota stigma* beetles is provided by a remarkably optimised polydispersity and anisotropy of the intra-scale chitin networks, which act as scattering elements [1]. Using time-resolved measurements, we show that light propagating in the scales of the beetles undergoes strong multiple scattering that is associated with the lowest transport mean free path and diffusion constants reported to date for low-refractive-index systems. The high-brightness white appearance from a small layer thickness and density that extends from near ultra-violet to the near infrared.

These findings are complemented by advanced finite-difference time-domain modelling on three-dimensional networks with controlled anisotropy ratios to understand the important parameters in the design of efficient scattering media. The systems extracted optical parameters infer new designs for efficient strongly-scattering 3D bio-inspired photonic structures.

Hyperuniform Disordered Photonic Structures

Marian Florescu
Advanced Technology Institute, Faculty of Engineering and Physical Sciences, University of Surrey
Guildford, Surrey, GU2 7XH, UK

Abstract— Hyperuniform disordered solids (HUDS) are a new class of materials [1] that harness structural disorder and control light transport, emission and absorption in unique ways, beyond the constraints imposed by conventional photonic architectures [2–8]. HUDS materials are statistically isotropic and possess a constrained randomness such that density fluctuations on large scales behave more like those of ordered solids, crystals or quasicrystals, rather than those of conventional amorphous materials [9].

We present new design strategies for light flow and confinement on HUDS platforms, which exploit the interplay between disorder, topological correlations and hyperuniformity. In an otherwise unperturbed HD structure, we demonstrate that it is possible to create localized states of the electromagnetic field by reducing or enhancing the dielectric constant at a certain points in the sample. Due to the presence of the defect, a number of localized cavity modes are created within the photonic band gap at specific frequencies. Despite the statistical isotropy of the network structure surrounding the cavity, the modes display well defined (approximate) symmetries and our simulations show that 2D quality factor of the confined modes is higher than 10^9. We also demonstrate waveguides ("linear" defect mode created by filling of network cells along a connected path), which exploit the statistical isotropy of the photonic band gap. The physical properties of the localized modes in HUDS materials are determined by PBG formation mechanisms in these materials and the elimination of the constraints imposed by long-range order has a major influence on the properties of the localized modes.

In conclusion, we have employed their unique properties to introduce novel architectures for optical cavities that achieve an ultimate isotropic confinement of radiation, and waveguides with arbitrary bending angles. Our results demonstrate low-loss waveguiding and high-Q cavities in hyperuniform structures and open the way for the realization of highly flexible, disorder-insensitive optical micro-circuit platforms.

Abstract— Multiple scattering of light in a random media is a subject of great interest in fundamental and applied photonics research [1]. García et al. [2] presented a new three-dimensional system called "photonic glass" that is composed of monodisperse polymer spheres arranged in a completely disordered way. Due to the resonant behavior of the spheres discrete light states exist so that every sphere acts as a meta-atom for light. Applications such as random lasing [3] and structural coloration [4] have been suggested. However, strong scattering of light in the disordered structure and resulting high diffuse reflectance over a broad wavelength range make photonic glass also attractive for other fields of science and technology. Here we report on high-temperature stable ceramic photonic glasses which benefit from the high refractive index and high temperature stability of refractory ceramics.

Direct and inverse ceramic glasses were studied. A direct photonic glass was obtained by sedimentation of monodisperse zirconia microparticles [5]. For fabrication of inverse photonic glass from yttrium-stabilised zirconia (YSZ), a single-step deposition method was developed [6]. These novel materials can be used for a wide range of applications, such as thermal radiation barrier coatings, high-temperature stable structural coloration, broadband reflectors, resonant random lasers, and photonic Anderson localization. We show that disordered arrays of ceramic microparticles or shells can efficiently reflect visible and infrared electromagnetic radiation in a broad wavelength range. The hemispherical diffuse reflection from the disordered structure has broadband characteristics with a cut off defined by the sphere size. A reflectivity up to 93% in the visible range was achieved for 40 µm film thickness.

Abstract— The adoption of a statistical mechanics framework in optics provides realistic models for multimode laser systems in random media whose experimental implications are presented and critically analyzed. The approach is based on the hypothesis of effective equilibrium. Lasers are manifestly off-equilibrium and energy is pumped into the system but as the system power is kept constant, though, the resulting stationary regime can be described as if at equilibrium with an effective "thermal bath" whose "temperature" is related to the pumping rate and to the true environment temperature. The analytic solution of a mean field model for multimode laser in open and irregular cavities will be first addressed. The model is exact for a narrow bandwidth and extended modes and includes the mode intensity dynamics as well as the presence of a linear coupling between the modes, due, e.g., to leakages from the open cavity. The complete phase diagram, in terms of disorder strength, source pumping and non-linearity, consists of four different optical regimes: incoherent fluorescence, standard mode locking, random lasing and the novel spontaneous phase locking. A replica symmetry breaking transition is predicted at the random lasing threshold. In this situation, identical copies of the system show different amplitude equilibrium configurations, as the ergodicity is broken in many distinct states. For a high enough strength of non-linearity, a whole region with nonvanishing complexity anticipates the transition and the light modes in the disordered medium display typical discontinuous glassy behavior, i.e., the photonic glass has an exponential number of metastable states that corresponds to different mode-locking processes in random lasers. Symmetry breaking in the intensity fluctuation overlap is shown to be equivalent to the one occurring in the complex amplitude overlap, providing an easily verifiable test in typical experimental setups. The relevance of this order parameter is considered in describing the laser transition in random media and in explaining its glassy nature in terms of emission spectra data. The theoretical analysis is compared to recent measurements. Further on, the mode-locking lasers can be modeled and analyzed beyond the mean field approximation, accounting, e.g., for the presence of many well-resolved frequencies of the lasing modes. By means of optimized, parallel Monte Carlo simulations, system properties are studied varying interaction random dilution, gain profile and number of modes. The inhomogeneous structure in the nonlinear "mode-locked" interaction network is shown to yield short pulses and phase waves with nontrivial slopes, corresponding to a phase delay of the pulsed laser signal.

Invariance Property of Wave Scattering through Disordered Media

Abstract— The diffusion of particles and waves through disordered media encompasses a large variety of phenomena, from the motion of insects to the scattering of electrons or light in complex environments. A fundamental insight in the theory of diffusive random walks is that the mean length of trajectories traversing a finite open system is independent of the details of the diffusion process [1]. Instead, the mean trajectory length depends only on the system's boundary geometry and is thus unaffected by the value of the mean free path. This result is particularly counter-intuitive when considering that many other quantities in disordered transport do depend on the mean free path, like the transmission and the reflection through a disordered system as well as the associated times. In my talk I will demonstrate that this invariance property follows from the so-called Weyl law for the average density of states in a system and is thus rooted on a much deeper level than that of a random walk. As a result, we can extend the reach of this universal invariance property beyond the diffusion approximation [2]. Specifically, we demonstrate that an equivalent invariance relation also holds for the scattering of waves in resonant structures as well as in ballistic, chaotic or in Anderson localized systems. Our work unifies a number of specific observations made in quite diverse fields of science. Potential experimental realizations using light fields in disordered media are discussed and analyzed in terms of their promise for practical applications.

Abstract— We investigate the formation of localized modes in 1D randomly-perturbed optical periodic media near the photonic band-edge. While the group index is generally considered to be the key quantity in this process, we demonstrate that the relation between the disorder level and the spatial extent of individual localized modes is driven instead by the effective photon mass. Near-field measurements on photonic crystal waveguides and statistical numerical calculations on various structures reveal that periodic media exhibiting flat dispersion bands can support surprisingly small localized modes at almost imperceptible disorder levels ($\sigma < \lambda/1000$). A scaling law that relates the disorder level to the modes spatial extent is proposed and is found to agree well with the numerical and experimental results.

Introduction: Random imperfections can have a profound impact on light propagation in periodic media, the most striking phenomenon being undoubtedly the formation of localized modes in the vicinity of photonic band-gaps. Localization in photonic crystal waveguides (PhCWs) has garnered special attention due to the important limitations it imposes on the realization of slow-light photonic devices, but also for the opportunities it offers for strong light-matter interaction in quantum electrodynamics experiments. It is widely accepted that Anderson localization is enhanced with decreasing group velocity, i.e., when approaching the band-edge [1], and that tiny perturbations are sufficient to create defect modes forming the decaying Lifshitz tail in band-gaps [2]. These behaviors are generally described via ensemble-averaged quantities, namely the localization length [3, 4] and the density of states [2]. Conversely, very little is known on the properties of individual localized modes. In this work we are showing that, surprisingly, disorder level of the order of $\lambda/1000$ allows to form modes with spatial extents comparable to those achieved with engineered nanocavities. In contrast with the widely-held view that the key quantity impacting localization near photonic band-edges is the group index, we argue that the relation between the disorder level and the mode spatial extent is driven by the effective photon mass, i.e., the second-derivative of the dispersion band.

Results: We have performed near-field measurements of a PhCW in the slow light regime where the disorder is only due to fabrication imperfections (of the order of 1–2 nm). A localized mode with a spatial extent of 6 µm was observed in the scanning area. To complete this observation, extensive numerical calculations have been performed on PhCWs and Bragg stacks, two 1D periodic media, with different disorder levels and effective masses. Results are showing a threshold-like behavior, defining a minimal spatial extent of the modes $L_{\min}$. To explain this phenomenon, a simple model has been made that link $L_{\min}$ to the disorder level and the effective mass m. The relation $L_{\min}\alpha(m\Delta\omega)^{-1/2}$, where $\Delta\omega$ is a frequency shift of the mode induced by the disorder, is in good agreement with the numerical results.

Conclusion: To summarize, we have provided new understanding into the physical mechanism underlying the formation of localized modes at band-edges of periodic media, showing that the relation between the disorder level and the spatial extent of individual localized modes is driven to a large part by the effective photon mass. In particular we have investigated the possibility to form wavelength-scale localized modes at vanishingly-small disorder levels, revealing that such modes naturally form up in PhCWs at intrinsic disorder levels due to the flatness of the dispersion curve.

Polaritonic Behavior of Quantum Scatterers in a Nanoguide

H. R. Haakh[1], **S. Faez**[2], **and V. Sandoghdar**[1]

[1]Max-Planck-Institute for the Science of Light, Erlangen, Germany
[2]Institute of Physics, University of Leiden, Leiden, Netherlands

Abstract— Recent demonstrations of efficient coherent coupling between quantum scatterers and guided modes of a subwavelength optical fiber (nanoguide) [1] or photonic crystal waveguides [2, 3] have introduced a novel platform for studying polariton formation and optical transport in reduced dimensions (Fig. 1). We present a theoretical characterization of the polariton modes arising from ensembles of quantum emitters coupled via a waveguide, that yields a full phase diagram, indicating the presence of several phases dominated by either localized or extended states. A rigorous theoretical treatment based on many-body Green's functions [6] allows for a careful analysis of the interplay of nonradiative near-field coupling [6], density, and disorder. We link the different phases to the optical transport properties and the spectral response of the waveguide. The results can be immediately transferred to various emitters such as NV centers in diamond structures [4], quantum dots in silicon waveguides [2, 3, 5], or molecules in nanoguides [1].

Impact of Anderson Localization on the Light-matter Interaction in Low-dimensional Photonic Nanostructures

Søren Stobbe
Niels Bohr Institute, University of Copenhagen, Blegdamsvej 17, Copenhagen DK-2100, Denmark

Abstract— Photonic nanostructures enable confining light to subwavelength dimensions as well as controlling its propagation and enhancing its interaction with matter. This unprecedented control over light opens new opportunities ranging from fundamental studies of quantum electrodynamics to applications in optical interconnects. However, enhancement the electromagnetic field strength leads to an increased sensitivity to random structural disorder. In some cases this is a nuisance but it may be an advantage that unlocks new regimes of the statistical physics of cavity quantum electrodynamics, spatial correlations, and random lasing in the Anderson-localization regime.

Any fabrication method has a finite precision, which careful engineering can improve but not completely diminish. Structural disorder is therefore a fundamental phenomenon prevalent in all structures and devices and while it plays a rather trivial role in many situations, sufficiently pronounced disorder leads to Anderson localization. Low-dimensional photonic systems may greatly enhance the local density of optical states [1], which increases the interaction between light and matter but also enhances the influence of structural disorder. Anderson localization plays an important role when the light-matter coupling is increased.

We have studied the effect of structural disorder on photonic-crystal structures with embedded light emitters. In photonic-crystal waveguides in the slow-light regime, Anderson localization gives rise to localized photonic modes. The Anderson-localized modes give rise to pronounced cavity quantum electrodynamic effects, which can be probed by embedded quantum dots [2].

Using quantum dots as internal light sources enable probing the local density of optical states. Interestingly, the variance of the fluctuations in the local density of optical states contain information about non-universal spatial correlations intensity correlations in the far-field emission [3].

The Anderson-localized modes may also be employed for studying random lasing in the Anderson-localized regime. This study reveals a complex interplay between gain, dispersion-controlled slow light, and disorder [4].

Lasing in Plasmonic Periodic, Aperiodic, and Disordered Systems

Hinke Schokker, C. I. Osorio, and Femius Koenderink
Center for Nanophotonics, FOM Institute AMOLF, Amsterdam, The Netherlands

Abstract— Motivated by seminal proposals for surface plasmon amplification by stimulated emission, we conduct experiments on 2D plasmonic particle arrays in waveguiding layers that provide gain. We find that purely periodic plasmonic particle systems provide lasing characteristics similar to DFB lasers, yet on basis of a quite different underlying band structure. Using a newly developed spectrally-resolved Fourier microscope [1] we perform "high-NA band structure microscopy" and find that the strong and resonant scattering by plasmon particles markedly modify stop gap widths and band anti-crossing topology. Since stop gap size is inversely related to the number of unit cells required to generate the stop gap, our large stop gap system is very suitable to study the fundamental question: how much can we perturb our system? We find that these plasmon lasers are exceptionally robust against disorder: lasing persists even when removing as many as 98% of particles from a square lattice and shifting them by as much as a quarter of the periodicity. We quantify the transition from DFB to random lasing by analyzing laser output in terms of intensity statistics and real-space autocorrelations using tools borrowed from speckle analysis. Plasmon particle systems in waveguiding layers are an ideal platform to study lasing in purely periodic systems, completely disordered systems and systems with correlated disorder. As point in case, our latest result map lasing as function of spatial correlation order parameter in a suite of quasiperiodic, aperiodic and random systems, ranging from Fibonacci to Thue-Morse and Rudin-Shapiro lattices.

New Directions for High-Q Optical Micro Cavities

Kerry Vahala
California Institute of Technology, Pasadena, California, USA

Abstract— Over the last ten years there has been remarkable progress in boosting the storage time (Q-factor) in micro and millimeter-scale optical resonators (1). Chip-based devices have attained Q factors of nearly 1 billion (2) and micro-machined crystalline devices have provided Q_s exceeding 100 billion (3). The resulting long, energy-storage times combined with small form factors have made it possible to access a wide range of nonlinear phenomena and to create laser devices that operate with remarkably low turn-on powers. Also, new science has resulted from radiationpressure coupling of optical and mechanical degrees-of-freedom in the resonators themselves (4).

After a brief review of nonlinear physics in high-Q micro cavity systems, this talk will focus on recent progress in generation of high-coherence light and application of optical frequency division for stable microwave synthesis. For the former, Brillouin lasers on a silicon chip are described (2, 5). These devices leverage both the small form factor and high optical Q of silicon-chip-based disk resonators (see Figure 1) to achieve high efficiency (less than 100 microWatt turn-on power) and high coherence (short-term, optical line width near 0.1 Hertz). It is also shown how the process of Brillouin cascade can be used to generate stable X and K-band microwave signals through direct detection (6). Finally, a new form of optical frequency division (OFD) is described (7). Similar to frequency comb based OFD methods (8) the technique allows coherent frequency division of very high (non-detectable) rate optical signals down to radio-frequency rates. It is applied to the Brillouin laser system to show that many orders of additional frequency stability can be extracted from these devices to generate high-performance microwave signals.

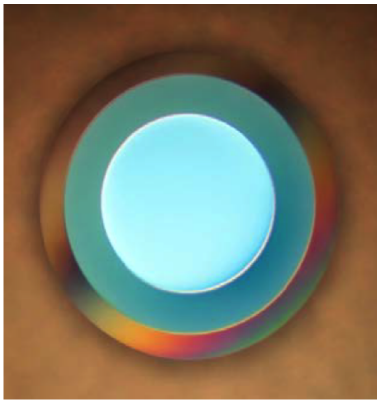

Figure 1: Optical micrograph showing a silica-onsilicon disk resonator having a Q-factor of nearly 1 billion (2).

Applications of Second Order Microring Resonators

C. Vázquez
Department Tecnología Electrónica, Universidad Carlos III Madrid
Av. Universidad 30, Leganés, Madrid 28911, Spain

Abstract— single microring resonator may not perform properly in those applications were a high number of channels with minimal crosstalk within a free spectral range (FSR) is required. In those cases, filterbanks consisting of second-or higher-order microring [1, 2] can be used. But in some cases, the control of the resonant frequency of each ring requires dimensional precision in the order of tens of picometer [3], so more thermal tunning is required to overcome the frequency mismatch between the two rings of a channel and each channel location mismatch. Some novel configurations of second order microring resonators more robust to fabrication tolerances [4], based on previous designs [5, 6] will be discussed along with potential application. Special emphasis will be given to the properties provided by designs on high index contrast waveguides.

Coupling-tuned Silicon Ring Resonators for Optical Modulation and Microwave Phase Shift

Linjie Zhou, Rui Yang, Haike Zhu, Yanyang Zhou, and Jianping Chen
State Key Laboratory of Advanced Optical Communication Systems and Networks
Department of Electronic Engineering, Shanghai Jiao Tong University, Shanghai 200240, China

Abstract— Optical ring resonators are fundamental building blocks in integrated photonics. A variety of passive and active, linear and nonlinear devices can be built using ring resonators as the core components. Usually, rings are coupled with single or double waveguides in a photonic integrated circuit with tuning performed either on the ring cavity or the coupling region. These two tuning methods have different effects on the resonances: cavity tuning shifts the resonances wavelength while coupling tuning adjusts the resonance extinction ratio. Here we report our recent process on coupling tuned silicon ring resonators to generate high-speed optical modulation and microwave phase shift. The coupling of the ring resonator is enabled by a Mach-Zehnder interferometer integrated with single-drive push-pull electrodes. With two DC biases applied to the electrodes, the phase shift of the two arms can be separated controlled and thus the coupling can be freely tuned while resonance wavelength is fixed. It is advantageous to separate the coupling tuning from the resonance shift.

We first characterize the high speed modulation performances of this device. Silicon modulators are key components in photonic integrated circuits for both optical communications and interconnects. The coupling modulation can eliminate the cavity lifetime limited speed bottleneck as accounted in resonance modulation. The on-chip insertion loss of the device is ~ 3 dB. Critical coupling is obtained with the resonance extinction ratio exceeding 35 dB at the wavelength of 1544.3 nm. Near critical coupling, the transmission is very sensitive to the drive voltage, allowing for low voltage modulation. On-off-keying (OOK) eye diagrams are measured with a modulation depth of 7 dB at a date rate of 25 Gbps and RF drive voltage of $V_{pp} = 1$ V. The modulation depth reduces to 3 dB at 32 Gbps. Binary-phase-shift-keying (BPSK) modulation is also achieved at 28 Gbps by setting the resonance at critical coupling. The eye diagram shows a Q-factor of 6.3 dB and the constellation diagram reveals an error vector magnitude (EVM) of 23.3%.

The transmission phase of the ring resonator sees rapid change around resonances. At the under-coupling regime the phase change is less than π, while at the over-coupling regime the phase change can be a full 2π. Therefore, the resonance phase can be tuned by coupling. Utilizing this feature, we can generate microwave phase shift by setting one of the frequency tones of a microwave modulated optical signal to the resonance wavelength. By tuning the coupling, the microwave phase shift can be varied with a large and continuous tuning range.

Silicon Nitride Waveguides for Plasmon Optical Trapping and Sensing Applications

Abstract— Optical force has long been investigated and proved by moving micro-scale particles, membranes and optical micro cavities. On one hand, the use of strong field confinement at the apex of a sharp metallic tip enables optical trapping of low-contrast Rayleigh objects or metal nanoparticles. Extensive studies on prism platform using noble metal antenna and objective lens for optical tweezing have been put forward. However the system is composed of discrete components, making it bulky and sensitive to environment vibration. One the other hand, microfluidic channels proved to be successful platforms for sorting and manipulating particles by optical force. Nevertheless, lacking of on-chip launch light fails to make the system compact. Therefore, it is desired to integrate waveguides, antennas, and microfluidic channels in a planar structure, which can minimize the structure volume and make it more robust. Here we present the optimum waveguide geometries that can be utilized for optical sensing and particle applications. In particular, submicron silicon nitride waveguide geometries based on conventional optical lithography will be presented for plasmonic sensing and nonlinear optics applications.

Surface plasmons coupled with optical waveguides due to metallic colloidal particles demonstrate higher optical nonlinearities that can be used for two photon fluorescence, optical frequency mixing, spectral broadening and optical switching. Here we will discuss deposition of colloidal nano particles to enhance the optical nonlinearity of waveguides. Same deposition techniques can be tailored to fabricate plasmonic nanoantennas that convert evanescent modes into radiation. Here we present recent developments in plasmonic antennas in particle sensing and trapping applications. In particular, we discuss the optical trapping capability of silicon nitride planar waveguide geometries with plasmonic antennas, such as bowtie antennas. We show that the bowtie antennas can lead to 60-fold enhancement of electric field in the antenna gap. With the help of scattering by the antenna, the optical trapping force on a nanoparticle is boosted by three orders of magnitude. A strong tendency shows the nanoparticle is likely to move to the high field strength region, exhibiting the trapping capability of the antenna. Effect of trapping on spectroscopic measurements will be discussed.

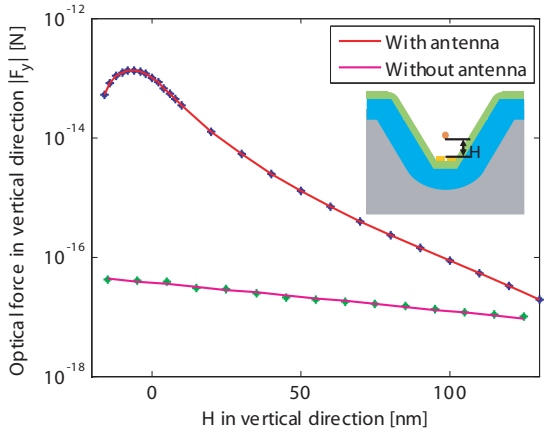

Figure 1: Optical trapping force in vertical direction (y axis) vs. vertical distance from the particle bottom surface to the antenna top surface. The force is enhanced by bowtie antenna compared to non-antenna case.

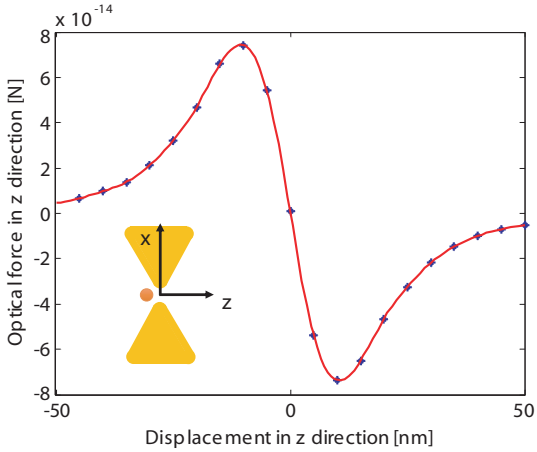

Figure 2: Optical trapping force in longitudinal direction (z axis) vs. displacement from the antenna center. The particle bottom surface is 4 nm below the antenna top surface.

Whispering Gallery Mode Biosensing: An Approach to Simultaneous Multiplexed Detection

Stephen Holler and John Murray
Department of Physics & Engineering Physics, Fordham University
441 East Fordham Road Bronx, NY 10458, USA

Abstract— The whispering gallery mode (WGM) biosensor has emerged as a robust tool for the sensitive detection of biological micro- and nano-particles, including bacteria, virus and protein. Relying on the specific biochemical interactions, perturbations to the cavity mode induced by the binding of such particles to the microcavity surface result in a quantifiable shift in the resonance mode frequency. The amount by which the resonance frequency shifts is directly proportional to the quantity of adsorbed material and the location at which it binds. Additives, such as plasmonic nanoparticles, can serve to enhance reactive effect and thus the degree to which the resonance frequency shifts, and have been shown to lower the detection limit of WGM devices to single protein level.

These optical microcavities may take on a myriad of shapes (e.g., spheres, spheroids, toroids, rings, disks, etc.) and, consequently, WGMs are also known as morphology dependent resonances (MDRs). Our work will focuses on the use of a spherical geometry because such microcavities offer low-cost ease of manufacture and accessible analytic models. Despite these advantages, spherical cavities offer challenges for multiplexed detection and monitoring of analytes. We will review the physics behind whispering gallery biosensing and introduce a detection/monitoring approach, which employs a sensing geometry that offers the prospect for robust and simultaneous multi-sphere monitoring. This multi-cavity approach allows for reference channels to account for common mode and environmental factors, and/or channels for additional target analytes.

Results will be presented for adsorption of biological nanoparticles. In particular we will demonstrate the approach using the human papillomavirus (HPV), the causative agent of cervical and head & neck cancers. Projections will be made for detection limits and maximum allowable resonators.

Optical Kerr Switching and COMB Generation in a Silica Whispering Gallery Mode Microcavity

Takasumi Tanabe
Department of Electronics and Electrical Engineering, Keio University, Japan

Abstract— Ultrahigh-Q whispering gallery mode microcavities exhibit optical nonlinearities at a very low input power. The efficiency of the nonlinearity often scales with Q/V, where Q is the quality factor and V the mode volume of the cavity.

First I will report on the demonstration of a Kerr switch at a record low power of a few tens of microwatts, achieved with a whispering gallery mode microcavity made of silica [1]. Comparisons between switches made with photonic crystal nanocavity and silica whispering-gallery mode microcavity are discussed in terms of speed, power, and different nonlinearities. Although the required energy is much lower for carrier based photonic crystal nanocavity switches [2, 3], the insertion loss of the whispering galley mode cavity system is much lower due to the higher Q of the cavity and low-loss of the tapered fiber. In addition, we can use Kerr nonlinearity when the cavity is made of silica, which is attractive for the use of various quantum applications.

Next, I will discuss about the generation of optical Kerr comb which is demonstrated by using a high-Q silica whispering gallery mode microcavity. It allows us to obtain ultrahigh repetition rate optical pulses (at a repetition rate $> 800\,\mathrm{GHz}$) when we pump the cavity with continues wave input. We numerically and experimentally studied the condition required to generate the comb, in respect to the pumping power and waveguide coupling. We found that the history of the input power variation is the key to obtain mode-locked comb, which is due to the hysteresis behavior of the nonlinear cavity. Particularly, we found that a stable comb is obtained only when we reduce the input power after hard pumping, whereas the cavity exhibit modulation instability when we increase the input [4].

Whispering Gallery Mode Microbubble Resonators

S. Nic Chormaic
Light-Matter Interactions Unit
Okinawa Institute of Science and Technology Graduate University
Onna, Okinawa 904-0495, Japan

Abstract— Whispering gallery mode microbubble resonators are a relative recent addition to the whispering gallery resonator family and have demonstrable applications across several areas of research, including pressure sensing, frequency comb generation and other nonlinear optics phenomena, and in the field of optomechanics. These resonators behave very similar to microsphere resonators, with the distinct advantage that their hollow core can be filled with fluids, thereby rendering them more functional for many sensing scenarios. In this paper, we will first introduce the concept of microbubble resonators and discuss how they can be fabricated in a controlled manner in order to ensure their design is optimised for high resolution sensing by operating in the quasi-droplet regime. Next, we will discuss some recent achievements in relation to fabricating high quality factor microbubbles from a variety of different materials. As a first example, we have fabricated PDMS-filled, silica glass microbubbles with very thin walls, thereby ensuring that they operate in the quasi-droplet regime whereby the optical mode penetrates deep within the core material allowing us to study temperature shifting on the optical resonances. As a further example, we have fabricated microbubbles using lead silicate glass, a material with high nonlinearities suitable for exploring a range of nonlinear optics effects such as Raman scattering and four-wave mixing at low optical powers. Finally, we will show examples of coupled-mode induced transparency that was achieved by internal pressure tuning of the whispering gallery modes in a silica glass microbubble. Overall, this paper aims to highlight the versatility of microbubble resonators across a variety of research topics and we will provide a number of examples of areas where their properties can be exploited in future work.

Femtosecond Laser Inscription of 3D Optical Waveguides in Glasses, Polymers and Crystals

Abstract— Focused femtosecond laser pulses drive nonlinear absorption in a wide variety of transparent materials including glasses, crystals and polymers. This nonlinear interaction enables a micrometer-sized modification confined to the focus, which allows one to pattern micro-photonic devices with novel three-dimensional geometries.

In glasses and crystals, the ultrashort laser pulse interaction leads to a permanent alteration of the refractive index, enabling the formation of 3D photonic circuits. In polymers, the laser-induced modification tends to decay with time, an effect which is unsuitable for the fabrication of photonic devices [1]. Among the many parameters used to tailor the modification in transparent materials, the pulse delivery rate (repetition rate) is perhaps the most significant. At suitably high repetition rates, typically greater than 100 kHz, the time between pulses is shorter than time for heat from the absorbed laser pulses to diffuse out of the focal volume. This leads to an accumulation of heat at the focus and if the pulse energy is sufficiently high, the material at the focus is melted. As further pulses arrive, the size of the melted zone expands outwards. After the final incident pulse, therapidly cools into a permanent modification with refractive index greater than the pristine bulk. In this way, the dwell time in static exposures or scan speed in scanned exposures can be used to tailor the final waveguide size for a specific application [2].

Here we will describe how high repetition rate fabrication can be exploited to form high performance and novel photonic devices in transparent materials for the burgeoning fields of quantum information, sensing and lab on a chip.

Abstract— Optical microresonators have attracted intensive attention due to their importance in practical applications as well as of fundamental physics interest in light-matter interaction. The optical confinement provided by a microresonator greatly enhances the coupling between optical spatial mode and the matter inside. Conventional fabrication of micro-cavities adopting semiconductor processing technology through either top-down or bottom-up approaches still faces some challenges. In this talk, we demonstrate the feasibility of constructing solid state micro-cavities with various configurations like spheres, hemispheres and fibres in a flexible way. We realize optically pumped lasing with high quality factor from these structures after loading gain materials (organic dyes or quantum dots). The optical modes are well defined by WGM lasing. We have demonstrated single-frequency operation in both spheres and fibres with reduced sizes. We are also able to tune the lasing by deforming the shape of micro-spheres, which represents the convenient manipulation of light matter interaction. Refractive index sensing with high sensitivity can be readily realized from these structures enabled by the existence of evanescent waves.

Meandering Waveguide Distributed Feedback Lightwave Elements: Phasor Diagram Analysis

Abstract— Meandering waveguide distributed feedback (DFB) structures are introduced as novel photonic lightwave circuits elements and their amplitude and phase response are studied in frequency and phasor domain. A preliminary transfer matrix method analysis is applied for taking the coupling purely directional and with constant coefficient on geometrically symmetric and anti-symmetric elements. The meandering loop mirror is the building block of all meandering waveguide based lightwave circuit elements. The simplest uncoupled meandering DFB structure exhibits Rabi splitting in the transmittance spectrum. The symmetric and antisymmetric coupled meandering DFB geometries can be utilized as band-pass, Fano, or Lorentzian filters or Rabi splitters. Meandering waveguide DFB elements with a variety of spectral responses can be designed for a variety of lightwave circuit element functions and can be implemented with generality due to the analytic approach taken. Meandering waveguide distributed feedback structures with a variety of spectral responses can be designed for a variety of lightwave circuit element functions.

Novel Fiber Array Scheme for Light Guiding and Trapping in Ultra-thin Solar Devices

Abstract— To obtain the maximum possible efficiency, in thin film light harvesting or light emitting devices, light incidence or extraction must be achieved simultaneously to light trapping in an orthogonal direction. This is the case, for instance, in many thin film solar cells where the most effective sunlight harvesting would require a bending of the incident light propagation path followed by a trapping within the active material layer. To some extent, the opposite behavior is needed in the light guiding plate from edge-lit electronic devices to achieve a homogeneous illumination of the LCD.

In here, we will consider configurations to effectively reach such, to some extend contradictory, behavior for the light propagation. We will pay special attention to light harvesting and photovoltaic performance of thin film solar cells deposited on the back side of an array of parallel fibers. In such periodically ordered system an ergodic light propagation resulting from a chaotic photon trajectory is achieved when the adjacent fibers are intercalated. The light intensity distribution brakes into a largely disordered pattern, but with a clearly identifiable larger light intensity on the caustic. This allows coupling to a whispering gallery mode (WGM) on the top interface of the array. In other words, the window opening in between fibers allows for an effective trapping of the light that was incident orthogonal to the plane of the array.

We fabricated a fiber array with a solar cell coated on the side opposite to the light entering side. The photovoltaic performance of such solar cell was measured and we showed that the efficiency in photon to charge collection can be increased by more than 30% on average and up to 50% at certain wavelengths. The performance for such fiber array solar cell will be evaluated against other light management configurations in thin film cells.

FDTD Simulation of a Cylindrical Waveguide Using Longitudinal Current Distribution as an Excitation Scheme

D. V. Peponis, G. P. Latsas, Z. C. Ioannidis, and I. G. Tigelis
Faculty of Physics, National and Kapodistrian University of Athens
University Campus, Athens 157 84, Greece

Abstract— In the study of high-power and high-frequency microwave structures several semi-analytical and numerical approaches are employed. In this work, we use the FDTD method to study the propagation characteristics in cylindrical waveguide structures with a longitudinal current distribution as an excitation scheme. Maxwell equations are formulated in cylindrical coordinates and a cylindrical mesh is used to obtain conformity to the geometry and avoid the staircase error that would arise by using Cartesian coordinates. The longitudinal current excitation distribution is selected, since it can probably model the excitation by an electron beam (in the small signal regime), or the excitation of the waveguide using an electric probe. The waveguide is terminated at both sides by Complex Frequency Shifted-Perfect Matched Layers (CFS-PML) in order to absorb both the travelling and the evanescent waves. In order to verify the method and benchmark the corresponding numerical code, the simple case of a smooth cylindrical waveguide is examined, excited by a current distribution with a Gaussian modulated sinusoidal time dependence. The current distribution is modeled as a longitudinal thin wire (placed on the axis of the waveguide), conducted by a constant spatial current density. Due to the location of the wire and the proper choice of the frequency range of the excitation, only TM_{01} mode can be excited. The radial distribution of the electric field components as well as the 2D (ρ-φ plane) contour plot are presented and compared with the theoretically expected ones, showing good agreement between them. Moreover, the presence of the CFS-PML layer is examined as well as how it affects the propagation characteristics. It is shown that by fine-tuning of its characteristics, satisfactory absorption rate can be achieved and thus infinitely long and open-ended waveguides can be properly studied. Finally, possible applications of the numerical code are presented as well as how this excitation scheme can model more realistic structures.

High Precision Range Measurement Processor Design with Low Complexity for FMCW Radar Systems

E. Hyun[1] **and J. H. Lee**
ART (Advanced Radar Technology) Lab
DGIST (Daegu Gyeongbuk Institute of Science & Technology), Korea

Abstract— FMCW (Frequency Modulation Continuous Wave) radar systems have been widely used for the measurement of range in a variety of industrial applications: automotive safety, traffic monitors, level gauges, security, defense seekers. Especially, level measurement is popular in almost every modern industrial plant for the measurement of bulk materials. That is, digital level measurement based on FMCW radar is a trend because the digital approach is more flexible and program updates are very easy.

In FMCW radar, when a continuous frequency modulated microwave signal is transmitted, the receive echo signal is down-converted into the baseband by the transmit frequency. The difference in frequency between the transmit and the receive signals is called the beat-frequency. The beat-frequency is typically obtained using FFT (Fast Fourier Transform) processing; range measurement is calculated using the detected beat-frequency. Thus, for exact level measurement in FMCW radar, it is very important to obtain a high precision beat-frequency. That can be realized using enough sample data and many FFT points. However, in a high precision FFT processor, many hardware resources and long processing time are required due to the increased computational complexity.

In this paper, we propose a low complexity frequency measurement processor. First, using the low precision FFT processor, the coarse ROI (Range Of Interest) is detected. Then, in the ROI, the fine frequency spectrum is analyzed using a frequency spectrum estimator consisting of a complex multiplier-accumulator. Compared with traditional FFT processors, even though the performance of the proposed processor is the same, the utilized hardware resources and the processing time can be decreased.

Schur Complement Based Method of Moments Solution for 2D Scattering Problem from Mixed Dielectric-conductor Targets

Mehmet Nuri Akıncı and M. Çayören
Department of Electronics and Communication Engineering, Istanbul Technical University, Turkey

Abstract— In this paper, we deal with the two dimensional scattering problem from mixed dielectric-conductor targets. In particular, we analyze a Schur-complement based Method of Moments technique as the solution procedure. In fact, different solutions to the mixed dielectric-conductor scatterer problem [1–3] and several works on Schur preconditioners can be found in the literature [4, 5]. Here, what we propose is simply that the currents on different kinds of scatterer must be appended in different vectors. For this purpose, we use a rectangular mesh to discretize the dielectric scatterers. Pulse functions are used as basis functions and the integral of the Green's function on the discretized rectangles is analytically calculated by using the well-known circle approximation [6]. For the conductor objects the surface is discretized into points and the integrals of Green's function is numerically calculated on the lines which connect the discretized points. Finally, dirac-delta functions are used as weighting functions and an equation system for the currents on the scatterers are obtained. As stressed above, the currents on the different kind of materials (dielectric-conductor) are casted into two different vectors. Then the inversion of "the object equation" are done by means of the Schur complement. By doing so, the inversion of the large Green matrix turns into the inversion of two subblocks of this matrix. The accuracy of this Schur complement based Method of Moments solution is tested against the analytical solution of the scattering from a dielectric coated conductor. Moreover, an error rate analysis is made by comparing the theoretical expressions with the simulated fields. Obtained results show that the Schur complement based inversion of object equation increases the validity range of the solution obtained from Method of Moments.

Abstract— Dynamic speckle is a scattering phenomenon occurring when coherent laser light illuminates an active surface. Scattered waves are Doppler shifted by movements of the scattering centres or other dynamic changes, such as refractive index time variations. These random coherent electromagnetic waves beat on the detector thus producing low-frequency intensity variations. As a result, the surface appears to be covered by tiny bright dots that fluctuate in a seemingly random way similar to boiling liquid.

The study of the temporary evolution of the speckle patterns may provide an interesting tool to characterize the parameters involved in the sample dynamic processes. It has been used for several applications in biology, medicine and industry.

In this paper, we use this technique to analyze the hygroscopic properties of different types of porcelain for electrotechnical purposes. Experimental speckle results showed different behavior depending on both physicochemical and textural properties of the samples.

The typical porcelain consists of a mixture of three aluminum-silicates in a ratio: 50% kaolin 25% quartz and 25% feldspar. This porcelain has basic electrical, mechanical, thermal and porosity properties which naturally vary according to the composition of the mixture.

These materials are commonly used due to their insulating quality (e.g., insulation resistance) which basically depends on its porosity and hygroscopicity.

This work analyzes four types of commercial electrotechnical-porcelain using both textural and physical-chemical methods and their water adsorption capacity by the Dynamic Speckle Laser technique.

Experimental results showed the evolution of the speckle patterns during hydro-adsorption process, permitting to discriminate different behavior for each material. It was determined that it is possible to correlate changes in the speckle patterns with the porosity and composition of materials.

Random Electromagnetic Interferometry Method Applied to Aluminosilicates Analysis

Abstract— The minerals based on aluminosilicates such as clays (kaolinite, montmorillonite) and zeolites (clinoptilolite) are abundant and inexpensive. These are used as adsorbents for the removal of bacteria and pollutants. It has been proven that the presence of hydrogen bonding interactions, and electrostatic forces of attraction on the surface of zeolites modified with anionic and/or cationic species have a significant effect on the process of microorganisms elimination. The treatment of the zeolite surface with concentrated acids or bases also modifies their hygroscopic properties.

This paper presents advances in the Dynamic Speckle Laser hydroadsorption analysis of materials based on a rich mineral "clinoptilolite" and their acidic and basic forms, which served as support for the incorporation of a binary complex sulfadiazine cobalt, promising in antibacterial drug design, fungicides, anti-inflammatory, etc..

To determine the water adsorption capacity of these materials as a function of time, the traditional method consists of introducing a sample in water and plotting the time dependent weight change in order to determine the amount of water adsorbed.

In this work we use a technologically advanced and methodologically more accurate method for determining the speed of hydroadsorption of a zeolite (clinoptilolite) based on the optical random interferometric phenomenon named "speckle", produced when a laser light illuminates a rough surface of zeolite. The data derived from the latter methodology is fitted using a numerical model that yields a better fitting as compared with several physicochemical (or physical) methods well established in the literature.

Modeling of Electromagnetic Scattering from Simplified Leaf Structures by Using Spherical Wave Expansion

Paul Jason Co and Jun-Ichi Takada
Department of International Development Engineering, Tokyo Institute of Technology, Tokyo, Japan

Abstract— Leaf scatterers are a type of obstacle that is abundant in rural propagation environments. These leaf scatterers interact with propagating radio waves which may affect the performance of wireless systems operating in such environments. Modelling the effects of these leaf scatterers in the propagation medium is necessary to ensure the performance of wireless systems in the presence of such obstacles. In this paper, deciduous leaf scatterers are modelled as thin dielectric disks. The electromagnetic scattering from these disks are modelled using the generalized Rayleigh-Gans (GRG) approximation as well as numerically using a commercial method of moments solver, and is evaluated at a frequency of 2 GHz. For the single scatterer case, results show good agreement between the GRG approximation and the numerical results, with the GRG approximation generally underestimating the scattered fields, as well as significant errors appearing in the null regions of the scattering. To evaluate the difference between the GRG approximation and the numerical results, spherical wave expansion is performed on the scattered fields from both the GRG approximation and the method of moments solution. The spherical modes of the scattered fields from both solutions are compared, and the number of spherical modes needed to represent the scattered fields from the single disk from both solutions are evaluated.

An approximation of the scattered fields for the multiple scatterer scenario is applied by performing a superposition of the GRG scattered fields from each of the individual disk scatterers. The scattering from multiple realizations of 30 disk scatterers randomly oriented and positioned within a 1 cubic meter volume is evaluated. First order scattering results which only consider the fields directly scattered from the incident wave show that the scattering pattern from the superposition approximation is similar to the scattering pattern from the full wave numerical solution, but under estimates the magnitude of the scattered fields by approximately 4 dB. Second order scattering is evaluated, where the scattered fields from the GRG approximation is used as secondary incident waves to other disks in the region. Results from the second order approximation showed an improvement in the accuracy of the scattered field magnitudes in the backscatter region to within 1dB of the numerical results, with minimal improvement in the forward scattering region. To isolate the error in the multiple scatterer approximation due to the errors in the GRG approximation, a hybrid superposition of the numerical results is proposed. The scattering from the individual disk scatterers are represented as a spherical wave expansion of the numerical results. Applying the superposition approximation to these spherical wave expansion of individual scatterers eliminates the errors from the GRG approximation.

Abstract— Planar Frequency selective surfaces (FSS) have attracted large attention during the last five decades because of their mechanical and electrical flexibility. They behave as spatial filters that are largely employed in applications like hybrid radomes for radars and antennas where high performance is necessary. The FSS have evolved from simple canonical forms to the complex geometries. For these structures, we must consider both the effects related to the periodicity that those related to the size of the individual elements. While periodicity impacts firstly on the general reflecting properties of the surface, the shape and the size of the individual element affects both spatial and frequency filtering behaviour. In particular the frequency response is dictated mainly by the scattering of the incident plane wave by the individual element and attains its maximum at resonance conditions. Accordingly, we mean to investigate whether the same occurs also for non planar surfaces and curved elements, and in particular conical surfaces. The analysis is performed in two steps. As scattering by a passive single element depends also on the radiating behavior of the same element when fed as an antenna, first the frequency behaviour of its input impedence is numerically computed by a commercial code. Of course this computation is performed assuming the single active element emebedded within a number of similar ones to take into account partly mutual interactions within the FSS. In the paper, as scattering elements, both radial and circumferencial strips conforming a conical shape are considered. Subsequently the frequency behiavour of the conical surface is fully analysed by a numerical code solving the Electric Field Integral Equation for a FSS of finite size made of thin elements conforming a curved surface.

Time Domain Transient Analysis for Ellipsoidal and Hyperbolic Reflector Antennas

Shih-Chung Tuan[1] and Hsi-Tseng Chou[2]

[1]Department of Communication Engineering, Oriental Institute of Technology, Pan-Chiao, Taiwan
[2]Department of Communication Engineering, Yuan Ze University, Chung-Li, Taiwan

Abstract— In this paper we present an early-time transient analysis of electromagnetic (EM) fields scattered from a perfectly conducting ellipsoidal and hyperbolic reflector when it is illuminated by a spherical wave of a feed's radiation with a cosine-tapered pattern and transient time response. This work is motivated by the needs of transient EM analysis in the booming applications of ultra-wide-band or short-pulse antenna systems for target identification and remote sensing such as in the design of impulse-radiating antennas (IRA). A transient-step response of the feed's radiation is considered because it will produce an impulsive response near the second focus of the ellipsoidal reflector, which is very interested in the applications of impulse-radiating antennas (IRA). Furthermore, an ellipsoidal reflector may reduce to a either spherical or parabolic reflector and hyperbolic with a proper parameter assignment. Thus, the developed solution has an advantage of exhibiting field phenomena when the surface changes to hyperbolic or from a spherical to a parabolic reflector.

A Time Domain Analytic Solution to Predict the Transient Radiation for Phased Periodic Array

Shih-Chung Tuan[1] **and Hsi-Tseng Chou**[2]

[1]Department of Communication Engineering, Oriental Institute of Technology, Pan-Chiao, Taiwan
[2]Department of Communication Engineering, Yuan Ze University, Chung-Li, Taiwan

Abstract— Most recently the applications have been extended to treat the problems arising in the near zone of electrically large antennas such as the vital life-detection systems and noncontact microwave detection systems, where the objects under detection may locate in the near zone of antenna. A TD analytic solution to predict the transient radiation from a phased periodic array of elemental antennas is thus developed. The TD phenomena are investigated in this paper. The TD phenomena of Floquet modes in the quantity of field potentials with a transient impulse excitation in the current moments were examined. In this generalized analysis, one first considers a two dimensional finite array of current moments with phases impressed to radiate fields focused in the near zone of array aperture, where the focal field point can be arbitrarily selected.

Analytical Study on Transmission Characteristics of MSL with Dielectric Adhesive-backed NSS

Y. Tomizuka, G. Ichihara, M. Setsu,
T. Ohno, K. Tanii, and M. Uehara
National Institute of Technology, Kisarazu College, Japan

Abstract— In this paper, transmission characteristics affected by a dielectric adhesive between a noise suppression sheet (NSS) and a transmission line are examined. A microstrip line (MSL) based on IEC standard (IEC62333-2) is fabricated, and a transmission characteristic of the MSL attached with a dielectric adhesive-backed NSS is simulated and measured.

Figure 1 shows the measurement system of the MSL attached with an NSS. The substrate shown in Fig. 1 is fabricated on ARLON DiClad522 ($\varepsilon_r = 2.55$, $\tan\delta = 0.0022$). Fig. 2 shows the FDTD simulation model based on the measurement system above. The thickness of the adhesive is defined as d [mm].

Figure 3 shows the simulated and measured transmission characteristics in the case of $d = 0.0$ [mm] or $d = 0.1$ [mm]. The maximum difference of transmitted electric power between simulated and measured results is 2.8% in $d = 0.0$ [mm], and is 3.1% in $d = 0.1$ [mm], respectively. Therefore, the simulation model shown in Fig. 2 is available from the above results.

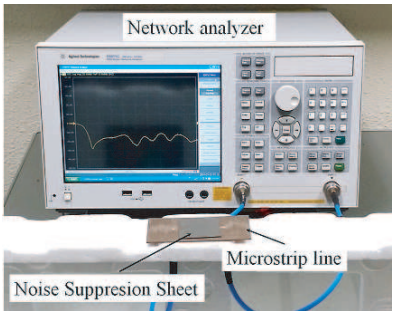

Figure 1: Measurement system of transmission characteristics on a microstrip line.

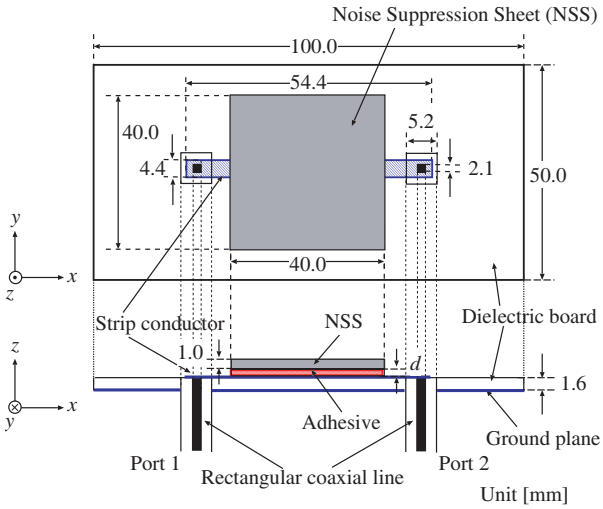

Figure 2: Simulation model of the MSL with NSS.

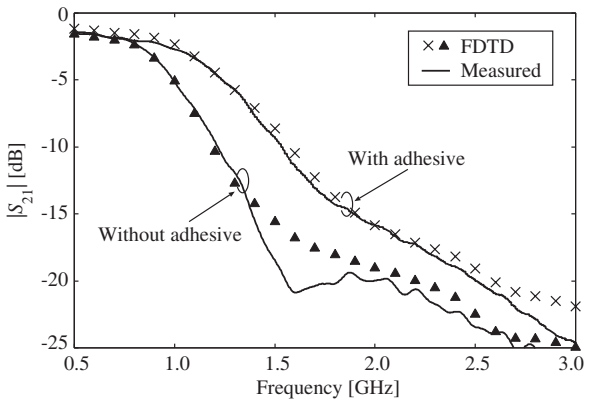

Figure 3: Simulated and measured results of Fig. 1.

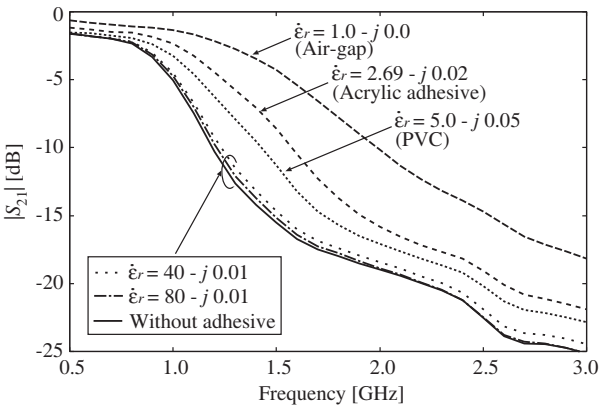

Figure 4: Simulation results of NSS with different adhesive.

Figure 4 shows the transmission characteristics of the MSL attached with the NSS using different dielectric adhesive. From Fig. 4, the cutoff frequency in the case of without adhesive is 0.87 GHz. The cutoff frequency is shifted to 1.33 GHz when the adhesive shown Fig. 2 is replaced by air-gap. Moreover, the effect to transmission characteristic is clearly decreased when adhesive is used compared to the air-gap. When the real part of permittivity of adhesive is increased to 40 or 80, these transmission characteristics are similar to the characteristic in the case of without adhesive. As a result, it is important to consider the complex relative permittivity in the adhesive between an NSS and a transmission line.

Ferroelectrics in RF and MW Adaptive (Electronically Tuned) Matching Circuits

Abstract— The creation of effective adaptive (electronically tuned) matching circuits is one of the key problems for development of modern RF and MW electronics. Traditional adaptive matching circuits are tuned by using semiconductor, ferromagnetic or MEMS elements. Ferromagnetic tuning consumes a large amount of power and rather slow tuning time (μsec scale); besides of slow tuning time (μsec scale) the MEMS elements have a limitedRF and MW operating power. Semiconductor elements in spite of their fast switching time (ns scale) have a limited power handling capability in point of a parasitic intermodulation product. The use of ferroelectric (FE) materials in paraelecrtic state makes it possible to suppress the negative featuresmentioned above.

Ferroelectric materials such as barium strontium titanate ($Ba_xSr_{1-x}TiO_3$ (BSTO)) in paraelecrtic state and strontium titanate ($SrTiO_3$ (STO)) are the most perspective compositions for RF and MW applications especially at high operation power. These materials have no frequency dispersion of dielectric constant (ε) up to 100 GHz and the suitable tunability ($k = \frac{\varepsilon(E=0)}{\varepsilon(E\neq 0)} \geq 3$) with time of tuning of 10 ps scaleunder electrical control voltages. Dielectric losses in a ferroelectric elements are comparable to the losses in semiconductor ones. In present work the properties of tunable RF and MW elements on the base of thin ($\leq$1 μm) films and bulk ceramics (thickness of $(0.15 \div 1.00)$ mm) of STO and BSTO compositions are analyzed. The parameters of theFE materials and elements on their base were obtained in a broad frequency range using a set of measurement procedures elaborated by authors.

It can be concluded that the main barrier for application of ferroelectrics on microwave is the residual polarization phenomena leading to the decrease of tunability of microwave devices and the degradation of the speed of tuning. Nature of residual polarization phenomena is considered and methods of their suppression are presented.

Modeling and testing the new multilayer FE capacitance construction which provides the operation under high RF power with low level of parasitic harmonics were done. Adaptive matching circuits on the base of the tunable FE capacitors were elaborated andtested and conclusions about their application inindustrial systems (drying chambers, food defrozen chamber etc.), systems of wireless device charging and front antenna end of communication system were done.

Local Field Effects for Left-handed Planar Metamaterials

O. V. Porvatkina, **A. A. Tishchenko**, **and M. N. Strikhanov**
National Research Nuclear University "MEPhI", Moscow, Russia

Abstract— Metamaterials are artificially designed materials that have effective properties, such as anomalous refraction or reflection. Particularly, planar metamaterials have unusual properties such as manipulation of the polarization states of light diffracted from the surface. These structures also demonstrate extremely high confinement of electromagnetic fields and thus strong variations of field intensities, which can significantly enhance near-field optical forces [1]. In addition the planar nature of these structures means they could be incorporated into thin-film coatings for numerous optical components [2].

We consider dielectric and magnetic properties of left-handed planar metamaterials with negative permittivity and permeability. In our work we investigate planar metamaterials consist of anisotropic particles. We obtain dependence of permittivity on dielectric polarizability and permeability on magnetic polarizability of the particles. Local field effects are taken into account in calculations. These effects are caused by interaction between single particles. The analogue of such theory for 3D metamaterials was developed in our recent article [2]. We also obtain the generalized Clausius-Mossotti relations for planar metamaterials made of anisotropic particles in the long wave approximation. We calculate a response function to an external electromagnetic field in case of planar metamaterial. This function describes connection between external electromagnetic field and the local field. On the one hand, such connection allows us to analyze structure of electromagnetic field in the near-field regime [3]. On the other hand,the relationship between the field interacting with particles in the planar metamaterials and the external field is of key importance for calculations of characteristics of the electromagnetic radiation generated by charged particles or particle beams passing through or near the planar structures [4].

Total Internal Reflection as a Technique for Study of Surface Optical Characteristics of Left-handed Materials

A. M. Feshchenko, **A. A. Tishchenko**, **and M. N. Strikhanov**
National Research Nuclear University "MEPhI", Moscow, Russia

Abstract— Real material surface is known to differ from ideal plane surface because of the presence of nonuniform near-surface layer. The properties of the layer may influence considerably on various processes of macroscopic electrodynamics, such as reflection and refraction of light, propagation of surface waves, radiation from fast charged particle beams [1–3]. As the thickness of the layer is much smaller than the light wavelength, all inhomogeneities caused by natural surface anisotropy, impurity atom adsorption, surface relaxation and reconstruction, fluctuations in surface electronic states, — all these can be taken into account via introduction of surface polarization current into boundary conditions [3]. This surface polarization current is linearly dependent on the electrical field, and proportionality factor is the phenomenological characteristic of dielectric and magnetic surface features.

In this work we consider an effect of surface inhomogeneities of left-handed materials on light reflection and refraction. It is shown that total internal reflection could be useful for investigation of surface optical characteristics of metamaterial. Scattering of refracted wave in the near-surface layer leads to existence of radiation propagating from the boundary to the point of observation. It is convenient to describe this radiation as a result of excitation of the surface current. Note, this radiation does not arise in the absence of the inhomogeneities in case of total internal reflection. The angular distribution of the resulting radiation is derived and the opportunity of getting information about the properties of metamaterial surface with help of this method is discussed. Information about surface properties can be of great use for developing of metamaterial optics, for example, multilayered structures and waveguides [4], perfect lens [5], terahertz optics [6], cloaking and so on.

Evaluation of a Buckypaper's Electromagnetic Shielding Efficiency in X Band

N. Curreli, **C. Puddu**, **G. Muntoni**, **M. Simone**, **and A. Fanti**
Department of Electrical and Electronic Engineering, University of Cagliari, Italy

Abstract— Carbon nanotubes (CNTs) properties and applications are one of the most innovative and interesting research areas in physics and engineering. The electromagnetic behaviour of CNTs composites and plastic material such as PE and PMMA has been analized in several works. Recent works have highlighted how CNTs can be effectively applied in electromagnetic interference (EMI) as high shielding material. Basically, this is due to their high aspect ratio and their tunable conductivity, which allows the electrical percolation (with a little number of CNTs). It is crucial to understand and control the electromagnetic properties of these materials to apply them to devices' design in several research fields. A buckypaper is a shield made only with CNTs, it is used mainly to protect electronic devices from electromagnetic interferences inside the plains to prevent equipment damaging and unintended setting modification. At the same time, CNT shields could be applied to avoid radar detection of militar aircrafts. Moreover, in the next years these structures could have a wide application in nano- and bio-science: Potential application in the electromagnetical shielding concern nanoelectronis devices, nano-biomedical imaging and sensing or, in the near future, the protect medical equipments from high-frequency radiations.

This paper studies the shielding efficiency of an buckypaper interposed between a multifrequency source and a electromagnetic waved detector. Our analysis has considered a frequency spectrum from the microwave (1 GHz) to the UV band (10^7 GHz).

Waveform Measurement of Ultra-high Repetition Mode-locked Pulses Generated from a Silica Toroid Microcavity

Zhelun Chen, Takuma Nagano, Yusuke Okabe, Tomoya Kobatake, and Takasumi Tanabe
Department of Electronics and Electrical Engineering, Faculty of Science and Technology
Keio University, 3-14-1 Hiyoshi, Kohoku-ku, Yokohama, Kanagawa 223-8522, Japan

Abstract— An optical frequency comb exhibits a pulse train when we observe it in the time domain. The repetition rate of the pulse train is determined by the frequency interval of the comb space. Since the spacing of a frequency comb generated from a microcavity is extremely large, it exhibits an ultrahigh repetition rate and the phases of the modes are locked. In this study, we demonstrated and measured the arbitrary generation of ultrahigh repetition rate pulses ranging from 0.8 to 8 THz by utilizing a silica toroid microcavity. The Kerr comb interval is controlled by changing the input laser power, wavelength and wavelength scan speed. The experimental results are shown in Fig. 1, where the pulses were measured with an SHG autocorrelator. We clearly observed that the generated comb exhibited mode-locking and also pulse trains at an ultrahigh repetition rate. It should be noted that such pulses are generated by continuous wave laser pumping. This demonstration of the generation of ultrahigh repetition rate pulses at an arbitrary frequency opens the possibility for future application of the Kerr comb as a high-speed signal-processing source.

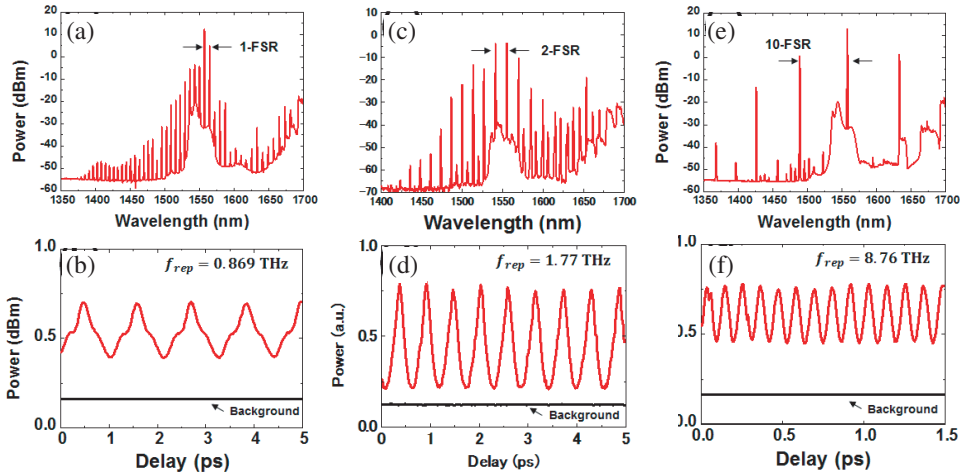

Figure 1: Experimental results for generated Kerr combs and their SHG autocorrelation traces. We used a toroid microcavity with a Q factor of 2×10^6 and a free spectral range (FSR) of 0.875 THz. The input wavelength and power are (a) (b) 1557.1 nm and 0.49 W, (c) (d) 1540.56 nm and 0.55 W, and (e) (f) 1557.1 nm and 0.49 W, respectively.

Fundamental Mode Cutoff Filter for Highly Sensitive Fiber Strain Sensing Applications

Photon-Avalanche-Like Nonlinear Excitation and Optical Low-Energy Ultrafast Switching in Solids

E. Yu. Perlin and A. V. Ivanov
ITMO University, 14 Birzhevaya liniya, St. Petersburg 199034, Russia

Abstract— A new mechanism of photoexcitation of transparent crystals is studied. The mechanism exhibits an exceptionally high degree of optical nonlinearity and shows itself even at moderate laser radiation intensities $j \sim 10^5\,\mathrm{W/cm^2}$. A three-band model of a crystal is treated. It is assumed that the photon energy of laser radiation $\hbar\omega$ is such that $\hbar\omega < E_g < 2\hbar\omega$, where E_g is the energy gap between the top of the valence band v and the bottom of the lower conduction band c_1. At the same time, it is assumed that, near the bottom of the band c_1, the energy $\hbar\omega$ is equal to the energy gap between the band c_1 and the upper conduction band c_2. At low excitation intensities j, no photo-induced transitions occur in the material, since in accordance with the above assumption, there are no free electrons in the band c_1 and there is no one-photon resonance between the bands v and c_1. At high intensities j, the situation is quite different. Due to two-photon transitions between the bands v and c_1, a certain number of free electrons appear in the band c_1. An electron generated in the band c_1 absorbs a photon and transits to the band c_2, in which it quickly falls (within a time of $\sim (2\text{–}7)\cdot 10^{-13}\,\mathrm{s}$) into the region of states close to the bottom of the band (e.g., because of emission of optical phonons). Then, due to "standard" radiative or nonradiative relaxation processes, however, in a longer time, the electron can transit to the conduction band c_1. In this case, the photon-involving Auger process $c_2 + \hbar\omega \to c_1 c_1 v$ is possible as well. In such process, in one elementary event, a photon is absorbed, and the electron from the band c_2 transits to the band c_1, liberating energy for the creation of an electron-hole pair consisting of a hole in the band v and an electron in the band c_1. As a result, there are now two electrons in the band c_1. In turn, these electrons, when transiting to the upper conduction band c_2, participate in the same process $c_2 + \hbar\omega \to c_1 c_1 v$, etc.. In this case, the concentration of nonequilibrium electrons in both of the conduction bands increases in an avalanche-like manner. The increase in the number of electrons in the lower conduction band yields a very sharp increase in absorption of light through one-photon transitions between the conduction bands.

The above-considered effect is in essence one of the modifications of the photon avalanche effect (see, e.g., [1–3]).

In this study, the probabilities of one- and two-photon interband transitions and the probability of the photon-involving Auger process are calculated. These probabilities enter into the system of differential balance equations for populations of free charge carriers in the bands v, c_1, and c_2. Numerical solutions of this system are obtained for a number of sets of typical band-structure parameters and relaxation times.

It is shown that, at the light intensities $j < 10^5\,\mathrm{W/cm^2}$, the crystal switches from state I, in which free electrons and holes are practically lacking and there is no noticeable absorption of light, to state II, in which the concentration of free charge carriers is as high as 10^{19}–$10^{20}\,\mathrm{cm^{-3}}$ and the absorption coefficient reaches 10^3–$10^4\,\mathrm{cm^{-1}}$. The switching time is 1–10 ns [4, 5].

A number of crystals, whose electron band structure allows the above-described photon-avalanche mechanism of photoexcitation and optical switching, are considered in detail.

[2]Theoretical Sector, Lebedev Physical Institute, Samara 443011, Russia

Abstract— Pattern formation and the evolution of complexity in spatially extended dynamical systems has been the subject of many investigations in widely diverse branches of science. In nonlinear optics, such studies have been motivated by the goal of developing a general understanding to describe the emergence of periodic and quasiperiodic patterns, vortices or spatial solitons using various nonlinear systems as well as gas, solid-state and semiconductor lasers. These systems are very complex devices having a rich spatiotemporal dynamics. The control parameter that determines the mechanism, which give rise to the transverse structure formation, is the Fresnel number.

In this work, we report on numerical and analytical investigations of the wave instability occurring for negative detuning (cavities tuned above resonance) in lasers class B. In that case, relations amongthe decay rate of polarization ,the decay rate of population difference and the cavity rate were $\gamma_\perp \gg \gamma_\parallel \gg \kappa$. We use the Maxwell-Bloch equations to describe the dynamics of transverse patterns in single longitudinal mode lasers, where the active medium is composed of two level atoms inside a cavity with flat mirrors. An important parameter for determining the behavior of the system is the cavity detuning of field frequency from the atomic resonance transition frequency.

With increase of the pump level the homogeneous solution becomes unstable against spatiotemporal perturbations with a finite wavelength. We have numerically simulated the dynamics of laser field above the second laser threshold in one- and two-dimensional cases. In the result of stability loss of steady solution, the regime that evolves in the system consists of a sequence of switches between traveling wave solutions with different wave numbers. The laser intensity presents the areas of nearly constant values which interrupted by bursts of large amplitude oscillations. The sequence of wave numbers can be predicted as perturbation with highest growth rate.

We use analytical and numerical approaches to perform the linear stability analysis. We found that the regime of dynamical switches is the result of secondary instabilities. By both methods, the evolution may be predicted with a relatively good precision.

Radiofrequency Impedance Spectroscopy of Active Optical Fiber Heating under Laser Generation and Amplification Conditions

Abstract— In active fibers, doped with rare-earth elements, in process of lasing some part of optical pump power is converted into heat. Main mechanisms responsible for fiber heating are optical quantum defect (difference between pump and emitting photon energies) and nonradiative relaxation of excited rare-earth ions. High CW power levels of modern fiber lasers (up to 20 kW in single-mode and 100 kW in multimode regimes) lead to the strong heating of active fiber, changing its absorption and photoluminescence optical spectra. Recently, we have proposed novel method based on radiofrequency impedance spectroscopy for temperature measurement of optical fibers [1]. Block scheme of the experimental setup applied for fiber temperature measurement (Fig. 1(a)) includes dielectric tube with copper wire reeled on it, forming connected in series induction coil and single-turn double-wire capacitor with placed inside active fiber segment and filled by additional polymer of the same type as cladding one. This configuration represents an oscillating LC-circuit. The resonant frequency of this circuit depends on temperature T, since the capacitance value $C(T)$ is specified by temperature dependent permittivity of the polymer. Equivalent temperature of the fiber amplifier segment in the operating mode (Fig. 1(b)) was measured using calibration dependence of resonant frequency measured in uniform heating experiment.

General theoretical model of fiber heating, based on solution of heat conduction equation with the heat source conditioned only by quantum defect inside active core [2], cannot explain experimental results. In order to find correspondence between measured equivalent temperature and actual temperature distribution inside fiber we developed coaxial model of fiber heating. Fig. 1(c) shows a cross-section of two-wire capacitor and mathematically simulated distribution of thermal field. Also additional verifying experiment was conducted, where optical fiber was replaced by the polymer coated copper wire, heated by the electric current. Simultaneous measurements of copper wire temperature basing on its resistance change and equivalent temperature of the polymer cladding showed that maximum equivalent temperature change of the polymer −41 K (measured at 120 W pump and 90 W lasing power) corresponds to 63 K of copper wire temperature change. In order to calculate true temperature distribution of the system we conducted one more experiment aimed at heat transfer coefficient determination by measuring kinetics of fiber cooling. This coefficient was found to be $60 \pm 5\ \mathrm{W/m^2{*}K}$. Using these data temperature distribution of the system was calculated. Average temperatures are: active core −57.6 K, silica cladding −52.6 K, polymer cladding −38.4 K. Developed theoretical model allowed us to find correspondence between experimentally measured equivalent temperature and actual temperature distribution inside active fiber.

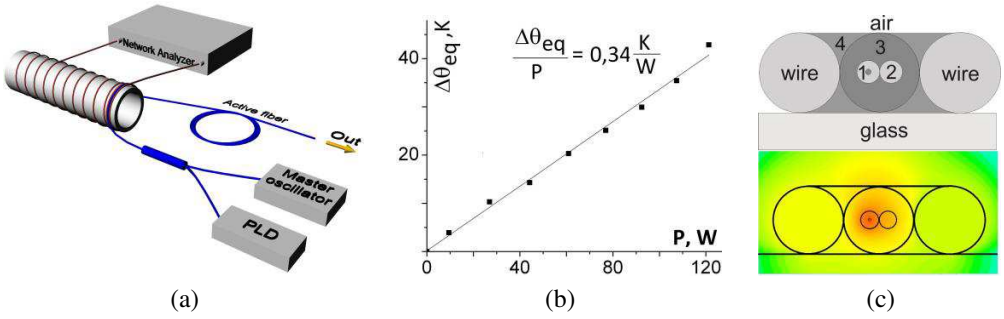

Figure 1: (a) Simplified block scheme of experimental setup. (b) Dependence of equivalent heating temperature of active fiber on pump power. (c) Cross-section of two-wire capacitor (1 — SM core, 2 — MM core, 3 — polymer cladding, 4 — additional polymer) (top) and its temperature distribution (bottom).

Abstract— Cerenkov effect [1] have a long history but it remains relevant in relation to the different areas of application of such a phenomena (the wide list of publication on this subject takes place, see, e.g., [2–4] and related references). The expression for the radiated power was obtained by solving the equations of classical electrodynamics in the medium. A large number of studies have been devoted to other aspects of the Cerenkov effect. They concern the extension to the case of magnetic media, a detailed analysis of radiation in crystals, the role of boundaries, etc.. The classical theory of spontaneous Cerenkov effect is fairly accurate, however the quantum analysis gives a more complete understanding of the phenomenon. Moreover, the quantum approach is most useful when considering the motion of a charged particle in a dielectric medium in the external electromagnetic wave. The radiation in this case has an induced nature and quantum approach gives a better understanding of the physical nature of phenomena.

Creation of powerful sources of electromagnetic radiation initiated extensive research in the area of particle-field interaction. The squeezed states of light [5] play an important role in such researches. These states generalize the well-known class of coherent states and are characterized by the fact that the uncertainty of one of the canonical variables of the electromagnetic field is less than in a conventional coherent state. The squeezed states are important in such areas as optical communication, interferometry, nonlinear optics, the detection of gravitational waves, etc.. It should also be noted that the squeezed states are objects of purely quantum nature. So the description of the motion of a charged particle on a background of the squeezed vacuum can be performed using the quantum field theory only. This problem is of great practical interest (new sources of electromagnetic radiation such as free-electron lasers and Cerenkov lasers).

In this work we investigate the Cerenkov radiation in the case of motion of a charged particle on a background of the squeezed electromagnetic vacuum. Using the quantum approach (time dependent perturbation theory) we obtain the following expression for the Cerenkov radiated power:

$$P = \left(1+|\nu|^2\right)\frac{e^2 v_e}{c^2}\int\limits_0^\infty \omega\left[1-\left(\frac{\hbar n(\omega)\omega}{2m_e c v_e}+\frac{c}{n(\omega)v_e}\right)^2\right]\Theta\left(1-\left|\frac{\hbar n(\omega)\omega}{2m_e c v_e}+\frac{c}{n(\omega)v_e}\right|\right)d\omega$$
$$+|\nu|^2\frac{e^2 v_e}{c^2}\int\limits_0^\infty \omega\left[1-\left(\frac{\hbar n(\omega)\omega}{2m_e c v_e}-\frac{c}{n(\omega)v_e}\right)^2\right]\Theta\left(1-\left|\frac{\hbar n(\omega)\omega}{2m_e c v_e}-\frac{c}{n(\omega)v_e}\right|\right)d\omega,$$

where ν is the squeezing parameter, $\Theta(z)$ is the Heaviside step-function. This expression contains two terms. First term corresponds to radiation power, while the second one corresponds to absorption power.

Abstract— Broadband electromagnetic measurement at frequencies above 100 GHz is still challenging problem because of limited frequency ranges of oscillators, complicated matching networks and ambiguous deembedding procedures. It is known that Josephson junction (JJ) is very sensitive to electromagnetic environment. When JJ interacts with external electromagnetic structure, characteristics of the structure in frequency domain are mapped into the modification of dc characteristics of JJ in voltage domain. Recently a new spectral technique based on nonstationary Josephson effect was proposed for frequency analysis of electromagnetic resonant structures, which were integrated with JJ. Here we extend this method to perform spectral characterization of planar resonators on separate substrates. We have studied resonator characteristics at frequencies from 50 GHz to 500 GHz, using $YBa_2Cu_3O_{7-x}$ high-T_c bicrystal grain boundary junctions on $NdGaO_3$ and MgO substrates. Differential resistance vs. voltage curves $R_d(V)$ modified by the interaction between JJ and resonator have been analyzed. Resonators were formed by from cooper thin films on Al_2O_3 separate substrates by UV photolithography. The planar resonator has been presented as RLC-circuit. Parameters of equivalent circuit have been obtained by fitting simulated $R_d(V)$ curves to experimental data. Set of resonance frequencies have been obtained for split ring resonators from 50 GHz to 500 GHz and quality factors have been estimated. An excitation of fundamental resonance mode in the planar resonator by Josephson oscillations was demonstrated. The technique developed might be used for frequency characterization of THz photonic elements and structures.

Stronger Nanoscale EM and BEM Solutions by CICT Phased Generators

R. A. Fiorini
Department of Electronics, Information and Bioengineering (DEIB)
Politecnico di Milano University, Italy

Abstract— There is no doubt that the IC (Infinitesimal Calculus) has played in the past and will play in future a major role in the mathematical treatment of EM (electromagnetic) and BEM (bioelectromagnetic) modeling problems, but we must be aware that its addiction hides some important features of the phenomenon being described, such as the geometrical and topological features. The addiction is such that, since the digital computer requires an algebraic formulation of physical laws, it is preferred to discretize the differential equations, rather than considering other more convenient tools for problem mathematical description like, for instance, FDC (Finite Differences Calculus) or more sophisticated algebraic methods. Hence, to apply the numerical methods we are forced to return to a discrete formulation using one of the many methods of discretization, starting from classic FEM, BEM, FVM, FDM, etc., to arrive to specialized algorithms to achieve fast operational compromises in specific application areas. Nevertheless, traditional FDC and even more sophisticated and advanced algebraic approaches are unable to conserve overall system information. In fact, misplaced precision leads to information opacity, fuzzyness, irreversibility, chaos, complexity and confusion. To find innovative solution and to open the door to more reliable scientific problem description and solution ("Science 2.0" approach), we just need to remember the Relativity's father inspiration quote: "We cannot solve our problems with the same thinking we used when we created them." Eventually, our overview suggests us that to grasp a more reliable representation of experimental reality and to get stronger physical and biological system correlates, researchers and scientists need two intelligently articulated hands: both stochastic and combinatorial approaches synergically articulated by natural coupling. The former, applied to all branches of human knowledge under the "continuum hypothesis" assumption, has reached highly sophistication level, and a worldwide audience. Many "Science 1.0" researchers and scientists up to scientific journals assume it is the ultimate language of science. The latter, less developed under the "discrete hypothesis" assumption in specific scientific disciplines, has been considered in peculiar application areas only. It has been further slowly developed by a few specialists and less understood by a wider audience. The computational information conservation theory (CICT) approach brings classical and quantum information theory together in a single framework, by considering information not only on the statistical manifold of model states but also from empirical measures of low-level multiplicative noise source generators, related to experimental high-level overall perturbation. According to CICT Infocentric Wordview, traditional elementary arithmetic long division remainder sequences can be interpreted as combinatorially optimized exponential cyclic sequences (OECS) encoding hyperbolic geometric structured information, as points on a discrete Riemannian manifold, under HG metric, indistinguishable from traditional random noise sources by classical Shannon entropy, and current most advanced instrumentation approach. In other words, if we want to achieve overall system information representation conservation and to get stronger solution to advanced problems, like resonant nanoparticle, nanophotonic, opti uidics structure modeling, etc., we have to look for convenient arbitrary scaling BU (bottom-up) point-of-view (POV) (from discrete to continuum view $\equiv$ BU POV) to start from first, and NOT the other way around! Then, a top-down (TD) POV can be applied for overall final model validation and endorsement, if needed. CICT formulation has the great merit of maintaining close contact between the mathematical description and the physical phenomenon described, showing how to obtain a purely algebraic formulation of information and physical laws relating directly elementary information generators to experimental measurements. A few examples are presented and discussed.

Dynamical Model of Elastic-plastic Hysteresis in Fullerens Film

Abstract— The hysteretic effects take place in various areas of material science (both in macro and micro levels). Depending on the purposes of investigation both the phenomenological and constructive models can be used and there are many literature sources on this subject (see, e.g., [1] and related references). As a rule in the constructive models which are described by the relations "input-state" "state-output" [2, 3] the dynamical properties of the hysteresis carrier have no taken into account. It is a well-known fact that the mechanical properties almost all the materials (these properties the elastic-plastic hysteresis) remain unchanched (hysteretic dependence of elastic-plastic materials does not depend on the speed of mechanical affection). However, the results of experiments with the fulleren nanofilms [4] show that the hysteretic curve in the coordinates "force-displacement" depends on the speed of force application.

In this work we propose the dynamical probability model of hysteresis for description of elastic-plastic properties of nanoscale fulleren film taking into account the electromagnetic nature of fulleren clusters binding. This model is based on the fact that the decay law for fulleren super-cluster $[C_{60}]_n$ (especially for $n = 2$) depends on the external conditions (temperature, pressure, etc.) as well as has a probability nature. The description of the decay law in the macroscopic level can be made using the theory of random processes (Kolmogorov-Chapman equation). The results of numerical simulations are in good agreement with the known experimental data.

Binary Collision with Energetic Ions of Carbon Nanotubes

D. Bajalan
St. Pölten, Austria

Abstract— Carbon nanotubes (CNTs) are very interesing technological branch. Due to their low dimensionality, nanometer size and remarkable electronic, mechanic and magnetic properties, nanotubes are promising structures for many purposes in several fields of physics, materials science or biomedicine [1]. Channeling of energetic ions through solids is a phenomenon which should be accounted for in the present day semiconductor technology, as it gives rise to deeper implantation and less lattice disorder. The channeling effects are particularly important for materials with high crystallization and anisotropic atomic structure [2]. Experiments on the irradiation of carbon nanotubes with energetic particles poses many interesting properties. These effects may potentially be used in various practical applications, such as nanoelectronicdevices.

Applications of Carbon Nanotubs and Other Nanomagnetic Nanowires

D. Bajalan
St. Pölten, Austria

Abstract— MWNTs are widely used in lithium ion batteries for notebook computers and mobile phones, marking a major commercial success [1].

Carbon nanotubes (CNTs) are hollow cylindrical molecules consisting of single or many sheets of graphite wrapped into cylinders with diameters of from less than 1 nm up to hundreds of nm. CNTs have extraordinarymechani cal and electrical properties. For example, their densitynormalized Youngs modulus and strength are estimated bo be, respectively, about 19 and 56 times that of steel. Depending on the wayof how the graphite sheets are rolled up, CNTs can be either metals or narrow-band semiconductors, which, along with their inherent nm-size, makes [2].

Carbon Nanotubes 1 atom thick, with diameters of only 1 to 2 nm, seems to be one of the perfect candidates to take us right to the end of Moores Law curve by 2019. We possibly cannot go beyond that. carbon Nanotubes is of importance for future nanodevice applications.

Abstract— Optical fiber strain sensors have been widely used in precision optical sensing application. The traditional fiber strain sensors can be made based on Michelson [1] and Mach-Zehnder interferometers [2, 3]. In this work, we show the air velocity sensor in fiber strain sensor made by single mode fiber. This sensor is constructed based on the stretched abrupt-tapered micro-fiber (SAT-MF). The single mode fiber will become to the tapered fiber with a diameter of around a few microns. So we used this structure to become the air velocity sensor.

Since the light program go through the abrupt tapered the fundamental mode will be converted and transferred into high order cladding modes and generate interference. We definition the taper diameter is D, first taper point to second taper point is L, as shown in Fig. 1(a). Fig. 1(b) shows experimental set-up of the air velocity sensor.

The thermal expansion coefficient of silica is as low as on the order of 10^{-7}, thus we can reduce the effect of temperature variations on strain sensitivity. The sensing area is a SAT-MF it can be easier to change the air velocity sensitivity.

Conception of Radiofrequency-optical Fiber-scanning Modulation Spectroscopy

O. A. Ryabushkin[1, 2] **and D. V. Protasenya**[1, 2]

[1]Moscow Institute of Physics and Technology (State University)
Dolgoprydnyi, Moscow region 141700, Russia
[2]NTO "IRE-Polus", Russia

Abstract— There are various methods applied for investigation of semiconductors electrical and optical properties. Some of them are based on excitation of charge carriers and measurement of light reflection from semiconductor surface. Changes in optical properties of semiconductors occur due to spatial redistribution of hot electrons, so that reflection spectra in the vicinity of fundamental absorption edge change considerably. In photoreflectance method, optical pump with quanta energy higher than semiconductor bandgap is used for excitation [1]. In microwave modulation reflectance method conduction electrons are heated by external high frequency electric field [2].

Investigation method that we propose is based on microwave modulation reflectance method. The main idea suggests localization of exciting field and probe light within microscopic area and spatial scanning in millimeter region. For this purpose probe made of optical fiber with two metallic electrodes inside cladding is used (see Figs. 1(a), (b)). Optical fiber is tapered in order to decrease both mode field diameter and distance between electrodes. Modern technology enables to fabricate such fibers with mode field diameters of several micrometers [3]. External surface of fiber is covered with metal and grounded in order to increase strength of localized electric field.

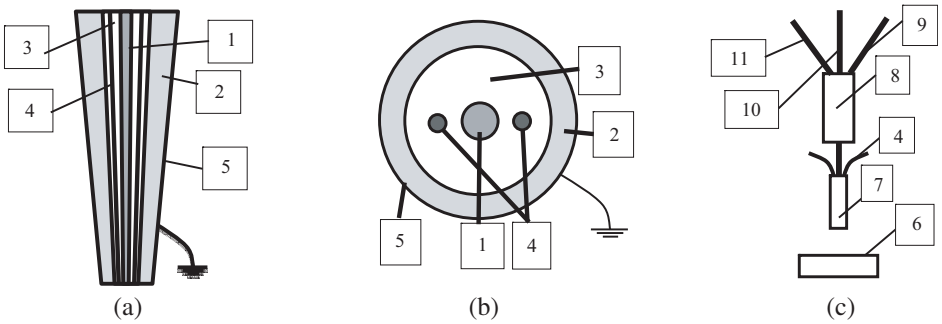

Figure 1: Structure of fiber with two electrodes inside cladding ((a) Side view and (b) cross section view) and scheme of the probe. Designations: 1-core, 2-outer cladding, 3-inner cladding, 4-electrodes, 5-metal cladding, 6-sample, 7-fiber structure, 8-3-to-1 optical coupler, 9-probe light channel, 10-reflected light channel, 11-pump light channel (optional).

Probe scheme is shown in Fig. 1(c). Probe is placed above the semiconductor structure and can be moved along the surface by positioning system. Radiofrequency field is created by application of alternating voltage to electrodes. 3-to-1 optical coupler is used for transmission of probe and reflected signals, it can also provide optical pumping of semiconductor. Reflected light is analyzed by spectrometer and its spectral changes are detected via lock-in detection at modulation frequency of radiofrequency electric field.

Calculations of radiofrequency electric field distribution and electrical capacity of the probe were performed. Capacity dependence on distance between probe tip and substrate surface can be measured experimentally.

Thus, principal possibility of conductive samples investigation by microstructured fiber with electrodes inside was demonstrated. Proposed combination of microscopy and radiofrequency-optical spectroscopy enables to study samples at a submicrometer level and to obtain useful information about field and current distributions.

Radiofrequency Calorimetry of High-power Laser Radiation

O. A. Ryabushkin[1, 2] **and A. V. Konyashkin**[1, 2]

[1]NTO "IRE-Polus", 141190 Vvedensky Sq. 1, Fryazino Moscow Region, Russia

Abstract— Output powers of modern CW laser sources, applied in laser industry for material processing, exceed 20 kW in single-mode and 100 kW in multimode regimes. Measurement of such high-power levels during laser operation is a great challenge. Most commercial CW high-power meters employ total conversion of laser radiation energy into heat and subsequent measurement of temperature distribution inside sensing element. This approach inevitably results in radiation beam quality impairment and does not allow online power control. Besides, it offers relatively low measurement precision especially for high laser powers.

We introduce novel principle for precise laser power measurement independent on beam quality. It is based on measurement of the definite small part (0.01–0.1%) of the overall radiation power transmitted through the piezoelectric resonator made of nonlinear-optical crystal. Absorbed part of laser power is determined by measuring calibrated piezoelectric resonance (PR) frequency shift. It is well known that PR can be observed in nonlinear-optical crystal response to the applied electric field when its frequency corresponds to one of the crystal internal vibration modes. PR frequencies Rf are highly sensitive to crystal temperature change. We demonstrated that thermodynamic temperature of the crystal heated by laser radiation can be replaced by its equivalent temperature that is directly determined by measuring temperature calibrated Rf shift with power [1]. Crystal heating depends on optical absorption $\alpha(\lambda)$ at the given wavelength λ and heat transfer coefficient h^T with ambient. It was demonstrated that both coefficients can be measured using equivalent temperature concept [2]. Block-scheme of experimental setup for laser power measurement is shown in Fig. 1. Cylindrical piezoelectric resonator made of low-absorption quartz crystal is placed inside electrical capacitor connected in series with radiofrequency (RF) generator and load resistor R_L, which is used for measurement of electrical current via lock-in detection.

In order to minimize capacitor heating induced by scattered radiation its electrodes are made of two sets of thin metallic wires. For optical power measuring it is necessary to know values of the PR frequency $Rf(T)$ at any crystal uniform temperature T. Calibration measurements of Rf dependence on T give linear function: $Rf(T) = Rf(0)+K^{\mathrm{prt}}T$. Dependence of Rf on laser power P is also linear: $Rf(P) = Rf(0) + K^{\mathrm{pro}}P$. Unknown power P_x is then directly obtained from measured frequency shift $\Delta Rf(P_x)$ and coefficient K^{pro} : $P_x = [Rf(P_x) - Rf(0)]/K^{\mathrm{pro}}$ using extrapolation of $Rf(P)$ power calibration. In measurement process the irrelevant frequency shift caused by the ambient temperature change is excluded using $Rf(T)$ temperature calibration.

Introduced technique allows direct measurement and control of high average laser powers in wide dynamic and spectral ranges independently on radiation beam quality because any suitable nonlinear-optical crystal with appropriate absorption properties can be used as piezoelectric resonator.

Separating the Field Radiated by Two Rectilinear Sources

A. Natale, **M. A. Maisto**, **R. Solimene**, **G. Leone**, **and R. Pierri**
Dipartimento di Ingegneria Industriale e dell'Informazione, Seconda Universita' di Napoli
via Roma 29, Aversa 81031, Italy

Abstract— When dealing with electromagnetic field measurements for antenna diagnostics or even in inverse scattering problems one collects the radiated field (resp. the scattered field) over a domain and from such measurements the features of the antenna (resp. scatterer) under test have to be inferred.

It often happens that beside the field due to the structure under test (SUT), the fields produced by further sources (generally unwanted) are collected as well. This give rises to clutter signals from which the useful field signals (i.e., those one due to the SUT) must be singled out.

In this contribution we tackle a related problem for a canonical configuration. More in detail, two electric current sources are considered radiating in free-space. They are assumed to be supported over two parallel strips whose positions are a priori known. Their radiated fields are collected over a single domain located in far-zone (with respect the whole radiating system). Invariance is assumed along the direction orthogonal to the strips, which coincides with the currents' directions as well. Hence, a two-dimensional scalar framework is set.

The problem of concern is to distinguish between the two contributions. To this end, the problem is addressed by a two-step procedure. First, the currents are reconstructed by the radiated field measurements. This entails dealing with an inverse source problem that is tackled by comparing three different strategies of inversion. The first strategy consists in inverting the radiating operator, which rigorously describe the radiation by both the sources. In the second one, the radiated field data is inverted by considering each source as being radiating alone. Of course, in the latter case we have an approximate modeling but a less expensive computational procedure. Finally, the third method is a modification of the second one. Now, having reconstructed one of the two sources the corresponding radiated field is synthetically computed and subtracted from the data. Then the second source is reconstructed. The second step of the overall procedure then consists of computing the radiated field due to each source once they have been estimated according to the previous step.

Numerical examples are provided in order to compare the different strategies from the achievable performance and numerical complexity point of views.

A Bowtie Antenna Using a Broadband Microstrip to CPS Transition Balun

H. S. Ro and Y. S. Choi
Electronics and Telecommunications Research Institute, Korea

Abstract— A dipole patch antenna is widely used to obtain the performance of wideband and omnidirectional radiation pattern in wireless communication. Especially, a patch element of a bowtie shape offers good performances in the bandwidth and radiation pattern. By the way, this bowtie patch has to be fed by a suitable feeding network to satisfy the requirement.

A microstrip to coplanar stripline(CPS) transition balun has been used commonly used as feeding networks in this kind of antenna design. Various structures of microstrip to CPS transitions have been reported before. However, the previous structures have the difficulty in fabrication, or require large surface area for sufficient coupling.

In this paper, a bowtie antenna using a broadband microstrip to CPS transition balun is proposed. This antenna with a new transition structure has several advantages such as small size, wide bandwidth, and good impedance matching. In the balun of this antenna, the electric field distribution of the microstriop line as unbalanced transmission line is transformed to one of CPS as a balance one by using a via-hole and a tapered ground line on the bottom plane. In addition, the low impedance of the mircrostrip lines is gradually changed to the high impedance of the CPS. We had achieved an electrical contact between two different layers by only one via-hole in this transition.

The proposed antenna was optimally simulated for bandwidth from 2.2 GHz to 6 GHz. The antenna was fabricated on Teflon substrate with a dielectric constant of 3.5 and measured. The measured insertion loss is less than 10 dB from 2.1 GHz to 6.5 GHz. The measured gain is from −4.7 dBi to 2.4 dBi.

Both the measured and simulated results for return loss are in good agreement. The result of gain also shows a good performance.

Therefore, the proposed broadband antenna is very useful in various wireless application areas due to small size and simple structure.

Two Elements MIMO Antenna for a WLAN System

Hui Liu[1, 2], **Cheng Liu**[2], **Binjie Wang**[2], **Qibin Deng**[2], **and Youhuan Guo**[1]

[1]Computer Science and Engineering Department, Guangdong Peizheng College, Guangzhou, China
[2]Centre for Optical and Electromagnetic Research, Academy of Advanced Optoelectronics
South China Normal University, Guangzhou, China

Abstract— Many printed elements of antenna for MIMO system have the same structure element in literature recently. Because of the asymmetric structure of MIMO system in the actual engineering application, the same structure elements may not be suitable for MIMO system. For example, the S_{11} and S_{22} will be different if the two elements have the same dimensions in a real MIMO system, hence the design of elements should be consisted of different structures to improve good performance of the MIMO antenna.

A MIMO antenna with two elements, operating on 2.45 GHz ISM band frequency, for a asymmetric structure WLAN system was designed in this paper. One of the antenna element's dimensions was changed to make both of the antenna elements meet the same 2.45 GHz band frequency. The printed inverted-F and meander line structures were used for the antenna element. The parameters of S_{11}, S_{22}, isolation and envelop correlation coefficient (ECC) are discussed. It is shown that good results can be achieved with different dimensions of antenna elements.

A Printed Inverted-F MIMO Antenna for WiFi Applications

Cheng Liu[1], **Hui Liu**[1], **Binjie Wang**[1], **Zhibin He**[1], **and Sailing He**[1, 2]

[1]Centre for Optical and Electromagnetic Research, Academy of Advanced Optoelectronics
South China Normal University, Guangzhou, China
[2]The Royal Institute of Technology, Stockholm, Sweden

Abstract— Some Antennas with printed Inverted-F structure have been proposed in literature recently few antennas were discussed the antenna test with mounted ICs in the practical engineering applications. Because the mounted ICs have affects, the size of simulated antenna may not directly be used in some WiFi Applications.

A printed MIMO antenna system designed with compact size is presented. The proposed MIMO antenna, consists two Inverted-F antenna elements, is designed on a two-layer FR-4 printed circuit board (PCB). The MIMO antenna provides adequate bandwidth coverage for WiFi (2.45 GHz). The antenna simulation and test with mounted ICs results are discussed and compared. The MIMO antenna with and without mounted ICs show that working frequency is shifting. Therefore the sizes of simulation antenna should be changed to decrease the shifting frequency.

Design and Analysis of a Phased-MIMIO Array Antenna with Frequency Diversity

Nour El-Din Ismail, **Sherif Hanafy Mahmoud**, **Ahmed Hamed, and Alaa Hafez**
Faculty of Engineering, Alexandria University, Alexandria, Egypt

Abstract— Phased-Multiple-Input Multiple-Output (phased-MIMO) radar has been thoroughly investigated in the literature. This approach divides the transmit antenna array into multiple subarrays that are allowed to overlap. Each subarray coherently transmits a distinct waveform, which is orthogonal to the waveforms transmitted by other subarrays. While phased array radar enjoys the advantage of high coherence gain with no diversity gain, MIMO radar enjoys high diversity gain — whether waveform or spatial diversity gain — with no coherence gain. Phased-MIMO radar enjoys both advantages of coherence gain and diversity gain which enhance the main-to-side lobe levels but unfortunately decrease the antenna directivity.

Frequency diversity can improve antenna directivity by applying a small frequency increment between two successive elements but consequently increases average side lobes level. In this paper, we propose a new Phased-MIMO radar with frequency diversity which offers a tradeoff between main-to-side lobe levels and antenna directivity. This technique can exploit frequency diversity which is applied between subarray adjacent elements and between adjacent subarrays. The total beam pattern is an optimum case of the lowest side lobes level as phased-MIMO radar but with higher directivity.

A Simple Monopole Slot Antenna with High Band-notch Characteristics for Ultra-wideband Communication Applications

Yingsong Li[1], **Zhuqun Zhai**[2], **Wenxing Li**[1], **and Si Li**[1]

[1]College of Information and Communications Engineering
Harbin Engineering University, Harbin 150001, China
[2]Institute of Systems, Beijing 100161, China

Abstract— In this paper, a simple ultra-wideband antenna with flexible and tunable band-notch characteristics is proposed on the basis of a polygon slot structure. The notch band is realized by the use of an inverted V-shaped stub inserted into inside of the polygon slot. The flexible and tunable band-notch characteristics are achieved by adjusting the dimensions of the inverted V-shaped stub. The experimental results show that the proposed antenna can provide a wide bandwidth, a flexible and tunable band-notch characteristic and good omnidirectional radiation patterns, making it suitable for various UWB communication applications.

Dual-band Microstrip Antenna with Defected Ground Structure for WLAN Application

Wen-Chung Liu, **Ya-Yun Shih**, **and Chao-Ming Wu**
Department of Aeronautical Engineering
National Formosa University, Yunlin 632, Taiwan

Abstract— In recent years, more and more attention is paid in antenna design with multi-band operation for modern wireless communication systems. Therefore, in this paper, we present a novel compact printed antenna with dual strips and a defected ground structure (DGS), as shown in Figure 1, for dual-band operation. By folding and loading the twin strips, and defecting the ground plane of the antenna, multi-mode resonance with dual broad bandwidths can be excited. To verify the simulation results obtained from the CST electromagnetic simulator, the prototype of the proposed antenna was constructed and experimentally investigated. As shown in Figure 2, the measured bandwidths are 500 MHz (2.28–2.78 GHz) and 1.37 GHz (5.14–6.35 GHz) for the lower and upper bands, respectively, which agree well with the simulation. The experimentally obtained average gains across the two operating bands are 1.5 and 2 dBi, respectively, with typical monopole-like radiation patterns. The proposed antenna with a compact size of only $25 \times 25\,\text{mm}^2$ sufficiently covers performance requirement of the 2.4/5.2/5.8 GHz WLAN operation system. The proposed antenna with properties of simple and planar structure, dual and wide bandwidth, and easy fabrication can be effectively used in the upcoming generation of wireless communication systems.

Implementation of an Inverted-F Antenna with Improved Bandwidth

Jong-In Ryu, **Dongsu Kim**, **Jun Chul Kim**, **and Jong Chul Park**
Package Research Center, Korea Electronics Technology Institute, South Korea

Abstract— In this paper, an InvertedF Antenna (IFA) with improved bandwidth is designed and implemented in printed-circuit-board (PCB). Design objective is to apply an IFA with improved bandwidth in a Wi-Fi module. A normal IFA and a proposed IFA are designed and implemented. The performance is measured and compared.

A normal IFA and a proposed antenna are designed in 4 layers PCB [1]. The dielectric constant and loss of PCB are 4 and 0.03. A normal IFA is composed of short pin (L_{m1}, L_{m2}) and main radiation part (L_r). A proposed antenna has a sector shape with radius (L_r) as shown in Fig. 1. The proposed antenna is optimized through a simulation for verifying the difference in performance according to changes in the factors such as total length ($L_{m2} + L_r$) of antenna, width (W), and L_{m1}. As results, L_{m1}, L_{m2}, L_r and W, are 4.6 mm, 3.8 mm, 12.3 mm, and 1 mm. The size of the antenna is designed 48 mm × 12 mm × 1.4 mm.

In order to measure and compare the performance of a normal IFA and a proposed IFA, two kinds of antennas are implemented in PCB as shown in Fig. 2. The total size of implemented PCB in each antenna is 48 mm × 35 mm × 1.4 mm.

As can be seen from the measurement results of two kinds of picture antenna as depicted in Fig. 3, resonant frequency simulation both with about 150 MHz degree difference can be seen.

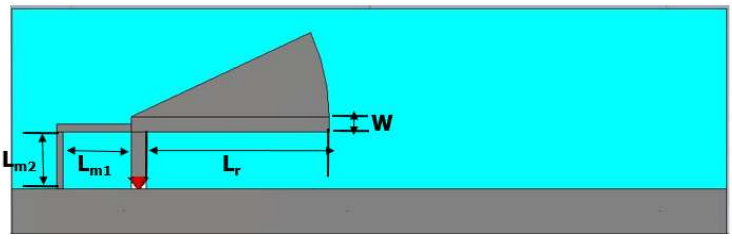

Figure 1: A proposed inverted-F antenna.

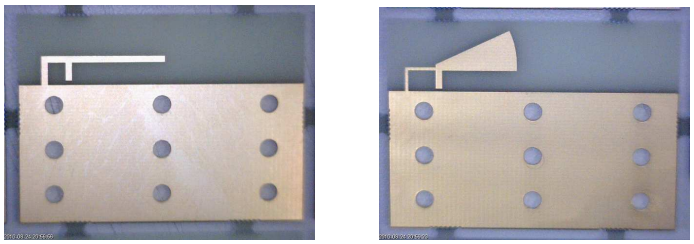

Figure 2: The implemented antennas for (a) a normal IFA and (b) a proposed IFA.

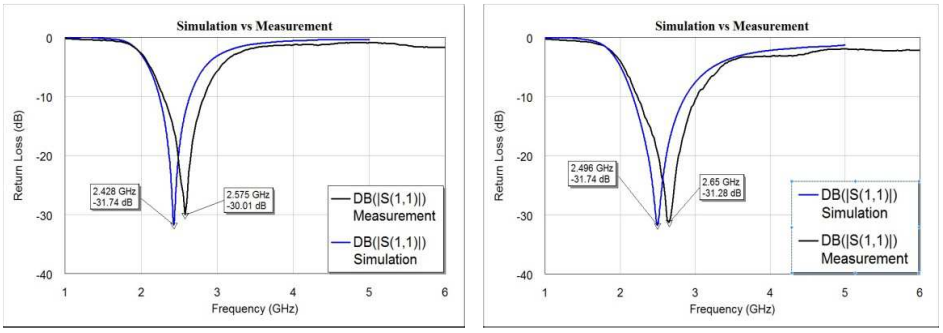

Figure 3: Simulation and Measurement for (a) a normal IFA and (b) a proposed IFA.

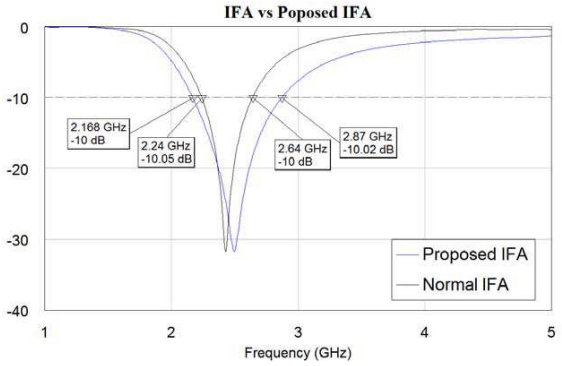

Figure 4: The compared results for antennas.

However, measured 30 dB return loss of resonant frequency and measured bandwidth did not differ significantly from the simulation results. And 10 dB bandwidth of the normal antenna and a proposed antenna is almost 400 MHz and 700 MHz as shown in Fig. 4. The proposed antenna has the increased bandwidth of almost 300 MHz. As a result, the resonant frequency was slightly different between simulation and measurement in each antenna, but results has good agreement with simulation for two antennas.

In this paper, a proposed IFA that improves bandwidth by modifying the shape of the IFA was designed and implemented. To obtain compared data, a normal IFA and proposed antenna were designed and measured. The bandwidth of almost 300 MHz was improved and total bandwidth was 700 MHz.

Isolation Improvement for Two Planar Dual-band Antenna Elements Placed Perpendicularly

Yu-Feng Shih and Ching-Lieh Li
Department of Electrical Engineering, Tamkang University, Tamsui, New Taipei City, 25137, Taiwan

Abstract— This paper investigated the MIMO dual-band antenna design for the isolation improvement with two planar antenna elements perpendicularly placed in a small device. The MIMO antenna consists of two antenna elements, of which each element consists of two antenna components: One is a narrow slit antenna, which is responsible for the radiation at low band (2.4 GHz), the other is a dipole antenna, which serves as the load of the previous narrow slit antenna and is responsible for the high-band (5 $\sim$ 6 GHz). These two antenna elements are perpendicularly placed in order to achieve the polarization diversity for the high band, such that the coupling between the antenna elements can be reduced. On the other hand, additional slot cut on the common ground plane is introduced to further enhance the isolation for the low band.

Simulated results show that the isolation for the low band and high band is about -30 dB, and -27 dB, respectively, while experimental results of the prototype show that the isolation for the low band and high band is about -22 dB, and -27 dB. As comparison, a MIMO dual-band antenna design is simulated with the same planar antenna elements parallel placed and without the slot cut on the common ground plane; and the simulated results show that the isolation for the low band and high band is about -6.31 dB ~ -9.03 dB, and -16.09 dB ~ -22 dB, respectively (with the separation varying from 20 mm $\sim$ 100 mm).

It is thus confirmed that the combined techniques can effectively inhibit the coupling to avoid mutual coupling of the MIMO dual-band antenna elements. This design techniques can keep the required FR4 board size small, and don't need additional lumped components. In general, the antenna design is able to meet the demands $|S_{11}| < -10$ dB and $|S_{12}| < -20$ dB for S parameters, and its scope of application covers IEEE (802.11a/b/g/n/ac) WLAN bands.

Design of a Compact Planar Spiral Antenna for Sensor Network

Ju-Derk Park and Byeong-Cheol Choi
IoT Convergence Technology Research Department
Electronics and Telecommunications Research Institute, 218 Gajeong-ro, Daejeon, Republic of Korea

Abstract— With the development of wireless sensor network systems and application devices, needs for various types of antennas are increasing. A compact planar spiral antenna composed with monopole is designed for sensor network, operating in the center frequency 420 MHz, is introduced in this paper. Doubled side spiral lines on the circular PCB (FR-4, lossy materials) are connected with via-hole electrically and central monopole element is driven by RF signal source. Length of the antenna is 45 mm, radius of the PCB is 15 mm. This size of the antenna is enough small to mount on sensor network devices. The variable parameters for simulation (radius variation of the spiral line, spiral line width, number of turns of spirals, position of via hall, so on) are chosen to correct center frequency, bandwidth, beam width (vertical radiation angle) and antenna gain. As the simulation results, the antenna is fabricated with case and then, tested. Test result shows that elevation beam width is about 90°, frequency band width is about 65 MHz (387 MHz–452 MHz), gain is about 1.7 dBi. This performances, especially wide beam width and wide frequency band width compared to characteristics of conventional monopole antenna, support several benefits for sensor network system operating in harsh environments such as landslide monitoring region.

Design of Wideband Multi-way Power Divider with the Modified Impedance Transformer

C. W. Tang and W. M. Chuang
Center for Telecommunication Research, Advanced Institute of Manufacturing with High-Tech Innovations
Department of Cmmunications Engineering, National Chung Cheng University, Taiwan

Abstract— In current wireless communication, the need for wide bandwidth is growing rapidly. Moreover, the compact size, low-power consumption, and low noise are also essential for the design of receivers and transmitters in a microwave communication system. Power dividers are important components in microwave applications. In addition, the multi-way power divider is a key component for phase-array antennas, power amplifiers, and multi-port circuits. Wilkinson power dividers are generally adopted for two-way power division. Consequently, the multi-way power divider can be realized by interconnecting two-way Wilkinson power dividers. The general method of designing the multi-way power divider is utilizing the binominal response on the multi-stage transmission lines. However, the available bandwidth of the multi-way power divider remains limited. A calculated method of designing the multi-way power divider with the interconnection between two-way power dividers had been published. Unfortunately, the interconnection between two-way power dividers may restrict the optimal design.

In this paper, the novel planar wideband power divider with compact size has been proposed. In order to obtain a wideband multi-way power divider, the corrected coefficients K_n are adopted for the modified impedance transformer. With the assistance the modified impedance transformer, the design of power dividers with required input reflection level can be simplified. Moreover, the even- and odd-mode analyses are provided to obtain the optimal isolation resistor values. Furthermore, a prototype of the wideband four-way power divider is designed, fabricated, and measured. With the proposed structure, performance of return loss at input port can be predicated in advance. Well-matched results of simulation and measurement validate the proposed approach.

Design for Ultra Wideband Filter Using Open- and Short-ended Stepped Impedance Resonators and Coupled Lines by Genetic Algorithm

M. Setsu, **G. Ichihara**, **Y. Tomizuka**, **T. Ohno**, **K. Tanii**, **and M. Uehara**
National Institute of Technology, Kisarazu College, Japan

Abstract— This paper describes a design for ultra wideband (UWB) filter by genetic algorithm (GA). The circuit structure consists of open- and short-ended stepped impedance resonators (SIRs) and coupled lines. The transmission characteristic of the UWB filter is simulated and measured.

Figure 1 shows a schematic circuit of a UWB filter using open- and short-ended SIRs and coupled lines. As shown in Fig. 1, l and Z are length and characteristic impedance of a transmission line and a SIR, and l_c, w and s are length, width and gap of a coupled line. Fig. 2 shows the simulated transmission characteristic of the UWB filter designed by GA. As shown in Fig. 2, the UWB filter obtains the bandwidth from 3.13 to 10.58 GHz, and almost fulfills the FCC (Federal Communications Commission) indoor limit in both low and high frequency. The pass band is obtained by the attenuation poles generated at 2.64 and 10.70 GHz by the open-ended SIR. The characteristics in both low and high frequency are attenuated by the short-ended SIRs. Therefore, the above result shows that using both open- and short-ended SIRs is effective for designing UWB filter.

Figure 3 shows a photograph of the fabricated UWB filter. Fig. 4 shows the measured transmission characteristic of the UWB filter. As shown in Fig. 4, the UWB filter obtains the bandwidth

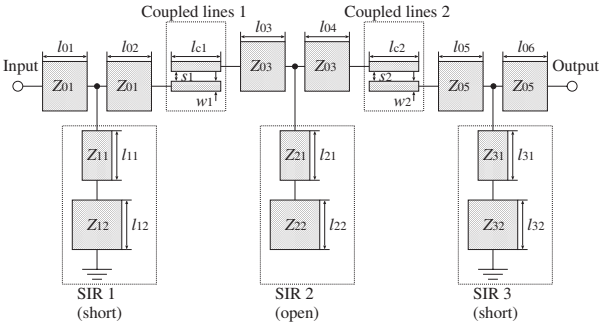

Figure 1: Schematic circuit of UWB filter using open- and short-ended SIRs and coupled lines.

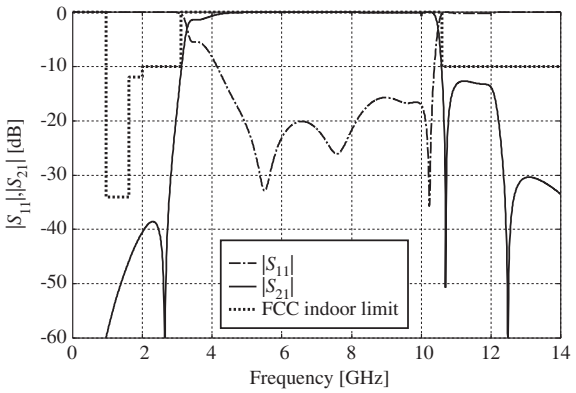

Figure 2: Simulated results of UWB filter shown in Fig. 1.

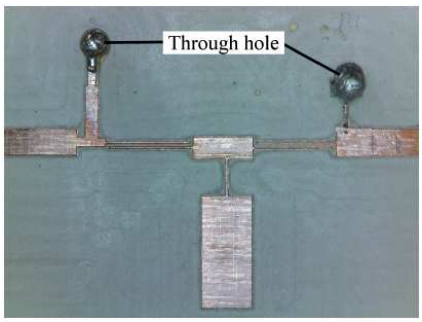

Figure 3: Photograph of UWB filter using open- and short-ended SIRs and coupled lines.

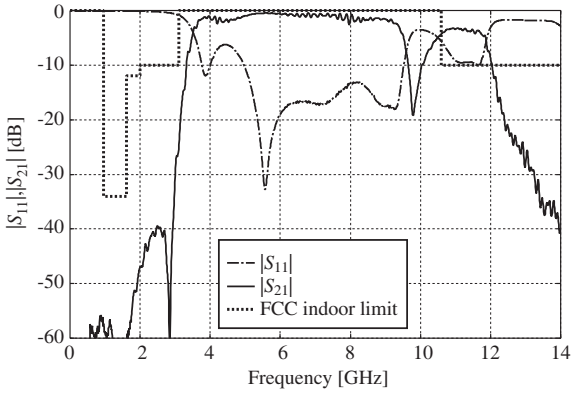

Figure 4: Measured results of UWB filter shown in Fig. 3.

from 3.33 to 9.65 GHz, and the result indicates similar transmission characteristic with the simulated result in Fig. 2. However, the characteristic in high frequency is not attenuated than the simulated result. It is assumed that electrical length of the through holes cause the narrower bandwidth and insufficient attenuation near 11 GHz. Therefore, a better transmission characteristic will be obtained by adding electrical length of through holes to GA calculation.

Novel Module Including a Waveguide for 40 GHz High-gain Amplifier Applications

Young Chul Lee[1], **Amran Bin Hj Naemat**[2], **and Zulkifli Bin Ambak**[2]

[1]Department of Electronics Engineering, Mokpo National Maritime University (MMU), Korea
[2]Telecom Malaysia Research & Development (TMR&D), Malaysia

Abstract— In this work, a 40 dB high-gain amplifier module has been presented for millimeter wave applications. Two amplifiers are integrated into the single module case by inserting a WR22 waveguide between them in the module case, in order to suppress oscillation. The high-gain amplifier module consists of two amplifiers and four WR22-to-microstrip line transitions which were fabricated on 5 mil thick RT5880 substrate. The transition loss of −0.44 dB per a transition was achieved from 35 to 50 GHz. The module showed the higher gain than 39.7 dB from 38 to 41 GHz. At 38.7 GHz, the maximum gain of 44.25 dB was obtained.

A Wideband Microstrip Line-to-waveguide Transition on LCP for 70 and 80 GHz-band Applications

Young Chul Lee
Department of Electronics Engineering, Mokpo National Maritime University (MMU), Korea

Abstract— In this work, a broadband microstrip line (MSL)-to-waveguide transition has been presented for E-band module applications. For improvement of a bandwidth, the extended GND and triple patches around the MSL probe are utilized on the low-loss liquid crystal polymer (LCP) substrate. Considering the loss contribution of the cable adapter and waveguide transition, the proposed transition loss can be analyzed as −1.45 and −1.59 dB per a transition at 70 and 80 GHz, respectively. The bandwidth of the proposed transition for reflection at −10 dB is 26 GHz at all test frequencies from 67 to 95 GHz.

Coaxial-line Structured SMT Pad for LTCC SiP Applications

Young Chul Lee
Department of Electronics Engineering
Mokpo National Maritime University (MMU), Korea

Abstract— In this work, a surface-mount type (SMT) pad using a coaxial-line structure is presented for low temperature co-fired ceramic (LTCC) SiP (system-in-package) applications. The vertical via transition is devised in type of the coaxial line. An overlap part between its outer conductor and a transmission line on the main board is cut off in order to eliminate their interaction. A cap on the top layer of the vertical via transition is designed in order to reduce radiation due to discontinuity. The designed SMT pad was fabricated using the standard LTCC process. The measured S_{11} and S_{21} are -14 and 0.9 dB, respectively at 15 GHz.

Reduction of Uncertainties of Resonant Properties for Permittivity Measurements by Considering Incompleteness of TRL Calibration Kit

Y. Kato and M. Horibe
National Institute of Advanced Industrial Science and Technology, Japan

Abstract— We have developed a new algorithm of the Monte Carlo calculations for the uncertainty evaluation of resonant properties, which directly relates to the incompleteness of the calibration standard used on a vector network analyzer (VNA). Resonant properties are derived from the resonant trace of S_{21} measured at discrete frequency points. In the previous study, the uncertainty propagations of S_{21} to the uncertainties of resonant properties are considered by using the Monte-Carlo method in which S_{21} at each frequency point is randomized independently. However, S_{21} at different frequency points have correlations with each other, because we measure S_{21} at all frequency points after performing a calibration on a VNA by using the same calibration kits. In this study, this correlation is rigorously taken into account by evaluating the S_{21} uncertainty from the incompleteness of calibration standards. Because the resonant properties are derived from the frequency dependence of S_{21}, this correlation is essential for the determination of resonant properties. Correlations between amplitudes and phases of S_{21} are also taken into account by performing the uncertainty analysis of S_{21} without resolving its amplitude from its phase. By considering these two correlations, the developed algorithm is expected to provide more rigorous analysis and reduce uncertainties of resonant properties compared to the conventional algorithm.

For the case when the through-reflect-line (TRL) calibration is used on a VNA, we confirmed that the uncertainties of resonant properties resulted from the propagation of S_{21} uncertainties were significantly reduced, and became negligibly small by using the developed algorithm. By applying this algorithm to permittivity measurements using resonant methods, the uncertainty of the permittivity can be reduced, and evaluated in a more rigorous manner.

Plasma Density Measurement Using Mutual Impedance Technique on the Jupiter Mission JUICE: The MIME Instrument

J. L. Rauch, P. Henri, J. P. Lebretoun, O. Le Duff, F. Colin, and D. Lagoutte
LPC2E, 3A av. de la Recherche Scientifique, 45071 Orléans Cedex 2, France

Abstract— Mutual Impedance Measurements, MIME, instrument is a part of the Radio Wave Plasma Investigation, RPWI, consortium which has been selected by European Space Agency, ESA, on the nest planetary mission JUICE. JUpiter ICy moons Exploer aims to launch in 2022 to explore Jupiter and its potentially habitable icy moons and study its plasma environment.

Impedance probes, which are well known in geophysical prospection, in particular for ground permittivity investigations, have been successfully transposed to space plasmas. Transmitting and receiving electrodes are used for measuring on open circuit the dynamic impedance of the system at several fixed frequencies over a range that includes characteristic frequencies of the ambient plasma. The measurements are then interpreted using a suitable theory and the values of plasma parameters, such as the electron density, temperature, and possibly the relative velocity of the plasma and the spacecraft, can be deduced. To show how powerful this technique is, results obtained in the Earth's plasmasphere by the mutual impedance probe onboard ROSETTA are presented as example. The MIME Mutual Impedance Measurements proposal is then described and its ability to make valuable measurements in the Jupiter space environment, and in particular round Callisto and Ganymede is investigated.

InISAR Imaging of Dechirp Data under Squint Model

Biao Tian, Gang Li, Shiyou Xu, and Zengping Chen
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha, China

Abstract— The interferometric ISAR (InISAR) technology has been proposed to enhance the probability of target identification. Through interferometric processing of each scattering point in two ISAR images, the corresponding coordinate of them on the target can be obtained. In previous InISAR research papers, targets are usually assumed to closely locate at the axis of antenna for convenience. In real situation, however, targets are usually far away from it. They are called as "normal mode" and "squint mode", respectively.

Aiming at InISAR imaging of dechirp data under squint model, this paper proposes a new 3D InISAR imaging algorithm based on joint squint iteration optimization and image distortion correction. The influence of squint model mainly includes two aspects, namely accessional phase and image distortion. The 3D imaging results degrade seriously as the squint angle increases. Then, through squint iteration optimization, the accessional phase can be compensated. While the image distortion can be corrected by the coordinate transform. In this way, the 3D reconstruction performance and imaging quality are improved. Simulation results demonstrate that the algorithm is effective under squint model, achieving high quality 3D InISAR images consequently.

The steps of squint iteration optimization and distortion correction can be summarized as follows:

1) Calculate the interferometric phase of antenna A and B, achieving $\Delta\varphi_{AB}$ and $\Delta\varphi_{AC}$.
2) Obtain the initial coordinate of scattering point P, where x_P and y_P are from $\Delta\varphi_{AB}$ and $\Delta\varphi_{AC}$, while z_p is from scaling of ISAR image.
3) Get the distance values of each scattering point to each antenna.
4) Update the coordinates x_P and y_P using the iteration equations.
5) Update the coordinate z_P using coordinate transform equation.
6) Repeat steps 3–5 until the convergence condition is achieved.

Using the method, all the 3D spatial coordinates of each scattering point on the target are obtained, and the high precision 3D InISAR image is obtained. According to the analysis, the proposed imaging algorithm is shown in the following figure.

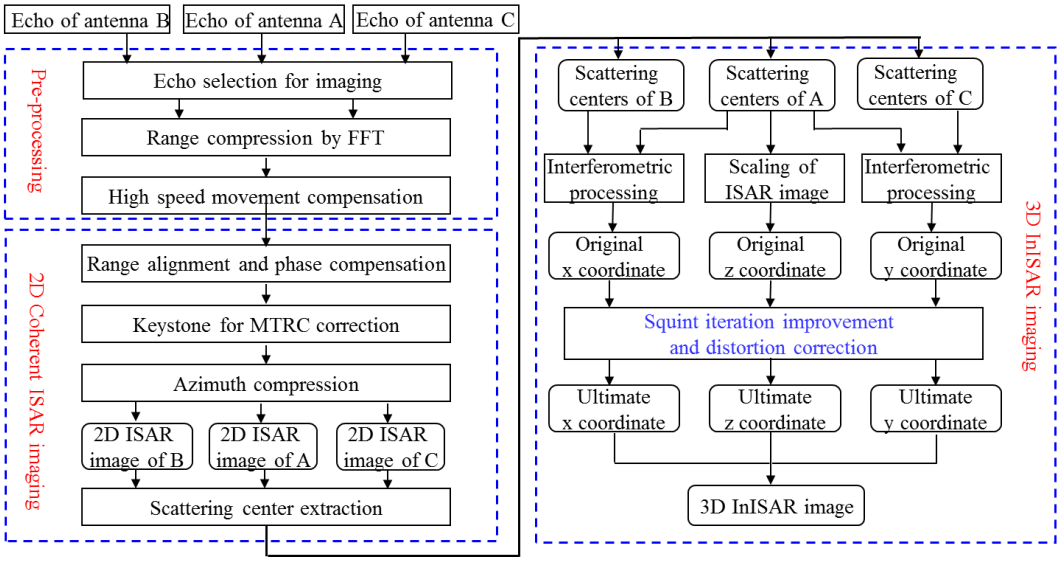

Figure 1: Block scheme of 3D InISAR imaging system.

Moving Radar Target Detection Using an Improved OFDM Chirp Waveform Scheme

Jiahua Zhu, **Pengzheng Lei**, **Chongyi Fan**, **Xiaotao Huang**, **and Zhimin Zhou**
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— Waveform diversity for moving target detection is always a challenging problem in radar field. Recently, a waveform design scheme — the orthogonal frequency division multiplexing (OFDM) chirp waveform, which combines the OFDM principle with the linear frequency modulation (LFM) waveform, was proposed with almost constant modulus, large time-bandwidth and good performance on correlation. However, the previous researches mainly discuss the processing techniques of multiple-input multiple-output (MIMO) synthetic aperture radar (SAR) systems with limited number of orthogonal subcarriers. Few achievement about target detection based on OFDM chirp waveform was published before. In this paper, the OFDM chirp waveform generation model is extended to arbitrary numbers of orthogonal signals in theory. Moreover, the OFDM chirp waveform is proved to have good target detection performance, which is better than the traditional OFDM and chirp waveforms.

First use an LFM signal spectrum as the input of each OFDM modulator, which could be given as

$$S[\bar{p}] = \mathcal{F}\{s[n]\} = \mathcal{F}\left\{\exp\left[j\pi k\left(nT_s\right)^2\right]\right\} \tag{1}$$

where $s[n]$ is the N-point discrete time samples of a complex LFM signal, k denotes the chirp rate, T_s means the sampling interval and $\mathcal{F}\{\cdot\}$ is the Fourier transform operator. Then, we can generate M input data sequence with zeros interleaved as follows using $S[\bar{p}]$.

$$\mathbf{S}_1[p] = [S[0], 0, 0, \ldots, 0, 0, S[1], 0, 0, \ldots, 0, 0, \ldots, S[N-1], 0, 0, \ldots, 0, 0] \tag{2}$$

$$\mathbf{S}_2[p] = [0, S[0], 0, 0, \ldots, 0, 0, S[1], 0, 0, \ldots, 0, \ldots, 0, S[N-1], 0, 0, \ldots, 0] \tag{3}$$

$$\ldots$$

$$\mathbf{S}_M[p] = [0, 0, \ldots, 0, 0, S[0], 0, 0, \ldots, 0, 0, S[1], \ldots, 0, 0, \ldots, 0, 0, S[N-1]] \tag{4}$$

where $p = 0, 1, \ldots, MN-1$.

Next, based on the binary hypothesis problem, we use two detectors: (1) MFD, which is the optimal detector when no clutter is presented in the scene; (2) ED, which is the generalized likelihood ratio test (GLRT) for conventional detection to analyze the detection performance under the ideal scenario with only target and noise. The simulation results prove that the OFDM chirp waveform performs better than the traditional OFDM and LFM waveforms on moving target detection, and the MFD shows a significant performance gain over the ED when clutter is not exist.

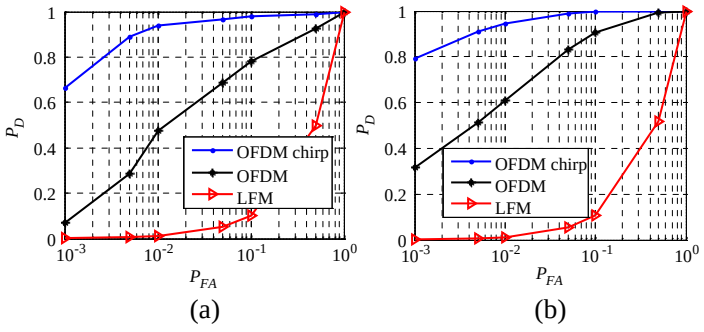

Figure 1: ROC curves of the OFDM chirp, OFDM and LFM waveforms using (a) ED; (b) MFD.

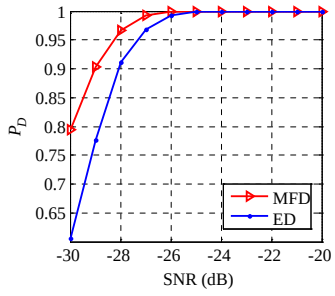

Figure 2: Detection probability versus SNR for the OFDM chirp waveform using two detectors.

Methods and Experiments for the Sensing and Evaluation of Ionosphere Changes and Their Impact on the Human Organism

Abstract— The impact of the environment upon living organisms constitutes a crucial problem examined by today's science. In this context, research institutes worldwide have analysed diverse positive and negative factors affecting the biological system of the human body. One such factor consists in the influence of the surrounding electromagnetic field. This paper presents the results of an investigation focused on ionosphere parameter changes and their impact on the basic function of the nervous system. It is a well-known fact that the frequency of the alpha waves of brain activity [1] ranges within 6–8 Hz. Changes in the electromagnetic and chemical structure of the Earth's surface may cause variation of signals in the above-defined frequency region of 6–8 Hz. Detailed examination of the overall impact of environmental factors upon the human organism is performed within a large number of medical disciplines. The research presented in this paper is concentrated on the sensing and detection of changes in the region of very low frequencies of the electromagnetic field; the authors use both theoretical and experimental procedures to define the effects that influence brain activity. It was tested in laboratory on a homogenous groups of people.

The Parameters of a Special High Voltage Function Generator

P. Marcon, **P. Fiala**, **M. Steinbauer**, **and P. Drexler**
Department of Theoretical and Experimental Electrical Engineering
Brno University of Technology, Technicka 12, Brno 616 00, Czech Republic

Abstract— The paper describes design, realize and test of a special high voltage function generator. This generator was designed for special use. A purpose of the generator is to generate a variable electrical field. In course of design of the generator the properties of the output electrode voltage was the key element.

The high voltage function generator is designed as a switched flyback high voltage source. Voltage of the output electrode of the realized generator is possible to regulate in range 0 kV to 20 kV. Shape of the output voltage is possible to choose as sine, square or ramp. Frequency capabilities of this voltage source start on 0 Hz and reach 300 Hz. Frequencies close to 300 Hz are affected by the parasitic capacitance. For special use, the high output impedance was required. Generator use PWM modulated signal from control unit for regulating primary coil current of the high voltage transformer.

This article discusses the parameters of special high voltage function generator and also presents special application of this generator.

Measurement of Tissue Cultures of Early Somatic Embryos of Norway spruce

Abstract— The objective of this study was to determine the effects of static magnetic fields to growth of plant tissue cultures (callus). Following the previously performed and described experiments that failed to clearly confirm nor deny the positive effect of static magnetic fields on the development and changes in growth of ESEs (early somatic embryos). The experiment was performed using of the static magnetic field, which is formed by the action of 4.7 T MR.

In this experiment we used a Petri dishes with a diameter of 60 mm, into which was inserted always one cluster ESEs of Norway spruce. The dishes were divided into two groups, and after the initial determination of the size ESEs were successively exposed to the influence of the stationary magnetic field with predefined parameters. The experiment time was set at an interval of three days and the duration of the experiment at 14 days. At this time, was given a Petri dish with ESE exposed always to the same kind of configuration stationary magnetic field. The growth of the ESEs was regularly documented, evaluation was carried out using MATLAB programs. To evaluate changes of the parameters inside the tissue was used Marevisi program, in which were analyzed changes in the examined tissue and other parameters.

This article evaluates the used parameters and sequences and their effect on the growth and development of the ESEs and the possibility of further use of MRI for this type of experiments.

Comparison Study of Layered Homogeneous Models with Detailed Human Tissue Models for Through-body Communications

Muhammad Ali Babar Abbasi, **Dimitris Philippou**, **and Symeon Nikolaou**
Department of Electrical Engineering, Frederick University, Nicosia, Cyprus

Abstract— Any wireless communication between an implanted antenna and an external, on-body antenna suffers from significant link degradation due to the lossy nature of the human body. Before an implantable system is proposed, it is usually thoroughly simulated, using numerical methods in order to study the electromagnetic propagation loss inside human body. A number of 3D models, deduced from MRI scans of living subjects, depicting indirectly measured electrical properties of human tissues, are widely used, for case to case based, implantable device design problems. These models generally have frequency dependent electric properties, and they are similar in shape to realistic human body parts and thus geometrically complex. Alternatively another simpler approach is widely used, where dense material blocks or homogeneous layers with constant electric properties similar to those of predominant human tissues are built and used in EM simulations for implantable devices problems. These mainly homogeneous blocks consist of simple geometric shapes which result in low mesh complexity, during modeling in 3D CAD tools, and are therefore far less resources hungry when simulated using full wave EM solvers. The main problem limiting the use of layered homogeneous models, is related to their accuracy and consequently their reliability. This study aims to assess the reliability of such simpler models in comparison with the more complex, and realistic structures of body-mimicking models. To study this comparison, an implantable antenna, placed inside a human stomach model, is set to communicate with an off-body antenna at Medical Implant Communication Service (MICS) band. Keeping the distance between implantable antenna and off-body antenna constant, the realistic human body phantom is then replaced by two types of layered body phantoms with different complexity. It was observed that when a realistic phantom was replaced by widely used simpler phantom models, significant detuning of the resonant frequency of the implantable antenna occurred. Due to the narrow bandwidth of MICS band, this detuning will be vital for any such implantable simulation setups. Results in the form of calculated s-parameters and phantom complexity matric are further investigated to conclude the study.

Analysis on SAR Values of Commercial Mobile Phones

Ae-Kyoung Lee, Seon-Eui Hong, and Jong-Hwa Kwon
Radio Technology Research Department
Electronics and Telecommunications Research Institute, Daejeon, Korea

Abstract— The SAR of mobile phones has been regulated since 2002 and more than 1200 models have been tested for SAR compliance in Korea. The limits of spatial peak SAR in the head referred to IEEE Std 95.1. A mobile phone model should be compatible with spatial peak SAR, i.e., 1.6 W/kg for 1 g of mass based on the measurement procedure of IEC 62209-1.

For epidemiological studies investigating the potential association between mobile phone use and the risk of brain diseases, more than 1400 SAR test reports from 2002 to June 2013 have been collected. We organized a large amount of data including a manufacturer, a frequency band, outer shape, antenna type (internal/external), a maximum output power, body dimensions, and spatial peak 1-g SAR values in the four test positions of cheek/left, cheek/right, tilt/left and tilt/right at the center frequency for all the models. SAR distribution of 70 mobile phones was measured in the flat phantom.

Eleven representative phone models were numerically implemented based on the SAR distributions and spatial peak 1-g SAR values from the SAR test reports [1]. The numerical phone models produce the mean SAR distribution for each corresponding phone type. However, radiation levels from commercial phones are in wide range even though they are the same type of models, as shown in Figure 1. As a part of the exposure assessment, spatial peak 1-g SAR values in the four test positions are statistically analyzed to include SAR characteristics of a specific phone model in the SAR calculation result for a representative phone model.

From scatter plots about SAR data of commercial models, the correlation between SAR values on the left and right sides was good (0.6–0.9) and the difference between SAR values under the cheek and tilt positions was clear. Therefore, the SAR optimizing factor for the test position is proposed.

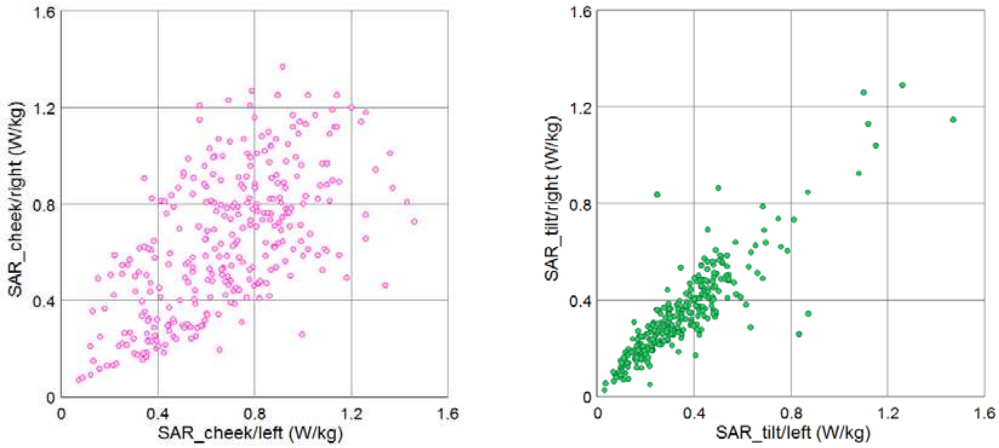

Figure 1: Scatter plot between SAR values measured at the right and left sides of the SAM phantom for the bar type of commercial phone models. (a) Cheek position. (b) Tilt position.

Central Taiwan University of Science and Technology, Taiwan

Abstract—

Objective: Polylactic acid (PLA)-based composite has been used as tissue engineering (GBR/GTR) materials for many years. Several substances, including nano-hydroxyapatite, were added to the composite to modify their material properties.

The aim of this study is to fabricate a magnetic biodegradable PLA-based composite using iron oxide magnetic nanoparticle as fillers for tissue engineering applications.

Material and methods: Nanoscale magnetite was incorporated into the PLA matrix with proportions of 0, 5, 10, and 20% (w/w). Standard samples were fabricated by means of injection molding method. After that, the physical properties of these samples were tested using Differential scanning calorimetry (DSC) analysis and contact angle (CA) assess.

Result: Our results demonstrated that PLA incorporated with nanoscale magnetite significantly increase the intensity of the PLA composite. In addition, addition of magnetite has negative effect on the crystallization temperature of the polymer. The measured contact angle of the nano-magnetite/PLA was 69.3 degree which was significantly lower than the pure PLA (77.3 degree).

Conclusion: In this study, we found that addition of nanoscale magnetite significantly increase hydrophilic property compared to the pure PLA material. This results suggests that the nano-magnetic composite has a potential to be a biomaterial in tissue engineering.

Parameter Identification of PMSM Nonlinear Part

Abstract— The following paper describes the identification of quadrature inductances of permanent magnet synchronous motor. The identification is based on the principle of Hammerstein model.

The electrical diagram of permanent magnet synchronous motor could be divided into two parts. First one is a static nonlinearity and second one is a linear dynamics. The identification of quadrature inductance from nonlinear part is in this paper. Only inputs and outputs can be read, when the Hammerstein model is used. The others variables are computed or estimated. Because only nonlinear part is used, the outputs of this part must be calculated from system outputs.

The identification is carried out on the non-linear part by Newton method. One specific feature of this identification is that it identifies during constant current and it has a large error if the current is not constant. The ratio of the measured current and noise level affects the accuracy of the method. The effect of noise is partially removed by changing the calculation of the non-linear output. It uses the fact that the method works only at constant current. Further improvement is achieved by identifying the inductance as a polynomial function of the current, where one element is already known. This is the value of inductance at low currents. The identification can be replaced by this value of inductance if the current is small enough and could be too much affected by noise. This method could be used as auxiliary method for other methods which do not identify during the constant conditions.

Simulation of Circulation Module

Abstract— Paper describes a model for lung nutrient circuit and its control. This circuit is currently developed and it is the part of a project dealing with the transport of the lungs. Lung tissue is very sensitive and it loses its quality during a few hours without nutrition. If such lungs is transported the transportation time must be as short or nutrition system must be used.

As mentioned above, the lung is very sensitive and some conditions must be complied. The first one of these conditions is the maintenance of required temperature and the second one of these conditions is the maintenance of required pressure. The whole system was expressed by equations and modeled in Matlab Simulink for the better control design of real model.

The controlled system consists of several parts. The most important of them is the tank where the nutrient fluid is stored and its temperature is checked. The pump, which is controlled by the user, ensures the fluid flow. The pressure and flow sensors are deployed throughout the circuit and they are used for automatic control of these variables. The article discusses the equations, which is used for creation of model, the creation model and various verification tests on this model are carried out. The proposed controller performs temperature control in specific limits.

Design of Dual Band Monopole Antenna with Considering Human Body Effect for Wearable Device Applications

Ho-Jun Lee[1] **and Jin-Myung Kim**[2]

[1]Convergence Communication Components Research Center
Korea Electronics Technology Institute, R. O. Korea
[2]ACE Technologies Co., Ltd., R. O. Korea

Abstract— In this paper, a dual band monopole antenna with considering human body effect is proposed. The proposed antenna is designed to operate at 2.4 and 5.8 GHz. The lower-frequency band (2.4 GHz) can be obtained by using the folded monopole, and the upper-frequency band (5.8 GHz) is operated by using a U-shaped microstrip line. Whether the antenna which is placed on the human body phantom or in free space, the performance of the proposed antenna including dual bandwidth (2.4, 5.8 GHz ISM band) is good enough to be used for wearable device applications.

The proposed antenna configuration is shown in Figure 1. Antennas in this paper are simulated by using the CST Microwave Studio (CST MWS). A prototype of this antenna was fabricated on FR-4 substrate with thickness $h = 1$ mm and dielectric constant $\varepsilon_r = 4.4$. The measurements of electrical characteristics such as radiation patterns, VSWR, and return loss of the implemented antenna were conducted in an anechoic chamber equipped with network analyzer and far field measurement system. Figure 2 shows a photograph of the fabricated antenna and return loss (S_{11}) characteristics. We manufactured the antenna based on the results of optimized simulation results and measured characteristics of the suggested antenna in the anechoic chamber. Details of the proposed antenna designs are described, and typical experimental results are presented and discussed.

High Gain and Low Noise Brain-Machine-Interface (BMI) SoC and Module for Dry Contact Electrode

Sanghoon Park, Ki-Jin Kim, Kwangho Ahn, and Jin-Sup Kim
Convergence Communication Components Research Center
Korea Electronics Technology Institute, South Korea

Abstract— A medical device to monitor the human's electroencephalography (EEG) has gained lots of interests more and more. Its application varies from the traditional medical to fast changing IT fields. However, the traditional way to investigate one's EEG signal is very inconvenient and time-consuming. We designed a high gain and low noise BMI module to extract one's EEG signal under more human friendly condition. A specially designed dry electrode, as shown in Fig. 1(a), has lower tension and a round head, and so most of the user can feel comfortable when the dry electrodes contact their scalp. The EEG signal sensed by the dry electrode is processed by the following SoC. The SoC divided into two parts. First, the front-end analog blocks process the incoming EEG signal. It consists of two stages of instrumental amplifiers and the 4th order Bessel filter. The 1st stage instrumental amplifier is designed to focus on increasing noise performance and the 2nd stage instrumental amplifier is for the variable gains. The 4th order Bessel filter is basically has programmable cut-off frequency and removes all the high frequency due to the chopping technique. The amplified and filtered EEG signal is digitized by the following analog-to-digital converter (ADC). The successive approximation register (SAR) ADC is designed to minimize the power consumption and increase the efficiency. The digitized EEG signal will be post-processed by the DSP module.

Abstract— An experiment to measure the effects of low frequency magnetic fields on cell proliferation was performed. Magnetic fields of low amplitudes, ranging from 1 to 4 mT, at frequencies of 60, 100, 800, 1500 and 2450 Hz were used to stimulate cell cultures of yeast Saccharomyces cerevisiae. The stimulation was carried out during 5 minutes, with intervals of 5 minutes rest, for 8 hours. A control and an experimental sample were measured two times for each frequency at the beginning of the experiment and at 2, 4, 6 and 8 hours later. In each measurement series a new cell culture was prepared for both non-stimulated and stimulated samples. The cells were grown in a liquid medium composed by 0.3 g yeast extract, 1.0 g gelatin peptone and 2.0 g dextrose for 100 ml solution of growth medium, with pH adjusted to 4.5 with NaOH. Measurements of cell proliferation were based on light absorbance using a spectrophotometer BECK-MAN DU 650 at 600 nm wavelength. A comparison of growth rate increasing of cell proliferation in stimulated cells larger than the non-stimulated ones, with differences from 8% to 16% after 8 hours of exposure, for most of the frequencies employed, except at 60 and 800 Hz, where the control sample showed an increasing larger than the stimulated cultures, particularly at the final of the experiment. For the first hours of the experiments the results are variable, coming to present a clear trend only after 4 hours. In conclusion, the results of this experiment show an influence of magnetic fields on cell evolution, which is a function of both the exposure time and the stimulation frequency.

IMA for a Mobile Phone Using the Coupling Method

Ho-Jun Lee[1] **and Jin-Myung Kim**[2]

[1]Korea Electronics Technology Institute, Korea
[2]ACE Technologies Co., Ltd, Korea

Abstract— Antenna, since the transmitting and receiving performance is increased in proportion to the size and volume, downsizing is difficult, occupies a considerable part in the interior of the mobile phone. Antenna, acted as a major obstacle to the trend of mobile phone slimmer. Recently, a manufacturing method for the IM (In-mold) antenna of another new concept appeared the conventional antenna. IM antenna (IMA), since integrated with the cellular phone case is possible, can be further streamlining the mobile phone that does not require a separate space which has been existing accounts.

In this paper, we proposed a novel design of in-mold antenna integrated into the case of a mobile phone. The proposed antenna configuration is shown in Figure 1. The proposed antenna operating at 2.4/5.8 GHz dual band by mutual coupling in the rear case of the thickness of 1 mm (Case permittivity = 3). Figure 2 shows the design result reflection loss (S_{11}) of the proposed antenna.

We manufactured the antenna based on the results of optimized simulation results and measured characteristics of the suggested antenna in the anechoic chamber. Details of the proposed antenna designs are described, and typical experimental results are presented and discussed.

An Efficiency of Broadcast Mechanisms Based on Cluster Heads in Dependence on Clustering Algorithm Type

Wojciech Bednarczyk, **Jerzy Dołowski**, **and Jarosław Michalak**
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 Str., Warsaw 00-908, Poland

Abstract— It is well known that broadcast communication is a very popular type of transmission used in military systems for route discovering, topology dissemination, alarm notification, location update, multicast tree building etc..

Technical solution is dependent on a scenario and a network topology. Effectiveness of BC can be measured (assessed) by:

- Time of information delivery (or maximum delay),
- energy used by network and/or particular radios,
- probability of information delivery,

where energy used by a system has a special importance not only from energy consumption point of view (especially in battery supplied devices) but from interference level introduced by the system which has essential impact on a capacity of system and its ability to simultaneous working among others wireless links.

Efficiency of broadcast transmission based on Cluster Heads in clusterized wireless network in dependence on Clustering Algorithm type will be assessed in this paper.

The proposed clustering algorithms are based on Modified Lowest ID (own modification), Highest Degree and our own based on weighted parameters.

The main differences between mentioned above algorithms are:

- A position of CH in cluster in relation to other cluster members.
- Number of clusters in the network at the end of clustering process.
- Time of clusterization process.
- Energy used by the network in clusterization process.
- Stability of the network organized in clusters.

BC algorithms use MPR (Multi Point Relay) method based on Cluster Heads (CH-MPR-BC) compared with classical solution which uses Gateway nodes at the edge of clusters as retransmitters.

Simulations will be done for static network assuming Free Space Path Loss propagation model with chosen reliability of information delivery in a radio link.

Advantages of Weighted Nodes Parameters algorithm will be presented using numbers and graphs including energy analysis and its impact on interference level.

Restoration of Antenna Patterns Using Iterative Method

Jinhwan Koh and Fan Fan
Department of Electrical and Electronic Engineering, ERI
Gyeong Sang National University, Jinju, Korea

Abstract— A new approach to reconstructing antenna far-field patterns from the missing part of the pattern is presented in this paper. The antenna far-field pattern can be reconstructed by utilizing the iterative Hilbert transform, which is based on the relationship between the real and imaginary part of the Hilbert transform. A moving average filter is used to reduce the errors in the restored signal as well as the computation load. Under the constraint of the causality of the current source in space, we could successfully reconstruct the data. Several examples dealing with line source antennas and antenna arrays are simulated to illustrate the applicability of this approach.

Wave Packet Propagation of Guided Optical Modes in a Thin Left-handed Film near a Frequency of Zero Power Flux

Dmitry A. Konkin, Rudol'ph V. Litvinov, and Alexander A. Shibelgut
Tomsk State University of Control Systems and Radioelectronics
40 Lenina Prospect, Tomsk 634050, Russia

Abstract— Dependences of the propagation constants β of guided optical modes of a thin left-handed film with an air coating medium and a dielectric substrate on a frequency ω are considered. It has been showed that the power flux of guided mode (group velocity of the mode) vanishes at a definite frequency ω_0. Two branches of the dispersion dependence $\beta(\omega)$ of one mode converge at the point ω_0. The branches are determined by conditions $\beta(\omega) < \beta(\omega_0)$ and $\beta(\omega) > \beta(\omega_0)$. Phase and group velocities of the mode on the first (second) branch have the same (the opposite) directions. The dependences $\beta(\omega)$ in the vicinity of the point ω_0 can't be approximated by a truncated series in integral powers of a frequency deviation $\Delta\omega = \omega_0 - \omega$. In the case under consideration the dependences can be presented as a series in powers of the square root $\Delta\omega^{1/2}$.

A propagation analysis of narrowband intramode packets with frequencies of modes in the vicinity of the frequency ω_0 is performed. In the general case, two different pairs of the intramode packets correspond to this vicinity. The modes of these pairs of the intramode packets have the opposite directions of phase velocities. At the same time the modes of one of the packet of each pair have the same directions of phase and group velocities. The modes of other packet of the pair have the opposite directions of these velocities. Analytical relations for case of a constant spectral density of the modes in a mode packet and in a first approximation by parameter $\Delta\omega^{1/2}$ have been found. The relations describe a space-time transformation of the power flux of an intramode pulse. Contributions of the dispersion of propagation constants and the dispersion of a spatial distribution shape of electromagnetic field of the mode to this transformation are distinguished. It has been demonstrated that the propagation of the intramode pulse into the film is accompanied by a vigorous broadening because of the strong dispersion of the left-handed material. At that the velocity of maximum propagation of this pulse depends on the spectral width of mode packet and can be considerably lower than the group velocity of the optical pulse in a volume left-handed material. This effect can be used for a light deceleration in devices of the optical information processing.

Unconventional Relaxation in Metal-dielectric Iron Boron Nitride Nanoceramics in the Readiofrequency Range

Karen Oganisian[1], **Pawel Gluchowski**[1], **Andrzej Vogt**[2], **and Wieslaw Strel**[1]

[1]Institute of Low Temperature and Structure Research, PAS, Okolna 2, Wroclaw 50-422, Poland
[2]Faculty of Chemistry, Wroclaw University, F. Joliot-Curie 14, Wroclaw 50-383, Poland

Abstract— Metal-dielectric composition is one of the most intriguing system due to the possibility to unify incompatibility properties of the materials which could not to be found in nature, such as magnetic dielectric or transparent conductor. Within investigations of electromagnetic properties of magnetic dielectric composite of iron boron nitride (Fe:BN) it was found that even few percent of BN may drastically change not only conductivity but it also strongly modify the electromagnetic properties of this compound.

Here we report an observation of unconventional relaxation in metal-dielectric system of iron boron nitride nanoceramic in the radio frequency range. The samples of Fe:BN of 95:5, 94:6 and 93:7 mass ratio were studied by x-ray diffraction, scanning electron microscopy and by the measurements of capacitance as a function of frequency in the 1–1000 MHz range.

Structural studies revealed well separated core-shell structure of micro and nanoparticles of iron thoroughly covered by a thin layer of boron nitride. Such a structure characterized by reduced conductivity but high saturation of magnetic induction which is very important for high frequency applications.

Frequency dependence of permittivity showed unexpected relaxation for the samples of 94:6 and 93:7 mass ratio. The FeBN94:6 manifested electric resonance near 550 MHz, probably, related with grain boundary relaxation. But permittivity of the FeBN93:7 sample is continuously decreasing accompanying with wide absorption from 100 to 800 MHz. This anomaly can be easily detected from the frequency dependence of conductivity (see Fig. 1). As can be seen, FeBN95:5 showed conventional dependence of conductivity; FeBN94:6 revealed similar to FeBN95:5 behavior of conductivity with relaxation near 550 MHz. However, the FeBN93:7 revealed completely different semicircle-like dependence of conductivity with wide maximum between 100 and 800 MHz. It is clear, influence of BN on this complex system results unconventional behavior accompanied with wide relaxation in the radio frequency range suggesting on the Drude relaxations in the iron grains.

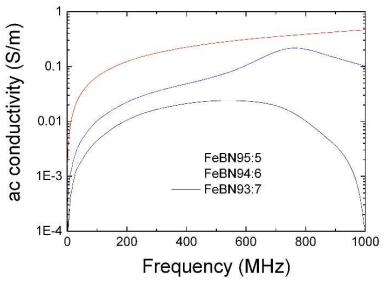

Figure 1: Ac conductivity of FeBN95:5, FeBN94:6 and FeBN93:7 as a function of frequency.

Lasing Emission by Side-pumped Emulsion Droplets in Pendant Positions

M. Boni[1, 2], **I. R. Andrei**[1], **V. Nastasa**[1, 2], **A. Staicu**[1], **and M. L. Pascu**[1, 2]

[1]National Institute for Laser, Plasma and Radiation Physics, Magurele, Romania
[2]Faculty of Physics, University of Bucharest, Magurele, Romania

Abstract— This paper presents the resonant interaction between laser beams and individual pendant dye-doped oily emulsion droplets. When the laser beam is partially or fully absorbed by the droplet's components the interaction is called resonant. Following absorption, laser induced fluorescence (and even lasing) effects are produced and are investigated through fluorescence spectra analysis. In the reported experiments it was studied the resonant interaction, a single droplet behaving as an optical spherical cavity in which the optical signal is amplified, as in the well-known whispering gallery modes (WGMs) case. By varying the dye concentration and pumping energy, we obtained typical fluorescence broad band and a narrow peak assigned to lasing effect.

The excitation is made with the second harmonic generated beam emitted by a pulsed Nd:YAG laser system at 532 nm. The pumping energies domain was chosen in such way to obtain resonant effects and at the same time to avoid mechanical effects (vibrations, liquid expulsion) specific to unresonant interaction.

The pendant microdroplets containing emulsions exhibit an enhanced emission signal. This effect can be explained as being due to the scattering of light by the sub-micrometric drops of oil in emulsion coupled with the spherical geometry of the pendant droplet. The droplet acts as an optical resonator amplifying the fluorescence signal with the possibility of producing a lasing effect. Here, we also investigate how Rhodamine 6G concentration, pumping laser beam energies and number of pumping laser pulses influence the fluorescence behavior. The results can be useful in optical imaging, since they can lead to the use of smaller quantities of fluorescent dyes to obtain the same quality of results.

The Time Approach to Analysis of the Probing Radiation and Electromagnetic Fields, Scattered by Rough Objects

V. I. Mandrosov
Moscow Institute of Physics and Technology, Russia

Abstract— It is proposed application of the time approach to analysis of the probing radiation and electromagnetic fields, scattered by rough objects, based on the use of the time correlation function $B_u(\tau) = \langle u(t)u*(t+\tau)\rangle_t$, where $u(t)$ is the modulation function of the probing radiation, and brackets $\langle\rangle_t$ mean operation of averaging over a time $T > 10\tau_c$, where τ_c is the coherence time of the probing radiation. This approach allow us to determine a clear boundary between a narrow-band and a wide-band of the probing radiation, and also to establish a clear boundaries between monochromatic, quasi-monochromatic and poly-chromatic probing radiations. These boundaries substantially depend on surface forms of scattered objects and dimensions of scattered fields monitoring area determine differences between coherent, partially coherent and incoherent scattered fields.

With the help of the time approach it is shown that there is the minimal coherence length L_{cm} of probing radiation. This length is estimated by means of analyzing the interference structure in the intensity distribution of fields scattered by rough surfaces or point-like objects, averaged over a time $T > 10\tau_c$, where τ_c is the coherence time of the probing radiation, under the condition that $\tau_c > 3/\omega_0$, ω_0 being the central frequency of the radiation spectrum. It is shown that the minimal coherence length L_{cm} of the probing radiation at which it is still possible to observe a interference structure of the scattered field is equal to $8\lambda_0$, where $\lambda_0 = 2\pi/\omega_0$ is the central wavelength of probing radiation.

It is discussed application of the time approach in low-coherence tomography on opposite reference and objects beams in optical and terahertz wave ranges. This tomography is provides the best layered resolution, equaled to $L_{\text{cm}}/4 = 2\lambda_0$. It is discussed also two methods of forming with the help of the time approach 3D-image of remote rough objects on the speckle-structure of their coherent image and on the picture of interference of two beams, propagated with a different pairs of various plots of these images. The latter method also allows us to define rotation angular velocities of remote rough objects.

Correlated-electron Emission in Nonsequential Double Ionization of Ar Atoms by Intense Laser Fields

Jingtao Zhang
Department of Physics, Shanghai Normal University, No. 100 Guilin Rd., Shanghai, China

Abstract— Electron correlation is the core of attoscience and molecular tomography. Nonsequential double ionization (NSDI) provides a process to study and control the electron correlation, in which the electron recollision plays a key role. Longitudinal momentum distribution of the correlated electrons is the principal tool to reveal electron correlation in NSDI and is frequently studied. It has been observed that the longitudinal momentum distribution exhibits an anticorrelation feature at lower laser intensities, but a correlation feature when the laser intensity is higher than the recollision threshold. Seeking for the physical origin of the transition provides a deep insight into the electron correlation in intense laser fields.

We use a classical ensemble method to study the NSDI of Ar atoms in a linearly polarized laser pulse of different intensities, and trajectory back analysis is performed. We classify the NSDI electrons by the interval between the ionization time of the second electron and the recollision time. The RII denotes the second electron was ionized shortly after the recollision, while the RESI denotes the recollision-excited electron was ionized by the laser field. We show that as the laser intensity increases, the RESI electrons always exhibit an uniform distribution in four quadrants of the momentum distribution diagram, while the RII electrons change their emission priority from anticorrelation to correlation. By following the instantaneous momentum distribution of the RII electrons, we find that the Coulomb repulsion between the two RII electrons contributes mainly to the anticorrelation feature, and that the drift momentum is responsible for the correlation feature in the longitudinal momentum distributions. The transition in the electron emission reveals a strong electron-electron correlation in intense laser pulses.

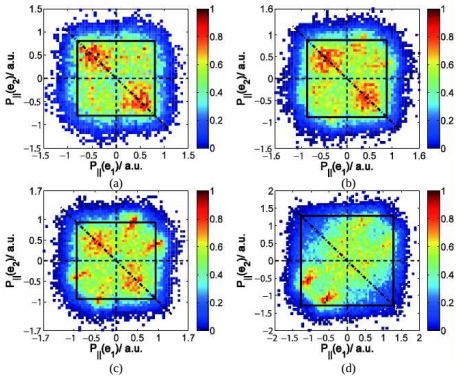

Figure 1: The correlated momentum distributions of the two electrons of Ar atoms by laser pulses of 800 nm wavelength and intensity: (a) 0.75, (b) 0.9, (c) 1.0, and (d) 2.0×10^{14} W/cm^2, respectively; The 2nd and the 4th quadrants in (a) but the 1st and 3rd quadrants in (d) are highlighted , denoting the transition from anticorrelated to correlated distributions of the correlated electrons.

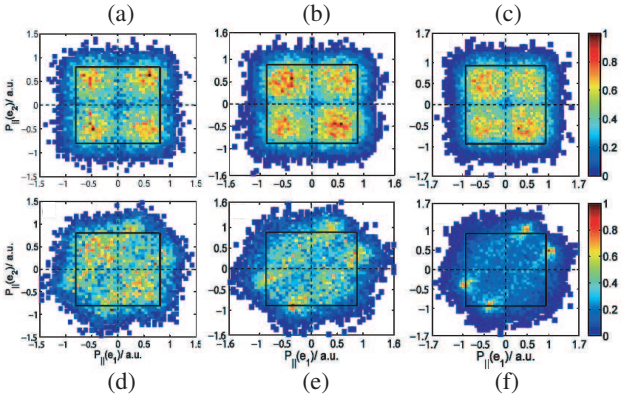

Figure 2: The correlated momentum distributions of the RESI (top) and the RII (bottom) electrons by laser pulses of intensity (a) (d) 0.7, (b) (e) 0.9, and (c) (f) 1.0×10^{14} W/cm^2, respectively.

Mutual Coupling between Parasitic Elements of Split Ring Resonator on Antenna

Dang-Oh Kim and Uooyeol Yoon
Wireless Power Transfer Research Center
Korea Advanced Institute of Science and Technology, South Korea

Abstract— The parasitic elements on antenna have become an important issue in improving the antenna performance in various wireless devices. These elements are mostly used as radiator and resonator in antenna. However, an investigation of the mutual coupling between parasitic elements is rare to be found in metamaterial resonator antenna studies. From this unusual approach, this paper presents the new mutual coupling structure of parasitic elements with the split ring resonator (SRR) on antenna. The suggested antenna consists of two rectangular SRRs and conventional monopole antenna. These resonators play the role of the parasitic element in antenna. In order to operate these SRRs, linear monopole antenna is used as an active antenna which can provide the time-varying magnetic field with normal direction. In metamaterial technology, a negative effective permeability can be generated at resonant frequency via periodic arrangement of these SRRs which are electrically small LC resonant elements with a high quality factor. Fundamentally, mutual coupling phenomenon has been observed between adjacent resonators, so that the antenna with two resonators has the same effect on parasitic elements, too. In this study, the coupling coefficient between two parasitic element resonators on antenna is obtained from scattering parameter simulation results. On the basis of the electromagnetic field characteristics and the result of antenna parameter, this study will be exquisite from the previous studies of antennas that utilize the SRR.

Near-field Imagery with Bow-tie Antenna Probes at 60 GHz

Laurent Chusseau, Rachid Omarouayache, Pierre Payet, and Jérémy Raoult
IES l'Institut d'Électronique, Université de Montpellier, 860 rue de Saint Priest, Montpellier 34097, France

Abstract— Near-field scanning microwave microscopy (NFSMM) is a well-established technique to characterize material properties such as conductivity, dielectric permittivity or magnetic permeability. Owing to very small probe sizes as compared to wavelength, high spatial resolutions at the micron scale can be achieved. So far, very few NFSMM experiments have been proposed at mm-waves.

In view of material and circuit inspection, we chose to develop a new NFSMM operating at 60 GHz. The experimental setup involves a Gunn source diode feeding a directional coupler connected to the near-field probe and we collect the reflectometry signal via a Schottky detector. Since we are interested in samples for which the imaging result may depends of the electromagnetic field (E or H) and polarization, we manufacture our own probes on the basis of nano antennas attached to the waveguide. Probe realization is done by bonding two equilateral triangles fabricated by femtosecond laser cutting at the end of a WR15 waveguide. Final assembly is done manually and the air gap g between tips can be adjusted at the end of the process. Two such probes with gap sizes of $g = 18\,\mu\text{m}$ and $g = 50\,\mu\text{m}$ were fabricated for the present study.

The first probe was used to acquire near-field profiles at constant distance above a cleaved semiconductor substrate figuring out a topological edge. The spatial resolution is estimated to $\approx 35\,\mu\text{m}$ ($\lambda/150$) at a $h \approx 25\,\mu\text{m}$ height above the sample. However if the distance h is further reduced, near-field profiles become much more complicated and depict polarization-dependent features with a strongly varying oscillatory signal when crossing the sample edge. This feature is identified as the near-field intensity of a point dipole which is known to produce a response that varies depending of the s or p polarisation and h-distance. Our results are in perfect agreement with these predictions, and clearly illustrate the nontrivial nature of topological near-field imaging in the mm-wave range.

The second probe was used to investigate NFSMM as an efficient technique for material characterization. Near-field profiles at constant distance were acquired above three metallic lines deposited on Si substrate and using three different metals: Al, Au and Cu. We clearly observed a sudden increase of the detected signal above the line for all three deposited metals but with intensities that is directly related to their conductivity. Worth to be related is that signal intensity is within a few % identical to the local conductivities deduced from DC measurements and physical characteristics of the lines.

We have built a new NFSMM operating at 60 GHz with a special effort in the design and fabrication of the bow-tie antenna probes. Near-field intensity profiles in extreme near-field conditions show the dipolar nature of the probe that may induce difficulties in image interpretation. We have also shown that this NFSMM is not only a topological instrument and that measurements can be quantitatively related to the conductivity in the near-field.

Abstract— An algorithm of a resolution increase of an automotive frequency-modulated continuous-wave (FMCW) radar with the synthetic aperture (SAR) using the multiple signal classification (MUSIC) algorithm is considered. The radar operates in the side-looking mode. It has been showed that in contrast to the classical case the automotive radar can't be considered as stationary during the repetition period of the FMCW signal. Furthermore, an approximation "stop-and-go" doesn't operate in that case.

To obtain a radar image, it is necessary to compensate the Doppler shift in a spectrum of beat signals and an video phase error. The video phase error appears in mixer by multiplication of a reference signal and an received signal. By moving car a range migration will be changed because of small values of slant distances within a scanned area in comparison with airborne SAR. It appreciably increases the complexity of compensation algorithm of this effect.

Analytical expressions which describe a contribution of the considered errors in the useful signal and expressions for elimination of the errors have been derived. Particularly to solve the problems of the range migration is proposed to use the Stolz interpolation. A mathematical model that takes into consideration the listed effects and an algorithm that eliminates the effects are realized.

After elimination of the described problems the image processing using the MUSIC algorithm is performed. As a first approximation an assumption is accepted. The assumption requires that the number of targets within a specified window on the radar image is a priori known. In the future this problem can be solved by AIC, BIC, WIC methods. A result of post-processing is an increase the range and azimuth resolution which allows to separate the targets within a magnitude of a resolution cell. The radar images for the classical and proposed algorithms of the signal processing are obtained by simulation. The images have a difference over the resolution by the example of two closely-spaced point targets. Simulation parameters are taken into account with the equipment available for the experimental verification of the considered algorithms.

Bioradar in Study of Low-power Radio Frequency Radiation Influence on Sleep of Laboratory Animals

L. N. Anishchenko, E. S. Gaysina, and I. L. Alborova
Remote Sensing Laboratory, Bauman Moscow State Technical University, Russia

Abstract— At present an influence of low-power RF on physiological parameters of biological objects is of high interest because the number of RF sources, which surrounds us in everyday life, is increasing. Studies concerning these effects have been carried out all over the world, however the results of them are controversial.

To investigate the influence of low-power RF on biological objects we used a specially designed complex, which allows generating RF in frequency range from 1 to 20 GHz with different types of modulation and RF output lower than 3 mW. Control of the biological objects vital signs during the experiments with and without additional RF exposure was done remotely by mean of bioradar BioRASCAN-14 designed at Remote Sensing Laboratory of the Bauman Moscow State Technical University. Two rats (female, 4 month old each) were used as biological objects in the experiments. The complex for RF exposure and bioradar were located at the distance of 0.5–1.0 m from a plastic box with a sleeping rat inside. For each rat, 30 records of received bioradar signals were collected for each of simulated experimental conditions (with and without additional modulated or non-modulated RF exposure).

Experimental data were analyzed. For each bioradar record mean value of respiration frequency and total duration of movements artifacts were used for comparison of the data in different experimental conditions (with and without RF exposure). The results of the experimental data analysis showed that respiration frequency increased in RF exposure conditions compared with non-exposure conditions (62 ± 2 and 71 ± 3 acts per minute increase, respectively; $P < 0.05$, t-test).

Several study groups made an assumption that biologically informative modulation should impose on vital signs of the examinee. In our future work it is planned to study this hypothesis by using respiration pattern of a sleeping animal as modulation signal.

Specific Absorption Rates in Women of Three Different Body Types Exposed to EM Waves from 30 MHz to 6 GHz

Tomoaki Nagaoka and Soichi Watanabe
National Institute of Information and Communications Technology, Japan

Abstract— The continuing spread of radio-frequency (RF) devices has led to the increased presence of electromagnetic (EM) waves at various locations. Thus, concerns regarding the safety of humans exposed to RF electromagnetic fields (EMFs) have been increasing. Computational human models with fine resolution have been developed by some research groups and have also been used as models for EMF dosimetry. However, most of the models constructed in previous works are of humans of average size. Physical features, such as height, weight, body type, and body fat percentage, vary between individuals even if the individuals are of the same age. Therefore, we require various models for studying EMF dosimetry. In this study, we developed computational human models of different body types by using a volume deformation framework to generate computational human models as target persons from existing human models. We used the magnetic resonance imaging (MRI) data of adult female models as target data and also developed three target models of different body types (slim, mildly obese, and severely obese) by deforming a Japanese female model. The target models were composed of $2 \times 2 \times 2\,\mathrm{mm}^3$ voxels. By the finite-difference time-domain (FDTD) method, we calculated the whole-body-averaged specific absorption rates (WBA-SARs) in the three female models exposed to vertically and horizontally polarized EM waves ranging from 30 MHz to 6 GHz. In the calculation, the human models were assumed to be in free space. The incident wave propagation was from the front of the body to the back. The cell sizes of the calculation domain including the human model were 2 mm from 30 MHz to 1 GHz and 1 mm from 2 to 6 GHz. The maximum WBA-SARs for each model were observed at 80 MHz. This frequency corresponds to the whole-body resonant frequency of each model. For vertical polarization, the WBA-SARs of the models tend to increase with decreasing weight. The maximum difference in the WBA-SARs between the models is 2.2 dB. This result indicates that the WBA-SAR is slightly affected by differences in body type, height, and weight.

Resonant Micro-strip Lines Analog to Electromagnetically Induced Transparency

Abstract— Electromagnetically induced transparency (EIT) observed in three-level atomic vapor media is a coherent quantum process whose optical response to a laser beam is modified by a second beam with a well-determined detuning. In references, some classical analogs to EIT have been presented. We propose a microstrip transmission line structure to mimic the optical behavior of a three-level Lambda type EIT phenomenon. This research may enable us to understand how the quantum coherence works in real atomic vapor experiments.

Measurement of Complex Permittivity of Warping Thick Film Using Cylindrical Cavity Resonator

G. Ichihara, **Y. Tomizuka**, **M. Setsu**, **T. Ohno**, **K. Tanii**, **and M. Uehara**
National Institute of Technology, Kisarazu College, Japan

Abstract— This paper discusses the relationship between warping thick film and complex permittivity using cavity resonator method.

Figures 1(a), (b), and (c) show the measurement system using 2.45 GHz cavity resonator, a sample (Polyimide $\dot{\varepsilon}_r$: $3.600 - j0.027$), and a sample holder (Polystyrene). The distance d shown in Figure 1(b) is defined as warpage of the sample. The complex permittivity of the sample with/without the holder is calculated by perturbation formula using measured result of a resonance frequency and Q factor.

Figure 2 shows the measured result of real part of complex permittivity of the sample without the holder. In Figure 2, the difference between the measured result and reference value is increased in accordance with increasing d. Figure 3 shows measured results in the case of using the holder to reduce the warping of the sample. As shown in Figure 3, the similar results to the reference value are obtained. Threfore, it has confirmed that the use of the holder is effective for determining the complex permittivity of the thick film which has warpage.

Improved Concept of Numerical Modeling of Dielectric Properties of Emulsions: Error Reduction Caused by Droplets Close to or Crossing Boundaries of Constant Electric Potential

J. Vrba, Jr. and D. Vrba
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— The existing 3D model was analuzed and following main source of higher variance of the predicted values of complex permittivity was identified. It corresponds to the effect when the droplets are close to or crosses the boundaries of defined time-harmonic electric and ground potential (sources of electric field in the unity cell). This effect can be reduced by a strategy developed here. Implementation of the strategy can be described by following steps.

A unity cell with randomly placement of droplets is generated. The geometry of the unit cell is generated as periodic in two directions, all droplets' parts exceeding a side wall(s) of the unit cell have to appear on the opposite wall(s) too (see Fig. 1).

A quasi-static numerical simulation of electric potential distribution within the unity cell is performed. Stored electrical energy as well as lost power between two contours of different two electrical potentials between ground and the maximal one are recorded.

A new unit cell is generated, which geometry corresponds to side walls from original geometry and upper and lower walls are of the same shape as of the contours of the above mentioned two potentials. Implementation of this strategy is not trivial and therefore the strategy is tested on 2D cases only.

In iterative manner quasi-static numerical simulations are performed while changing both parts of permittivity and conductivity and comparing the stored energy and lost power with the values recorded above. This was implemented as optimization problem. The presented strategy was implemented and the results are shown for test scenario of droplet in different positions within a unit cell.

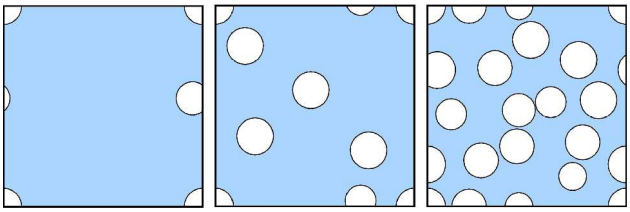

Figure 1: Representative top view of unit cells with different volume fractions ϕ. From left to right $\phi = 1\%$, 10% and 30%. A monodisperse emulsion is considered with droplet radius $r_{\text{droplet}} = 3.5\,\mu\text{m}$

Numerical Modeling of Dielectric Properties of Blood-glucose Solutions

J. Vrba, Jr., **P. Spurny**, **and D. Vrba**
Faculty of Biomedical Engineering
Czech Technical University in Prague, Czech Republic

Abstract— In 2014, 382 million people (8.3% of the overall population) have diabetes and it is expected that up to year 2035 the number of people with diabetes will rise to 592 millions. More than 11% of worldwide healthcare spending amount diabetes-treatment cost [1]. Current techniques for blood glucose monitoring are all invasive associated with number of obvious inconveniences. Regular blood glucose monitoring by diabetes patients would both significantly improve their quality of life as well as decrease the diabetes-treatment cost. Therefore, there is a clear demand for an inexpensive non-invasive blood glucose monitoring technique. There are already number of research groups and companies developing non-invasive blood glucose monitoring systems [2–5]. A company MediWiSe announced start pre-orders for their microwave device in late 2016. With respect of development of an electromagnetic non-invasive glucose monitoring system some authors reports dielectric properties of physiological saline-glucose [6] and of blood plasma-glucose solutions [7, 8]. In [9, 10], it has been shown that glucose influence dielectric properties of blood significantly, but an analytical model has not been published there. To authors best knowledge the only paper publishing empirical model of dielectric properties of blood-glucose solutions is [11]. In [12], the authors measured dielectric properties of blood-glucose solutions but mathematical model has not been published. In previous paper [Vrba et al. IJAP 2015] it was shown, both by numerical simulation results as well as by measurement results, that there are significant differences between dielectric properties of physiological saline-glucose and blood-glucose solutions. Correspondingly, the physiological saline-glucose solutions are, at least in the considered frequency range from 1 to 8 GHz, not suitable models of blood-glucose solutions for experimental design/evaluation of blood glucose level monitoring systems.

Furthermore, it was concluded that the empirical model of dielectric properties of blood-glucose solutions [11] should be, according to our observations, revised.

In this paper, an existing 3D numerical concept for estimation of effective dielectric properties of oil and water emulsions with random droplet distribution was adapted for estimation of effective dielectric properties of blood-glucose solutions. Geometries of different blood cells were used in generation of the numerical models. The adapted concept uses a numerical model in COMSOL Multiphysics controlled with MATLAB scripts. In this study dielectric properties of blood cells as well as of blood plasma-glucose and physiological saline-glucose solutions were considered. The results of the numerical simulations were compared to data estimated by the existing empirical model and differences were discussed.

Abstract— In this paper, a high-gain and low-profile mmWave Antenna solution for the 5G cellular user terminal is presented. A 28 GHz antenna solution for the upcoming 5G cellular communication is presented in detail. The proposed Antenna solution is for the handsets using switching beamforming structure. Extensive simulations and fabrication/measurement results ascertain the presented Antenna solution to be a simple and effective for cellular handsets operating in mmWave environments.

Broadband Slotted Bow-tie Antennas for Terahertz Resonant Tunnelling Diode Based Oscillators

Khalid Hamed Alharbi, Afesomeh Ofiare, Jue Wang, Monageng Kgwadi, Ata Khalid, and Edward Wasige
High Frequency Electronics Group, School of Engineering, University of Glasgow
Oakfield Avenue, G12 8LP Glasgow, Scotland, UK

Abstract— Terahertz (THz) radiation, whose frequency range lies between millimetrewaves and infrared light in the electromagnetic spectrum has many potential applications in different scientific fields such as medical diagnostics, security imaging, and wireless communication. Resonant tunnelling diode (RTD) based THz oscillators in integrated circuit (IC) form have recently been shown to be the technology in which many of these applications could be implemented. They operate at room temperature and have the potential to produce output power of around 1 mW at these frequencies. In this paper, a broadband bow-tie slot antenna for THz applications will be presented. The coplanar waveguide (CPW) fed bow-tie antenna is fabricated on an InP substrate for same chip integration with the promising resonant tunnelling diode terahertz oscillator. The antenna exhibits a very wide bandwidth (return loss $S_{11} < -10$ dB) around the design frequency (300 GHz). However, most of the radiation in the initial design is directed into the substrate because of the large dielectric constant ($\varepsilon_r = 12.56$) of the InP substrate. A technique to overcome this problem employing a reflector ground plane underneath a thin substrate of low dielectric constant is presented. The substrate used is benzocyclobutene (BCB) with dielectric constant $\epsilon_r = 2.6$. This substrate is realised by spinning it on a carrier substrate such as InP substrate with a coating of metallisation to act as the ground plane (and isolate the high permittivity InP substrate from the high frequency radiation). Initial simulation results (at 300 GHz) of this technique are reported and experimental validation at lower frequency (17 GHz) shows the feasibility of the concept.

On-wafer 2D Characterization Technique for Quasi-Yagi Antenna for G-band Applications

Khalid Hamed Alharbi, Afesomeh Ofiare, Jue Wang, Ata Khalid, David Cumming, and Edward Wasige
High Frequency Electronics Group, Division of Electronics and Nanoscale Engineering
School of Engineering, University of Glasgow, Oakfield Avenue, G12 8LP Glasgow, Scotland, UK

Abstract— The G-band of the electromagnetic spectrum (140–220) GHz is of great interest for different applications such as detection of concealed weapons and explosives, aircraft navigation in adverse low visibility weather conditions, and automotive collision-avoidance radar. Planar and directive antennas integrated in monolithic microwave/millimeter-wave integrated circuits (MMIC) could offer many advantages for such applications. High directivity will ensure that most of the RF power is radiated into a specific direction and, as a consequence, offer larger coverage distance and improve the communication link in the adverse weather conditions. This paper presents a G-band quasi-Yagi antenna and an associated on wafer setup for the characterization of its radiation pattern using a vector network analyser (VNA). The designed antenna shows a wide bandwidth (return loss < -10 dB) across the entire G-band. The proposed radiation pattern setup consists of identical one receiver and multi-transmitter antennas distributed angularly around the receiver antenna. All these antennas are fabricated on the same InP substrate that makes the angular positioning precise using lithography. Apart from the transmitting antenna directly opposite the receiving antenna, the antenna under test (AUT), all other transmitting antennas were realized with longer and curved lengths of coplanar waveguide (CPW) feed lines to ensure that these antennas always faced the AUT and that they could be probed Figure 1 shows the fabricated planar quasi-Yagi antennas for on-wafer radiation pattern characterization. The antenna exhibits an end-fire radiation pattern at frequencies around 200 GHz. The setup allows for E-plane radiation pattern to be measured and there is good agreement between measured and simulated results.

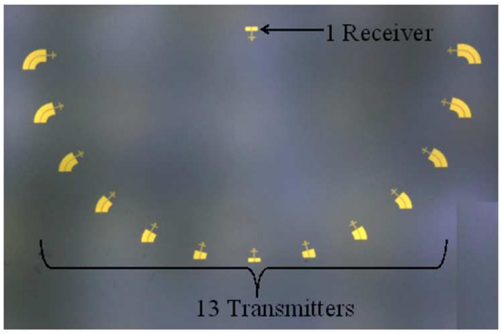

Figure 1: Fabricated planar quasi-Yagi antennas for on-wafer radiation pattern characterization. The extended CPW feed lines to facilitate probing and ensure the antennas face the AUT are clear to see.

Spontaneous Hemodynamic Activity in Prefrontal Cortex of Depression Patients Assessed with Functional Near-infrared Spectroscopy

Abstract— Patients with major depressive disorder (MDD) typically suffered from pervasive depressed mood or anhedonia, accompanied by several cognitive and physical symptoms. In this study, functional near-infrared spectroscopy (fNIRS) was applied to investigate the spontaneous activity of hemodynamic in the prefrontal cortex (PFC) of the brain. 21 patients with MDD (including 12 with antidepressant and 9 without medication) participated in 8-min resting state measurement. By analyzing the interhemispheric correlation and the correlation maps of the PFC, our results indicated that patients with MDD showed significantly reduced interhemispheric correlation in the PFC and disrupted cortical organizations in the PFC. This study showed that fNIRS could be an effect and convenient way to assess neural features of depression.

Abstract— We have experimentally demonstrated the broadband enhancement of single-photon emission from nanodiamond NV centers coupled to planar multilayer metamaterial with hyperbolic dispersion. A tapered metamaterial waveguide for efficient outcoupling of high-k metamaterial modes has been numerically studied and fabricated.

Introduction: The major thrust of research in quantum photonics is to build quantum computing and networking technologies [1]. The simplest and most fundamental quantum photonic states to be employed are single photons. Many techniques based on nonlinear phenomena and atom-like systems have been demonstrated to generate single photons. Nitrogen vacancy (NV) color centers in diamond have attracted widespread attention due to their stable, broadband, and anti-bunched emission at room temperature [2], however, the efficiency of such emission is naturally low. Massive research efforts to solve this problem have utilized resonant based structures, which are typically narrowband and have a relatively slow response.

Enhancement of Single-photon Emission by Hyperbolic Metamaterials: An unorthodox approach is to use metamaterials with hyperbolic dispersion (HMM) [3], which enables one to implement highly efficient, broadband, and fast single-photon sources. In our recent work, we have experimentally studied the broadband enhancement of single-photon emission from nanodiamond NV centers coupled to a planar multilayer metamaterials with hyperbolic dispersion [4]. The metamaterial is fabricated as an epitaxial metal/dielectric superlattice consisting of CMOS-compatible ceramics: titanium nitride (TiN) and aluminum scandium nitride ($Al_xSc_{1-x}N$). It has been demonstrated that employing the metamaterial results in significant enhancement of collected single-photon emission and reduction of the excited-state lifetime.

Tapered HMM as an Efficient Method for Outcoupling High-k Modes: The emission enhancement mechanism is based on the HMM ability to support extra radiative channels. These channels are surface and bulk high-k metamaterials modes. Hence, the emission rate of NV center coupled to HMM can be further increased by proper outcoupling of these high-k HMM modes into free-space modes. As a next step, we suggest a modification of both the HMM structure and the detection scheme to enable more efficient photon collection. In this new approach, adiabatically tapered HMM waveguides which transition from high filling fraction for maximal emitter enhancement to a lower filling fraction for optimal outcoupling were designed and fabricated using shadowed angle deposition technique. The total outcoupling efficiency of the high-k modes in the in-plane direction is expected to be two to three orders of magnitude better than standard out-of-plane outcoupling methods.

Omnidirectional Light Concentrators-absorbers — How to Make Their Core Flat?

Alexander V. Kildishev[1] **and Ludmila J. Prokopeva**[1, 2, 3]

[1]Birck Nanotechnology Center, West Lafayette, USA
[2]Novosibirsk State University, Novosibirsk, Russia
[3]Institute of Computational Technologies, Novosibirsk, Russia

Abstract— We review our previous and most recent progress in designing omnidirectional optical concentrators that can be used to trap almost all light with no dependence on the incident angle. The classical design is arranged of a spherical (circular cylinder) shell encapsulating a concentric absorbing core of the same shape. Omnidirectionality is an important feature for non-imaging applications, including efficient photovoltaic cells for mobile and drop-and-forget systems, as well as multicolor IR sensing, which is known to have problems with oblique incidence of light. An important desired feature is a thin and flat design of the absorbing semiconductor element which is integrated into the omnidirectional lens device. Our most recent results show that flattening the absorbing element is possible by using the oblate spheroidal (elliptic cylinder) shell as the trapping lens so that a disk (strip) absorber could be fabricated.

Previous studies [1, 2] have shown that almost total omnidirectional absorption of light can be achieved with a gradient radial distribution of the refractive index $n(r) = n_0(r_0/r)^p$ ($p \geq 1$, r is the radial coordinate, and n_0 is the refractive index of the ambient media) [1, 2]. Theoretical analysis was performed in terms of geometric optics and full wave propagation. Moreover, an estimation of the absorbing efficiency was obtained depending on the device parameters. Further, this design was successfully tested with microwave metamaterials [3], and most recently, a nanostructured device performance was validated in experiments for visible light [4].

We flatten the absorbing core [5] by mapping the radial distribution $n(r) = n_0(r_0/r)^p$ onto an elliptic distribution $n(u) = n_0(\sinh u_0/\sinh u)^p$ where u is either the elliptic cylinder or spheroidal coordinate. In contrast to the previous case where the Hamiltonian equations for ray traces can be integrated explicitly, here the system of equations is more complex. We have developed accurate numerical solutions of the Hamilton equations that agree well with our simulations in the Ray Optics module of COMSOL Multiphysics. The results confirm the trapping performance for two geometrical variations — elliptic cylinder and oblate spheroid. Further we add an absorbing core to our designs and full-wave simulations with a Gaussian beam are done to finally prove the trapping and absorbing capability of the proposed designs.

Equipped with flat absorbing cores, which are easily fabricated, microlenses with omnidirectional absorption open up unparalleled possibilities for designing efficient sensing devices and photovoltaic low-power sources for mobile and unattended applications.

Farfield Sub-wavelength Imaging with Compact Dielectric Lens

Jingjing Zhang
Department of Photonics Engineering, Technical University of Denmark
DTU Fotonik, DK-2800 Kgs. Lyngby, Denmark

Abstract— For decades researchers have made various attempts to beat the diffraction limit and realize subwavelength imaging. Here I present the approach to design modified solid immersion lenses that deliver the subwavelength information of objects into the far field, yielding magnified images. The lens is designed by combining a transformation optics forward design with an inverse design scheme, where an evolutionary optimization procedure is applied to find the material parameters for the matching layers. Compared to previous approaches based on the simple discretized approximation of a coordinate transformation design, my method allows for much more precise recovery of the information of objects, especially for those with asymmetric shapes. The lens can be realized by an isotropic dielectric core and anisotropic or isotropic dielectric matching layers. The total radius of the lens is only 2.5 wavelengths and the resolution can reach up to $\lambda/6$. It allows for the far-field subwavelength imaging at optical frequencies with compact dielectric devices.

A Wide-angle Broadband Polarizer Based on a Field Transformation Approach

Junming Zhao[1, 2], **Yang Hao**[2], **and Yijun Feng**[1]

[1]School of Electronic Science and Engineering

Queen Mary University of London, London E1 4NS, United Kingdom

Abstract— Controlling polarization states is one of the most important topics in electromagnetic (EM) wave manipulation. Up to now, various polarizer designs have been proposed for both transmission and reflection achieving polarization conversions between TE (transverse electric) and TM (transverse magnetic), LCP (left-handed circular polarization) and RCP (right-handed circular polarization), linear and circular polarizations. However, most conventional designs are only adapted to normal incidence with fundamental physical limitations in the product of bandwidth and incident angle. Transformation optics offers a geometrical approach in designing optical components, which can automatically work for arbitrary excitations. Such a transformation technique has been extended to the polarization domain based on a recently proposed field transformation (FT) method [1]. By employing a reduced-parameter approximation in constructing FT media with purely dielectric composites, we design and demonstrate a FT-based polarizer in converting between TE and TM and between LCP and RCP with both wide-angle and broadband operation. Such a polarizer can also be easily extended to different operation modes for both transmitted and reflected waves by adjusting its thickness and adding an optional metallic ground plane. We prove that the proposed technique has its potential to overcome the fundamental limit of current polarizers and can be applied to a broad range of applications from microwave to optics.

Design Metasurface from Transformation Optics

Yadong Xu, Yangyang Fu, and Huanyang Chen
College of Physics, Optoelectronics and Energy, Soochow University, Suzhou 215006, China

Abstract— In this talk, we will show that transformation optics could be used to design metasurface in steering beams. Such a metasurface or slab could be realized by a sub-wavelength grating with dielectrics and metal. The generalized laws of reflection and refraction should be modified in such a structure. We also realized a related acoustic metasurface based on this similar idea.

Transformation Optics and EELS in Plasmonics

Matthias Kraft[1], **Yu Luo**[2], **and John B. Pendry**[1]

[1]Blackett Laboratory, Imperial College London, SW7 2AZ, UK
[2]School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore

Abstract— Transformation optics is a relatively new subfield in electromagnetic research. Yet, it has been at the heart of many of the most promising advancements in electromagnetism in recent years. Originally developed to aid numerical simulations in cylindrical geometries, it has since been applied as a design tool for such exotic devices as invisibility cloaks or negative refractive index lenses. Within the last 5 years, Transformation optics has entered the field of plasmonics. It has proved valuable as a design tool for devices such as beam shifters, surface cloaks or light harvesters. Moreover, it has also proven itself as an analytical tool in the study of interacting plasmonic nano-particles or van der Waals forces. In this talk we would like to add an entry to the already long list of fields where Transformation optics can make a difference. The study of electron energy loss spectroscopy of plasmonic nano-particles.

Passive and Active Devices for Spoof Surface Plasmon Polaritons in the Microwave Frequency

Tie Jun Cui
State Key Laboratory of Millimeter Waves, Southeast University, Nanjing 210096, China

Abstract— We propose planar plasmonic metamaterial on thin metal films with nearly zero thickness to support spoof surface plasmon polaritons (SPPs) in microwave and terahertz frequencies. From the theoretical simulations and experiments, we show that spoof SPPs can propagate along an ultrathin metallic film by corrugating its edge with periodic array of grooves. Such a planar plasmonic metamaterial can sustain highly localized SPPs along two orthogonal directions in broadband by keeping good modal shape and propagating long distance with low bending loss. The ability to bend spoof SPPs freely on ultrathin film makes the planar plasmonic metamaterial more practical to produce passive plasmonic devices, such as the SPP bends, splitters, filters, polarizers, and resonators. Experiments validate the feasibility of planar plasmonic metamaterial. Based on the above idea, we present the concept of conformal surface plasmons (CSPs), i.e., the surface plasmon waves that can propagate on ultrathin and flexible films to long distances. The flexible ultrathin films can be bent, folded, and even twisted to mould the flow of CSPs.

We also propose and experimentally demonstrate spoof localized surface plasmons (LSPs) on a planar textured metallic disk at the microwave and terahertz frequencies. We design and realize the plasmonic metamaterial using ultrathin metal film printed on a thin dielectric substrate and observe the multipolar plasmonic resonances in both numerical simulations and experiments, including the dipole, quadrupole, hexapole, octopole, decapole, dodeca-pole, and quattuordecpole modes. The simulation and experiment results have very good agreements. We show that the spoof LSP resonances are sensitive to the disk's geometry and local dielectric environments, and hence the ultrathin textured metallic disk has potential applications as plasmonic sensor in the microwave and terahertz frequencies.

Finally, we present active SPP devices using the subwavelength-scale amplifier chips in the microwave frequency, including the significant amplification of SPP waves and higher-order harmonic generations of SPPs, which result in SPP amplifier and SPP mixer. We also propose an efficient conversion between the conventional spatial waves and the SPP modes. Based on the conversion and passive and active SPP and LSP devices, we propose integrated spoof SPP/LSP circuits to realize a series of functionalities, and give experimental demonstrations.

Transformation Optics with Spatially Dispersive Electromagnetic Media

Jie Luo, **Yu Ting Yang**, **Zhi Hong Hang**, **C. T. Chan**, **and Yun Lai**
Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology
College of Physics, Soochow University, Suzhou 215006, China

Abstract— Metamaterials and transformation optics have enormously enriched human's ability to control electromagnetic waves and light, leading to novel applications such as cloaking, exotic lens, illusion optics, etc..

In previous designs of transformation optics devices, local media with special parameters and anisotropy have been widely used. However, the realization of these parameters is really difficult. For example, in most of previous experimental realization of cloaking, reduced parameters have been applied, which would lead to reflection and therefore compromised cloaking effect.

In fact, we demonstrate that ultra-transparent materials with wide-angle and even omnidirectional non-reflection and total transmission can be realized with spatially dispersive electromagnetic media, whose parameters are k-dependent.

We theoretically and experimentally demonstrate realization of ultra-transparent spatially dispersive media. We also demonstrate novel transformation optics devices beyond traditional theory based on local media [1].

Our work shows the possibility of spatially dispersive media in controlling electromagnetic waves and light in unprecedented ways.

Abstract— The latest experimental results undertaken as part of Exeter's metamaterials research theme are presented, and will include narrow (subwavelength) beaming of surface waves, reflection-less metamaterials and other transformation-optics devices.

This presentation showcases some of the most recent experimental work being undertaken in the field of microwave metamaterials and metasurfaces at Exeter as part of the EPSRC programme grant, "the Quest for Ultimate Electromagnetics using Spatial Transformations (QUEST)". This 5-year grant is shared with electrical engineers at the Queen Mary University of London, and material engineers at University of Oxford.

The patterning of surfaces with small, closely spaced elements is well known to influence their interaction with electromagnetic radiation. As long ago as the 1940s [1], radar engineers were considering how the addition of a sub-wavelength corrugation to a metal can modify its electromagnetic boundary condition so that surface waves become tightly bound to the interface. Our experimental research has demonstrated how metasurfaces and metafilms can be utilised to spatially engineer artificial boundary conditions and modify the mode-index of the waves supported [2]. We have very recently shown that a dumb-bell array (essentially a double-ended mushroom) can support surface waves with negative mode index, i.e., surface eigenstates that have antiparallel momentum and power vectors. The FFT of a 2D field scan from such a surface allows us to visualise the complete band structure of the modes of the system. Using this

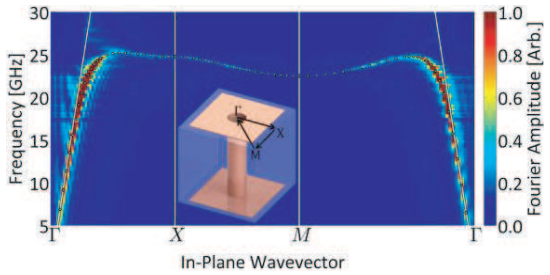

Figure 1: Experimentally determined band structure of surface waves on array of dumb-bells, illustrating the regions of negative mode index.

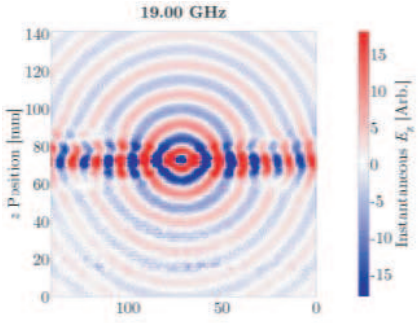

Figure 2: The electric field associated with beaming of surface waves measured above an array of complimentary double SRRs. Excitation is via a dipole antenna.

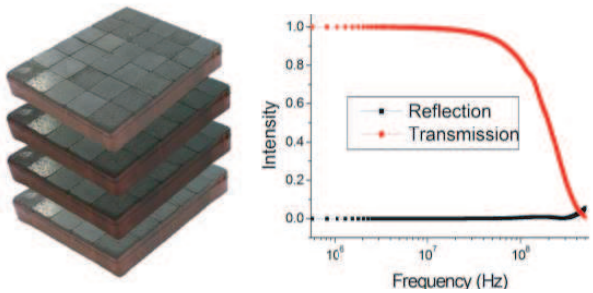

Figure 3: Anisotropic array of ferrite-composite cubes, and its anti-reflection response. (Layer spacing in photograph is not to scale).

Figure 4: Modelled radiation pattern from patch antenna, and the enhanced directivity achieved via the use of a lens designed via quasi-conformal mapping.

technique we also demonstrate surface geometries that can support channelling of surface energy into beams that have a subwavelength width, and which do not spread.

Other research themes being explored include the design and testing of broadband, reflection-less materials. Some of the advances that we have made in this theme have been brought about by the realisation that the particle size in a ferrite-composite (e.g., with PTFE as the matrix) yields an additional degree of freedom in the design of bespoke material properties. Impedance matching has been demonstrated via the careful design of composites alone, or using structuring of the composites [3]. Whereas the use of ferrites for this purpose is often limited to frequencies below 1 GHz, a new and exciting approach, based on a Kramers-Kronig-like relation in space rather than frequency, is now being explored experimentally.

More conventional incarnations of spatial transformation techniques are also being explored. These include changing the radiation of simple antennas, using bespoke dielectric lenses designed using quasi-conformal mapping. We have also designed and tested a curved Luneburg lens and surface wave cloak for 2D geometries by utilising a combination of variation of guide curvature and thickness to provide the required mode index.

Realization of Invisible Cloaking for Multiphysics

Yichao Liu, **Jianfei Zhu**, **We Jiang**, **and Yungui Ma**
State Key Lab of Modern Optical Instrumentation, Centre for Optical and Electromagnetic Research
Zhejiang University, Hangzhou 310058, China

Abstract— Invisible cloaks have attracted great attentions for their magic application on electromagnetic waves [1, 2]. Recently this concept has been vastly extended to other fields and phenomena controlled by different equations. Previously we have successfully applied the coordinate transformation to thermal conduction equations by showing a transient heat cloak [3] and also a thin thermal plate that could provide a homogeneous heating surface with a tiny source [4]. In this talk, we will report our recent work on the first realization of a multiphysics cloaking experiment that showed a desired dual thermal-electric cloaking behavior [5]. In the end, we will also introduce our new experiment results on AC magnetic cloaks using combined nature materials that allows a promising application in hiding metallic objects.

Abstract— Surface wave such as surface plasmon polaritons in optical wavelength has become one of the most promising signal carriers for future information technologies with virtue of high energy confinement in a subwavelength volume. However, before it can be further applied in practical electromagnetic and optoelectronic applications, there remain several major obstacles that need to be addressed. One of the long-existing problems is that the propagation of surface wave is subject to high scattering loss on rough surface. Here we propose some cloaking devices that can realize near-perfect suppression of surface wave scattering at rough surface.

Generalized Refractive Index for Transformation Optics and beyond

M. McCall, **P. Kinsler**, **and D. Topf**
Department of Physics, Imperial College London, Prince Consort Road, London SW72AS, UK

Abstract— The refractive index $n(\mathbf{r})$, of an inhomogeneous electromagnetic medium is a familiar, but derived electromagnetic quantity, that not only governs the rate of phase advance of electromagnetic waves in a medium, but also determines the trajectory of optical rays according to the ray equation

$$\frac{d}{ds}\left[n(\mathbf{r})\frac{d\mathbf{r}}{ds}\right] = \nabla n. \tag{1}$$

This equation also results from the conformal transformation space according to $g \to n^2 g$, where g is the metric of the initial (e.g., Euclidean) space. In discussing transformation optics, and its possible extensions beyond electromagnetics, it would be useful to have available an analogous quantity $n(\mathbf{r})$ that generalizes to arbitrary, non-conformal transformations. The direction at a given point $\mathcal{P}$ on a ray is characterized by its tangent vector $\mathbf{v}$. If the ray is deformed via the (diffeo)-morphism φ: $\mathbb{R}^3 \to \mathbb{R}^3$, then we find that a generalized index is given by

$$n_{\varphi(\mathcal{P})} = \left[\frac{g_{\mathcal{P}}(\mathbf{v},\mathbf{v})}{g_{\varphi(\mathcal{P})}(\varphi_*\mathbf{v},\varphi_*\mathbf{v})}\right]^{1/2},$$

where $\varphi_*\mathbf{v}$ is the so-called *push forward of* $\mathbf{v}$. Although the generalized index is a scalar quantity, it carries an angular dependance through the choice of the direction of the vector $\mathbf{v}$.

The concept of the generalized index seems to lie at the heart of all ray-based transformation theories (e.g., transformation optics, transformation acoustics, etc.). In transformation optics, for example, the morphism φ defines an electromagnetic medium for which

$$\epsilon = \mu\frac{\mathbf{J}\mathbf{J}^T}{|\det(\mathbf{J})|} = \kappa \quad \text{say},$$

where $\mathbf{J}$ is the Jacobian associated with the morphism φ. In this case we find that the generalized refractive index is given by

$$n(\theta,\phi,\mathbf{r}) = \left[\det\left(\kappa^{-1}\right)_{\perp}\right]^{1/2},$$

where $\perp$ indicates a projection perpendicular to the direction defined by the angular variables θ and ϕ. In fact we find that $n(\theta,\phi,\mathbf{r})$ defines an ellipsoid at each point $\mathbf{r}$.

Turning the argument around, *given* some $n(\theta,\phi,\mathbf{r})$, say the generalized index distribution for an optical cloak, we can *derive* the principal coefficients of the associated electromagnetic medium via

$$\kappa_1 = \frac{n_2 n_3}{n_1}, \quad \kappa_2 = \frac{n_3 n_1}{n_2}, \quad \kappa_3 = \frac{n_1 n_2}{n_3},$$

where $n_{1,2,3}$ are the principal indices associated with $n(\theta,\phi,\mathbf{r})$.

Moving to acoustics we find the relationship between generalized index and the acoustic medium parameters is given by

$$n(\mathbf{r}) = \left[\frac{(B/\rho)_{ij}s^i s^j}{B_0/\rho_0}\right]^{1/2},$$

where

$$(B/\rho)_{ij} = \left(\frac{B_0}{\rho_0}\right)(\phi_*)_i^m\,(\phi_*)_i^n\,g_{mn}$$

We will present our numerical evidence to support the correctness of these ideas.

A Revisit to Transformation Optics: A Precise Or Approximated Method?

Jin Hu
School of Information and Electronics, Beijing Institute of Technology, Beijing 100081, China

Abstract— Transformation optics is one of the most important design tools in the field of artificial electromagnetic materials or metamaterials. It is well accepted that the transformation optics can precisely control the electromagnetic fields. In this talk, we revisit this method and find in general it is in fact an approximate one in controlling the fields amplitudes if the transformation is started from isotropic and homogeneous materials. The transformation optics is usually established based on the Maxwell's equations without the Gauss's laws, and then it can be noted that there are no derivations of materials parameters, the physical model is thus a piece-wise homogeneous one that the variations of the materials round any point are ignored, the equations have same form whether $\boldsymbol{\varepsilon}$ or $\boldsymbol{\mu}$ is constant or variable of the positions, the locally affine based transformation relations can be applied in such a model. However, if the Gauss's laws are included into consideration, the derivations of the materials parameters appear which means the variations of the materials round any point cannot be ignored, the whole system will have different forms depending on the character of $\boldsymbol{\varepsilon}$ or $\boldsymbol{\mu}$, thus the physical model is not a piece-wise homogeneous but higher order one. The local affine feature of the transformation relations makes it is impossible to transform a piece-wise homogeneous element to a higher order one, and vice versa. That is to say, in general the system loses the form-invariance through the given transformation relation. The approximation is verified by an example of isotropic lens for electromagnetic wave control. The application scope of transformation optics thus is clarified. The conclusions here are important to the applications that utilizing the transformation field amplitudes and the study is also helpful to develop the framework of transformation optics.

Analogue Transformations and Their Application to Optics

Carlos García-Meca[1, 2]

[1]Nanophotonics Technology Center, Universitat Politècnica de València, Spain
[2]Instituto de Astrofísica de Andalucía (CSIC), Granada, Spain

Abstract— During the last few years, transformation acoustics has emerged as a powerful tool for designing devices able to control sound waves in an unprecedented manner. This technique takes advantage of the form invariance of the acoustic equations under spatial transformations to obtain the material parameters that deform acoustic space in a prescribed way, e.g., for cloaking acoustic waves [1].

However, this approach has been undermined by the Galilean character of fluid mechanics, which reduces the power of the traditional transformational method when applied to acoustics. Specifically, classical acoustic equations are not form invariant under transformations that mix space and time [2, 3]. As a consequence, the method cannot be applied to design devices based on this kind of transformation, contrarily to what has been done in optics.

Recently, the problem of transformation acoustics was approached from another angle [2, 3]. Instead of using directly the symmetries of the acoustic equations to bridge between different solutions for the propagation of acoustic waves, the symmetries of an analogue abstract space-time (described by relativistic form-invariant equations) are exploited. In this method, each couple of solutions connected by a general coordinate transformation in the analogue space-time can be mapped to acoustic space. This way, it is possible to find the relation between the acoustic material parameters associated with each of these transformation-connected solutions. The result is an alternative version of transformation acoustics as powerful as its optical counterpart.

On the other hand, with their underlying relativistic geometry, Maxwell's equations are invariant under any space-time transformation. In this sense, the use of an optical analogue transformation technique is, in principle, not required in any case.

Nevertheless, in this talk we show that the concept of analogue transformations can be applied to the field of optics in order to achieve a variety of effects different from those obtained with the standard transformation technique. We illustrate the potential of this new approach with some practical examples.

Toroidal Dipole Induced Scattering Transparency of Nanoparticles

Wei Liu[1, 2]

[1]College of Optoelectronic Science and Engineering
National University of Defense Technology, Changsha, China
[2]Nonlinear Physics Centre, Research School of Physics and Engineering
Australian National University, Australia

Abstract— We show that toroidal dipoles can be excited within high-permittivity dielectric nanoparticles and significantly influence the scattering profile in the optical regime. We further reveal that the scattering transparencies of core-shell plasmonic nanoparticles can be classified into two categories: i) the *trivial* transparency with no effective multipole excitations within the particle, and ii) the *non-trivial* one induced by the destructive interferences of induced electric and toroidal multipoles.

The almost identical descriptions of multipole expansions for radiation sources in many textbooks (including the classical one by J. D. Jackson [1]) lead to a dogma that the decomposition into electric and magnetic multipoles are sufficient. Consequently, though the scattering of individual nanoparticles plays a profound role in the flourishing fields of plasmonics and metamaterials, scattering related interpretations are still based on electric and magnetic resonances only, where the toroidal components are overlooked [2]. This unfortunately results in inaccurate explanations for some fundamental scattering properties, and thus may hinder further breakthroughs in both scattering related basic researches and applications.

We revisit the seminal problem of spherical nanoparticle scattering based on the multipole expansion method with toroidal components included [2–5]. In Fig. 1(a) the configuration of the scattering problem is shown and in Fig. 1(b) we show the schematic illustration of the magnetic field and current distribution of the toroidal dipole (TD) excited. As is shown, the TD can be interpreted as a series of magnetic dipoles aligned along a circle [2], which actually also represents the field-lines of **H**. Then we study a dielectric (refractive index $n = 3.5$) sphere of radius $R = 100\,\mathrm{nm}$ and show the near-field distributions at the TD (can be effectively excited within the sphere) resonant position in Fig. 1(c), which agree well with the results shown in Fig. 1(b). We further study the hybrid metaldielectric core-shell nanoparticles (results not shown), and identify two different mechanisms of the scattering transparencies of those particles: i) the *trivial* transparency without effective multipole excitation inside and ii) the *non-trivial* one caused by scattering cancellation of electric and toroidal dipoles excited simultaneously. We note here that though there have already been extensive studies on the transparency phenomena in core-shell nanoparticles (e.g., see Ref. [6]), the crucial roles that could be played by toroidal multipoles have not been clearly identified as we have done here.

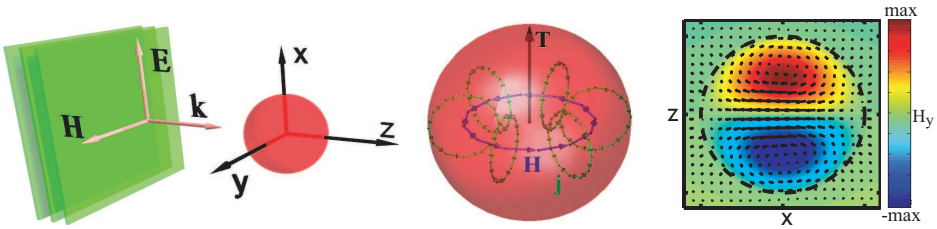

Figure 1: (a) The scattering of a spherical particle with an incident plane wave. (b) Schematic illustration of the toroidal dipole excited within the particle. Both the current **j** and magnetic field **H** distributions have been shown. (c) Near-fields of the TD resonance on the x-z plane (color-plot: $\mathbf{H}_y$; vector-plots: electric fields on plane).

The introduction of toroidal multipoles into scattering particles sheds new light to many related studies and can possibly expand significantly the applications of scattering particles. Moreover, investigations into light-matter interactions involving toroidal multipoles can possibly merge with the fields of topological and low-dimensional photonics, and thus help to establish new platforms for the study of many exotic optical effects.

Using Complex Coordinates to Understand Reflection

S. A. R. Horsley
University of Exeter, Stocker Road, Exeter, UK

Abstract— In this talk I will explain that to understand the propagation of waves it can be useful to treat the space-time coordinates as complex numbers. For instance, our results demonstrate that there is a simple way to control reflection from an inhomogeneous medium in terms of the properties of the permittivity in the complex position plane. This technique is distinct from existing work that makes use of complex coordinates in transformation optics [1, 2]. Rather than *transform* the propagation axis from the real line into the complex plane, here we solve the wave equation in the entire complex plane and relate properties of the wave at complex positions to the propagation on the real axis.

To illustrate how complex coordinates can be useful, we'll take simple example. Consider wave propagating in one dimension according to the equation

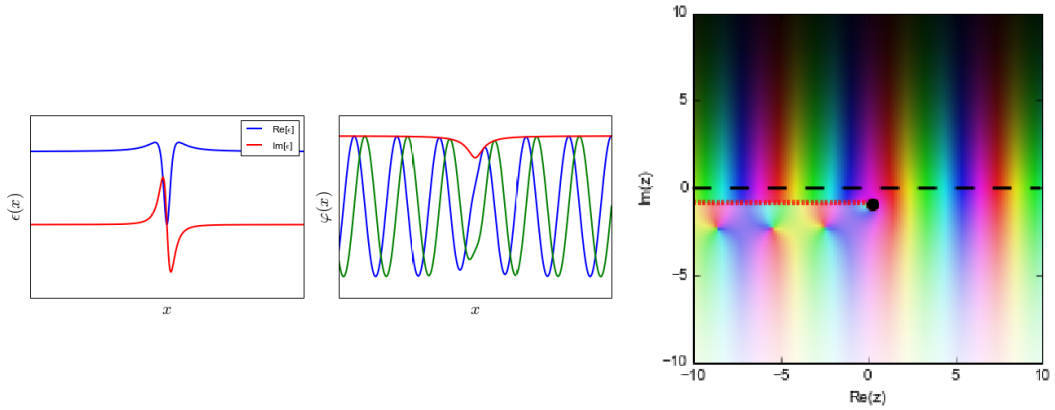
$$\left[\frac{d^2}{dz^2} + k_0^2\epsilon(z)\right]\varphi(z) = 0 \tag{1}$$

where φ could be single component of the electric field, or some scalar field such as sound, and z is complex number representing position. In this case take the following permittivity profile

$$\epsilon(z) = 1 + \frac{1}{(z/a + i)^2}. \tag{2}$$

which has single second order pole at the point $z = -ia$. Figure 1 shows plot of the permittivity (2), and wave propagation both along the real line, and in the entire complex position plane.

There are several things to notice about Figure 1. Firstly, this is PT-symmetric permittivity profile with zero reflection for wave incident from the left (such behaviour of PT-symmetric structures is already known [4]). In the complex position plane the profile has single pole at $z = -ia$, and from this pole runs branch cut in the value of the field φ. In fact, we have found that when there is pole in the permittivity in the complex position plane then there is nearly



(a) (b) (c)

Figure 1: (a) Shows a plot of the permittivity profile (2), and (b) shows wave propagating to the right within this profile (the real part of the wave is green, the imaginary part is blue, and the absolute value is red). Evidently this particular profile exhibits PT-symmetry, and the lack of oscillations in the absolute value of the field means that there is zero reflection from the profile. (c) Shows plot of the value of the field φ in the complex position plane where brightness indicates the magnitude, and colour the phase (zero phase is red, π phase is light blue). The real axis is shown as black dashed line, and the pole in (2) is the black circle. The red dotted line runs from the pole to infinity, and indicates branch cut in the field in the complex position plane. The position of this branch cut determines whether the profile reflects radiation.

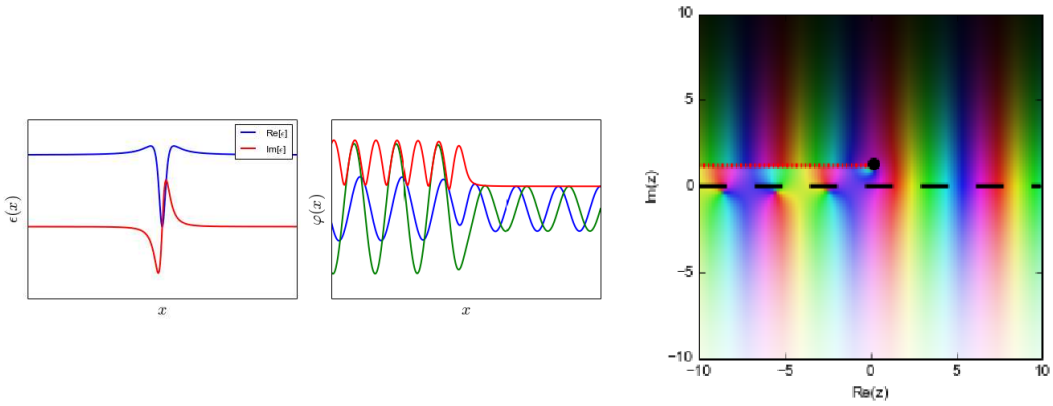
always branch cut in the field. The position of the branch cuts is important. We have found that whenever all the branch cuts in φ can be placed *below* the real axis then the profile will not reflect radiation from the left, and whenever they can be placed *above* the real axis then the profile will not reflect any radiation from the right. Figure 2 shows the effect of moving the pole in $\epsilon(z)$ from $z = -ia$ to $z = ia$. Notice that the branch cut in φ now occurs above the real axis, and there is large reflection for incidence from the left.

The phenomenon shown in Figures 1–2, can be generally stated as follows: poles in the permittivity at complex positions lead to branch cuts in the field. When these branch cuts are all below the real axis then there is no reflection for incidence from the left, and when the branch cuts are all above the real axis then there is no reflection for incidence from the right. This means that if we have any permittivity profile where all the poles occur in the lower half position plane, then all such profiles will not reflect any radiation incident from the left (and vice versa for all the poles in the upper half plane).

In turn this means that to guarantee zero reflection for incidence from the left we can use the Kramers-Kronig relations *in space* to determine the real and imaginary parts of the permittivity,

$$\mathrm{Re}[\epsilon(x)] - 1 = \frac{1}{\pi} \int_{\infty}^{\infty} \frac{\mathrm{Im}[\delta\epsilon(y)]}{x - y} dy \tag{3}$$

Figure 3 illustrates an example of an index profile that obeys (3), showing that there is indeed zero reflection, which we have found to be true for the full angular range of emission, and both polarizations.



(a) (b) (c)

Figure 2: Identical to Figure 1, but the pole in $\epsilon(z)$ has been moved from $z = -ia$ to $z = ia$. Notice that now there is large reflection.

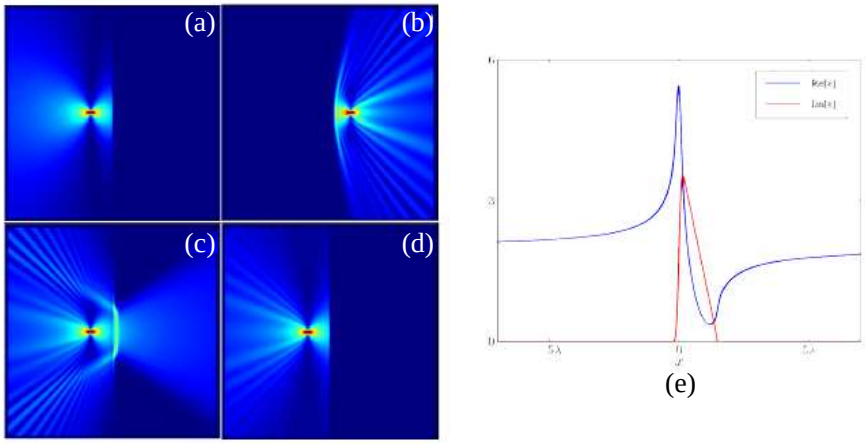


Figure 3: (a) Shows the results of a numerical calculation of the absolute value of the field of dipole emitter placed in front of the permittivity profile shown in panel (e) which satisfied the Kramers-Kronig relations in space. In (b) the dipole is place to the right of the profile, and panels (c) and (d) show the field in the case when only the real or imaginary parts of the permittivity are included, respectively.

Abstract— Optical metasurfaces have developed as a breakthrough concept for advanced wavefront. Key to these "designer metasurfaces" [1] is that they provide full 2π phase coverage and that their local phase can be precisely controlled. The local control of phase, amplitude and polarization of an optically thin plane will lead to a new class of flat optical components in the areas of integrated optics, flat displays, energy harvesting and mid-infrared photonics, with increased performance and functionality. However, reflection and/or absorption losses as well as low polarisation-conversion efficiencies pose a fundamental obstacle for achieving high transmission efficiencies that are required for practical applications.

A promising way to overcome these limitations is the use of metamaterial Huygens' surfaces [2–4], i.e., reflectionless surfaces that can also provide full 2π phase coverage in transmission. Plasmonic implementations of Huygens' metasurfaces for microwave [2] and mid-infrared spectral range [3], where the intrinsic losses of the metals are negligible, have been suggested for efficient beam steering [2, 3], beam shaping [2], and focusing [3]. However, these designs cannot be transferred to near-infrared or even visible frequencies because of the high dissipative losses of plasmonic structures at optical frequencies.

Here we introduce highly efficient Huygens' metasurfaces for near-infrared frequencies with high-permittivity all-dielectric nanoparticles with tailored Mie-type resonances as Huygens' meta-atoms [4]. Our low-loss Huygens' surface is realized by two-dimensional subwavelength arrays of loss-less silicon nanodisks with both electric and magnetic dipole resonances [4, 5]. By controlling the intrinsic properties of both resonances, i.e., their relative electric and magnetic polarizabilities and their quality factors in addition to their spectral position, we can design silicon nanodisks to behave as near-ideal Huygens' sources. This allows us to realize effective all-dielectric Huygens' metasurfaces that lack dissipative losses and also suppress unwanted reflections. At the same time they provide full 2π coverage for the phase shift imposed onto a transmitted light wave without relying on cross-polarization schemes and, thus, without suffering from polarization-conversion losses as most of the plasmonic counterparts. As a result, silicon-nanodisk Huygens' metasurfaces in principle allow for light-wave manipulation with ideally 100% transmission efficiency and also provide almost arbitrary spatial distributions of phase discontinuities depending on the design of the meta-atoms at each position. We provide a comprehensive analytical analysis and numerical modeling of the properties of this Huygens' metasurface and we experimentally demonstrate a Huygens' metasurface in the near-infrared spectral range which results in complete 360 degrees phase coverage of the transmitted light in combination with high transmittance values. We show that that near-unity transmission efficiency can be achieved for an optimized design and we discuss several applications including efficient wavefront-shaping, dispersion-control devices, and optical holograms where the unique properties of all-dielectric Huygens' surfaces play a key role for the realization of highly efficient metadevices.

Electrodynamics of Cylinders with Radial Anisotropy

H. Kettunen[1], **H. Wallén**[2], **and A. Sihvola**[2]

Abstract— In this presentation, we suggest an effective material configuration based on a lattice of dielectric radially anisotropic (RA) cylinders. Such all-dielectric metamaterials that are based on Mie resonances of high-permittivity objects are currently under much interest, as they could largely overcome the detrimental effect of materials losses that are characteristic to plasmonic metals. Dielectrics are also much less vulnerable to frequency dispersion enabling tunability in broader bandwidths.

To be more specific, we study scattering of a TE_z polarized plane wave from a circular infinitely long dielectric radially anisotropic (RA) cylinder, whose axis is parallel to the z-axis. The permittivity dyadic of an RA cylinder is given in polar coordinates as $\bar{\bar{\varepsilon}} = \varepsilon_0(\varepsilon_\rho \mathbf{u}_\rho \mathbf{u}_\rho + \varepsilon_\varphi \mathbf{u}_\varphi \mathbf{u}_\varphi)$, where ε_ρ and ε_φ are the radial and the tangential permittivity components of the cylinder, respectively. As shown in [1], in the long-wavelength limit, the external response of an RA cylinder resembles the one of an isotropic cylinder with effective permittivity $\varepsilon_{eff} = \sqrt{\varepsilon_\rho \varepsilon_\varphi}$. However, in the actual dynamic case, we need to apply the Mie scattering theory for radially anisotropic cylinders [2].

By solving the coefficients a_n of the expansion of the scattered wave, we are able to locate the resonances of the cylinder. We are especially interested in the magnetic and electric dipolar resonances, that are given by the maxima of the two first coefficients a_0 and a_1, respectively. By changing the values of the permittivity components ε_ρ and ε_φ, we also shift the occurrence of the resonances in frequency. We have earlier showed that by choosing ε_φ very large, the cylinders give rise to artificial magnetism enabling even negative effective permeability values [3].

Our objective for this presentation is to adjust the magnetic and electric resonances to appear simultaneously, which could be a way to construct an all-dielectric double negative material with negative index of refraction. We will also discuss photonic crystals consisting of RA cylinders.

Abstract— High-refractive index dielectric nanoparticles may exhibit strong directional forward light scattering at visible and near-infrared wavelengths due to interference of simultaneously excited electric and magnetic dipole resonances. For a spherical high-index dielectric, the so-called first Kerker's condition can be realized, at which the backward scattering practically vanishes for some combination of refractive index and particle size. However, Kerker's condition for spherical particles is only possible at the tail of the scattering resonances, when the particle scatters light weakly. Here we demonstrate that significantly higher forward scattering can be realized if spheroidal particles are considered instead. For each value of refractive index n exists an optimum shape of the particle, which produces minimum backscattering efficiency together with maximum forward scattering. This effect is achieved due to the overlapping of magnetic and electric dipole resonances of the spheroidal particle at the resonance frequency. It permits the design of very efficient, low-loss optical nanoantennas. We found that the results for spheroidal particles accurately describe the response of a wide range of shapes with the same aspect ratio.

Optical Magnetism and Active Devices from All Dielectric Metasurfaces

Igal Brener
Center for Integrated Nanotechnologies, Sandia National Laboratories

Abstract— Magnetic mirrors or high impedance surfaces were first demonstrated at microwave frequencies to improve antennas radiation efficiency. Magnetic mirrors exhibit unusual electromagnetic boundary conditions. In contrast to a normal mirror that exhibits a 180-degree phase shift of the reflected electric field, a magnetic mirror does not reverse the phase of the reflected electric field but reverts the phase of the reflected magnetic field. Therefore, while the emission from a transverse electric dipole placed close to a normal mirror will be largely canceled by its image, a transverse electric dipole emitter placed close to a magnetic mirror can radiate efficiently. Conversely, transverse dipole absorbers placed close to a magnetic mirror will be located at an anti-node of the total electric field and can absorb efficiently. These exceptional properties of magnetic mirror will lead to potential applications in the areas of sensors, photodetectors, and spectroscopy [1].

We used a special phase-locked time-domain system operating in the mid IR and directly observed that the electric field reflected from our dielectric optical magnetic mirror is in-phase with the incident wave, which directly demonstrates the magnetic mirror behavior [2]. This behavior is further confirmed by observing ~ 180 degree phase difference between the electric and magnetic resonances. I will also discuss the radiative rate enhancement of a dipole close to our optical magnetic mirror. This is in contrast to the behavior for regular metallic surfaces where dipole emission is strongly quenched. Finally, if time permits, I will present preliminary results on dielectric metasurfaces patterned on different semiconductors or with more complex fabrication steps, that can lead to the realization of active all dielectric metasurfaces.

Abstract— We study experimentally both magnetic and electric optically-induced resonances of silicon nanoparticles fabricated by femtosecond laser ablation [1] by combining polarization-resolved dark-field spectroscopy and near-field scanning optical microscopy (NSOM) measurements. First, to study the scattering properties of Si nanoparticles as a function of wavelength and polarization of the incident beam, we use a home-made polarization-resolved dark-field microscope with independent excitation and collection optical channels. The obtained spectra allow to determine spectral positions of optical magnetic and electric scattering resonances and demonstrate excellent agreement with the scattering spectra of a silicon sphere on a glass substrate calculated using analytical solution [2]. Comparing *s*- and *p*-polarized spectra we observe different polarization-dependent behaviour of the spectral features corresponding to electric and magnetic dipole resonances.

To gain even better data allowing to distinguish magnetic and electric dipole contributions, we complement our dark-field measurements with NSOM experiments performed at electric and magnetic dipole resonant wavelengths determined from the dark-field spectroscopy measurements. We show that the magnetic dipole response of the nanoparticle can be directly identified through the characteristic asymmetry in NSOM patterns obtained using an aperture-type probe operating as an effective magnetic field analyzer [3]. We also compare the experimental patterns to the near-field signal maps reconstructed from rigorous finite-difference time-domain (FDTD) simulations using an approach based on the reciprocity theorem of electromagnetism [4, 5]. The presented results confirm that the proposed experimental approach allows for discrimination of the dipole optical responses of both magnetic and electric nature. Importantly, this can be done directly from the experimental data without employing complementary numerical simulations.

Abstract— Over the past decade, extensive efforts have been dedicated to finding effective nonlinear optical media on the nanoscale [1]. The main strategy to enhance the efficiency of the nonlinear optical processes lies in utilizing localized modes, e.g., in plasmonic nanostuctures. In particular, a pronounced modification of the second- and third-order nonlinear response has been observed in various nano- and metamaterials [1–3]. In contrast, the effect of *magnetic resonances* on the nonlinear properties of nanostructures is much less studied and limited to conventional geometries such as split-ring resonators [4] or fishnet metasurfaces [5]. However, the nonlinear frequency generation in plasmonic nanostructures suffers from strong losses of metals at optical frequencies, losses which are further enhanced near the resonances.

To overcome this problem, in this work we study the third-harmonic generation (THG) from silicon-nanoparticle-based oligomers and metasurfaces. High-permittivity, dielectric nanoparticles are emerging as a promising alternative to metallic nanostructures for a wide range of nanophotonics applications; such nanoparticles exhibit both electric and magnetic multipolar resonances in the visible an near-IR spectral ranges [6]. In combination with their very low Ohmic losses, these nanoparticles and their composites offer many unique opportunities for tailoring their nonlinear optical response.

In single silicon nanodisks fabricated out of a silicon-on-insulator substrate, we report on a significant enhancement of the third-harmonic radiation intensity when the incoming femtosecond laser pulses excite the magnetic dipole resonance of the disk. Originating from the strong light confinement to a mode volume of $\sim \lambda^3/60$, the observed THG is shown to be approximately an order of magnitude larger that that of the bulk silicon slab [7]. Bringing the silicon nanodisks to the oligomer (trimer) arrangement provides an additional degree of freedom in tuning the spectral position of the magnetic resonance to a partial overlap with the electric resonance. We observe a pronounced reshaping of the third-harmonic spectra due to interference of the nonlinearly generated waves and an interplay between the electric and magnetic dipolar resonances. Packing the nanodisks to the metasurface arrangement provides a two order of magnitude THG enhancement over the THG from the bulk silicon; the THG is visible by the naked eye under the table-lamp illumination conditions [7]. Finally, the silicon nanodisk samples are shown not to suffer from the powerful laser radiation used in the experiment, as opposed to the widely used metallic nanostructures. To conclude, we demonstrate a novel platform that paves the way for nonlinear nanophotonics and silicon photonics devices enabled by resonant subwavelength low-loss all-dielectric nanoparticles.

Resonant Lithium Niobate Nanostructures for Nonlinear Frequency Conversion

Frank Setzpfandt, **Reinhard Geiss**, **Severine Diziain**,
Sina Saravi, **and Thomas Pertsch**
Abbe Center of Photonics, Institute of Applied Physics
Friedrich-Schiller-Universität Jena, Max-Wien-Platz 1, Jena 07743, Germany

Abstract— Lithium niobate is an excellent material for nonlinear optics due to its high nonlinear coefficients and large transparency window. These favorable properties have been extensively used for classical integrated optics. However, nanostructures, which allow for a much broader range of achievable optical properties, are much harder to fabricate in lithium niobate due to the complicated properties of this material. In recent years, we developed the technique of ion-beam enhanced etching. This electron-beam lithography based approach uses spatially structured irradiation with swift heavy ions, which locally destroy the crystal structure, to control the wet etching processes used to define nanostructures. With this fabrication technique we are able to manufacture different types of resonant nanostructures for nonlinear optical frequency conversion. In our talk we will summarize our recent experimental and theoretical result concerning the design and experimental characterization of such nanostructures for different applications.

In rectangular nano-waveguides, resonances in two spatial dimensions form transversely localized modes which propagate along the waveguide. Such waveguides achieve strong field localization and have low losses, thus enabling efficient second-harmonic generation and also the generation of photon pairs for quantum optical applications, which we demonstrate experimentally.

To further enhance the efficiency, the dispersion of the waveguide has to be controlled to achieve slow-light modes with a very low group velocity. This we achieve in Photonic Crystal waveguides. Here, waveguiding and dispersion control are enabled by resonant interaction of the light in the waveguide with the surrounding periodic structure of the photonic crystal. We will present systematic design guidelines and experimental realizations of such Photonic Crystal waveguides for efficient second-harmonic generation.

Finally, we will consider resonators, where the light is confined in all three dimensions. In comparison to the structures mentioned before, resonators enable much higher quality factors and thus higher nonlinear efficiencies. We experimentally characterized the linear and nonlinear responses of both disc-resonators and resonators in Photonic Crystals and measured strong second-harmonic signals.

Summarizing, we believe that lithium niobate is an ideal material platform for nonlinear optics. The results we will present in this talk will be an important step towards the practical implementation of lithium niobate's capabilities in integrated nanophotonics.

Integrated Nanophotonic Components Enabled by Alternative Materials

Abstract— Recent advances in alternative nanophotonic materials, specifically CMOS-compatible compounds, have propelled a unique class of integrated devices to achieve high performance with realistic materials.

Integrated optical technologies are critical for many fundamental applications such as telecommunications, chemistry, quantum science, and medicine [1]. However, for these devices to be realized in a large scale, they should be CMOS-compatible — a problem for plasmonic devices which have generally relied on noble metals [2]. Recently, there has been a flurry of research in the field of alternative plasmonic materials, but for telecommunication applications, CMOS-compatible materials titanium nitride and transparent conducting oxides (such as doped zinc oxide) are among the most promising materials currently available [3].

TiN is a gold-like ceramic material with a permittivity cross-over near 500 nm. In addition, TiN can attain ultra-thin, ultra-smooth epitaxial films on substrates such as c-sapphire, MgO, and silicon. Partnering TiN with CMOS-compatible silicon nitride enables a fully solid-state waveguide which is able to achieve a propagation length greater than 1 cm for a $\sim$8 µm mode size at 1.55 µm. In fact, similar designs using TiN have outperformed gold waveguides due in large part to the reduced scattering loss of epitaxial quality films [4].

Utilizing highly doped zinc oxide films as a dynamic photonic material, high performance modulators can also be realized due to the low-loss achieved by the TiN/Si_3N_4 waveguide. Simply by placing a thin layer of aluminum doped zinc oxide (AZO) on top of the waveguide structure, a modulator with very low insertion loss is achieved. However, to determine the performance of the device, the ability to which the AZO can be tuned must be understood. Our recent work has investigated optical tuning of AZO films by the pump-probe method, demonstrating a change in the refractive index of $-0.17 + 0.25i$ at 1.3 µm with an ultrafast response of 1 ps. Assuming this change in the refractive index for the AZO film, a modulation of $\sim$0.7 dB/µm is possible in the structure with $\sim$0.5 dB insertion loss and an operational speed of 1 THz. Further optimization of the design is expected to lead to an increased modulation depth without sacrificing insertion loss or speed.

Together, these alternative materials form the base of a fully integrated nanophotonic system, capable of exceptional performance with speeds greater than 1 THz, in large part due to the development of alternative materials. Consequently, nanophotonic technologies are reaching a critical point where many applications including telecom, medicine, and quantum science can see practical systems which provide new functionalities.

Abstract— The coupling of plasmons and non-linear materials is most likely a vital part in the development of future plasmonic devices. Strong coupling and the formation of new plasmon-exciton quasiparticles called excimons or plexcitons was previously observed in metal-semiconductor hybrid systems and organic dye-coated metal-gratings [1, 2]. The system presented here combines the stability and room-temperature operation of inorganic semiconductors with the potential of cost-effective large-scale production that is typical for organic dyes. Both aspects are preconditions for a commercial breakthrough of ultrafast-nanooptical devices.

Here, we study cyclohexenyl-ethyl-ammonium lead-iodide (CHPI), which is well known from solar-energy research, as a candidate material for active plasmonic devices. Due to the huge organic ion in the R position between the PbI_6 octahedra of the general R-PbI_3 perovskite structure, semiconducting sheets of lead-iodide octahedra are formed. These are separated by layers of the organic ions. CHPI shows strong excitonic response and high stability even at room temperature. It can easily be processed from solution and forms regular stacks.

In order to study the interaction of CHPI with plasmons, CHPI was grown on a silver grating by drying from a solution in a thermal process [3]. We present experimental angle-resolved reflectivity spectra in the visible range and compare to theoretical calculations. These spectra reveal the formation of collective plasmon-exciton modes that are coupled with a huge Rabi energy of 125–150 meV, see Fig. 1. We also observe a red-shift of the excitonic absorption. This shift is attributed to the formation of an image-biexciton: a quasiparticle made up by the excitonic dipole coupled to its own image dipole in the metal [4, 5].

In addition, we present theoretical calculations with the finite-element method (FEM). The calculations solve the full vectorial Maxwell equations taking the inherent anisotropy of the stacked material CHPI into account. The frequency-dependent response of the CHPI and the metal is taken into account by multi-Lorentzian and Drude-Lorentz fits, respectively, to experimental reference data. These calculations reproduce the important aspects of the far-field experiments and describe the experimentally inaccessible near-field distributions in the groves.

Abstract— Periodic arrays of metallic nanoantennas constitute a versatile system for enhancing light emission. Nanoantenna arrays sustain single-particle localized surface plasmon resonances (LSPRs), and hybrid plasmonic-photonic resonances due to the coupling between LSPRs and diffracted or guided modes. Recently, the mutual coupling strength between these modes was shown to transition from weak to strong [1]. Hybrid plasmonic-photonic resonances can lead to unconventional effects such as large fluorescence enhancements at frequencies and wave vectors of far-field induced transparency [2]. Here, we present recent results on an array of pyramid-shape nanoantennas and its interaction with fluorescent molecules [3]. Diffractive coupling of LSPRs in the array leads to a collective resonance known as surface lattice resonance (SLR) [4]. We designed an array wherein fluorescent molecules drived both LSPRs and SLRs. Interestingly, we observed an unbalanced forward-backward light emission spectrum which breaks the conventional forward-backward symmetry of planar structures. Through rigorous electrodynamic calculations we show that the pyramid shape of the nanoantennas enhances their magnetoelectric response, i.e., the excitation of magnetic moments by electric fields and viceversa. The enhanced magneto-electric response enables electric and magnetic dipole moments of similar magnitude to interfere distinctly in the forward and backward direction. In turn, different colors of light are beamed forward or backward. Our observations resemble the Kerker condition for light scattering of dielectric particles, but here realized in the context of fluorescence enhancement with metallic nanoantennas. In addition, we demonstrate that localized and delocalized magnetic surface waves with an excitation strength depending on the plane wave direction are linked to these effects. We discuss applications to the field of solid-state lighting [5], and to the potential realization of a quantum condensed plasmonic state [6].

Plasmonic Fano-like Resonances and Their Near-field Properties in Finite Arrays of Metal Particles

S. Bakhti, N. Destouches, and A. V. Tishchenko
Laboratoire Hubert Curien, Université Jean-Monnet, Université de Lyon
CNRS, UMR 5516, 18 rue Pr. Lauras, Saint-Etienne F-42000, France

Abstract— Localized Surface Plasmon resonances attract for many years a considerable attention due to their unique ability to concentrate electromagnetic energy at nano-scale. Fano resonances [1] emerge in finite structures from a strong coupling between individual or group of particles. This kind of resonance is characterized by a highly asymmetric line profile in the scattering or extinction spectrum of the structure, and provides a promising platform for sensing applications.

In this work, we characterize Fano resonances in finite silver particle arrays through the use of the coupled mode model [2]. This model is applied to the complex valued partial extinction of each particle (having the same phase behavior than their dipolar moment oscillation) on which a pole searching algorithm is used to retrieve all phenomenological parameters. By this way, the asymmetric line profile of Fano resonances appears as resulting from the combination of super-radiant and sub-radiant hybrid modes in the coupled system. In the case of a simple quadrumer (Fig. 1(a)), two coupling regimes appear depending on the inter-particle distance. The weak coupling regime is characterized by broad super-radiant and sharp sub-radiant modes, whereas the strong coupling regime shows a broader sub-radiant mode and a larger Fano dip in the extinction spectrum. In the case of a two dimensional array of particles (Fig. 1(b)), corresponding to a strong coupling regime, the Fano resonance exhibit an interesting near-field behavior. Depending on the excitation wavelength relative to the Fano dip, the hot spot can be localized on different lines of the arrays. This unique ability opens new opportunities to spectrally control the near-field enhancement location in a finite structure.

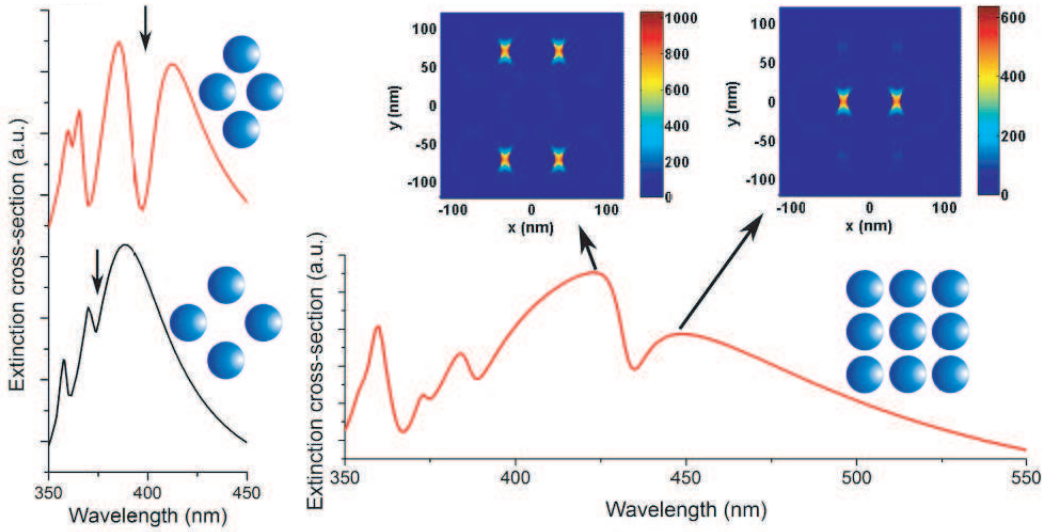

Figure 1: (a) Fano resonance (located by an arrow) in the extinction spectrum of a quadrumer in the strong and weak coupling regimes. (b) Extinction spectrum of a 3×3 array of particles with a mapping of near-field intensities on both sides of the Fano dip. All particles are silver spheres of 30 nm in radius and the structures are excited with a horizontally polarized incident plane wave.

Abstract— The manipulation of matter on the nanoscale provides a means to achieving material properties that are difficult or impossible to achieve in the bulk state. Progress toward nanoscale architectures with tangible utility requires (1) the development of methods to controllably and precisely locate nanoscale objects in multiple dimensions and (2) the formation of rigorous structure-function relationships across multiple size regimes. We use DNA as a programmable ligand to arrange gold nanoparticles into two- and three-dimensional crystalline superlattices. By controlling the spacing between gold nanoparticle building blocks, the superlattices can be transitioned from exhibiting the properties of the constituent plasmonic nanoparticles to adopting the photonic properties dictated by the mesoscale crystal habit (here a rhombic dodecahedron). In particular, thin films with dimensions smaller than the wavelength primarily resemble the absorption of the free nanoparticle. Comparatively, rhombic dodecahedron superlattices on the order of $\sim$1 micron exhibit distinct photonic red-shifted resonances far to the red of the free particle resonance. To rigorously quantify these seemingly disparate optical effects, we implement anomalous diffraction theory, a geometric optics approximation designed for low index materials. Using this generally applicable theoretical framework, we illustrate that crystal habit is a powerful design consideration for controlling far-field extinction and light confinement in plasmonic metamaterial superlattices. The precise control over nanoscale spacing, in combination with control over five distinct mesoscale crystal habits, gives rise to unprecedented control over far-field light manipulation in bottom-up optical materials. We envision that this work will impact the development of and progress towards functional nanoscale assemblies in energy harvesting, metamaterials, photovoltaics, and sensing.

Nonlinear Traffic Control Across Waveguides

Mikhail Lapine[1], **Alexey P. Slobozhanyuk**[2], **Ilya V. Shadrivov**[2], **David A. Powell**[2], **Ross C. McPhedran**[3], **and Yuri S. Kivshar**[2]

[2]School of Physics, University of Sydney, NSW 2006, Australia

Abstract— We implement an independent additional interaction channel between microwave waveguides, which otherwise would have no interaction with each other, mediated by an optical link. For this purpose, we employ nonlinear optical coupling [1] in a pair of split-ring resonators, equipping one SRR with varactors biased by a photo-diode (PD), and the other one with a light-emitting diode (LED), Fig. 1. We place the photo-coupled meta-atom at the intersection of the two magneto-inductive waveguides (Fig. 2), adjusted so as to maintain integrity in each of the waveguides. Due to the symmetry of the configuration, the waveguides have no explicit magnetic coupling and at low power, signal propagation in them is not mutually affected. However, when the power in the waveguide passing through the LED-SRR (shown red in Fig. 2) increases, the LED shines light onto the PD of the orthogonal SRR, which imposes additional voltage on the varactors and shifts the effective capacitance of the PD-SRR. This leads to the shift of the resonance in the element at the intersection, and affects signal propagation through the other waveguide (shown black in Fig. 2). Consequence is the "traffic light" effect, when the increasing intensity in one waveguide suppresses propagation in the other. Moreover, the dynamics of this effect is different at different frequencies, so the system actually supports power-dependent propagation control across multiple channels (see the two curves in Fig. 3). We will present alternative designs as well as experimental results, demonstrating that our approach enables efficient control of the transmission over one channel depending on the power supplied over the other, providing a "traffic light" for the signals.

Figure 1: Experimental prototype of the optically coupled meta-atom: one of the broadside-coupled split-ring resonators is loaded with photo-diodes (PD); the other one, orthogonally positioned, is equipped with a light-emitting diode (LED).

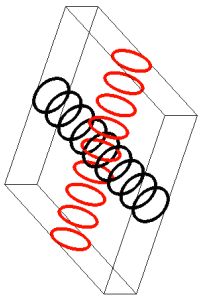

Figure 2: Conceptual schematic of the two perpendicular magnetoinductive waveguides with the opticallycoupled meta-atom at the intersection (black ring for the PD-SRR, red ring for the LED-SRR).

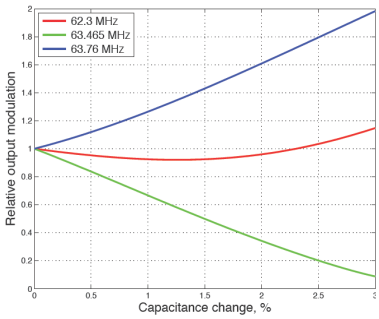

Figure 3: Relative change in the transmission coefficient (here, the ratio between the output and input current) over the PD-waveguide (black in Fig. 2) depending on the capacitance change in the PD-SRR, imposed by the increasing power over the LED-waveguide (red in Fig. 2); a 2% change in the capacitance corresponds to 1 W power increase. The results are shown for three frequency channels, demonstrating traffic suppression, enhancement or little variation, depending on frequency.

Retrieving the Polarizability Tensor of Wire Media

J. Ben Yakar[1], **P. Chen**[2], **Y. Sivan**[2], **and D. J. Bergman**[2]

[1]School of Physics and Astronomy, Raymond and Beverly Sackler Faculty of Exact Sciences

Abstract— Metamaterials consisting of long, circular, cylinders are very popular. It is a fundamental challenge to characterize the effective electromagnetic response of such composites. In this framework, the radius of cylinder is assumed to be considerably smaller than the external wave length, thus the dominant scattered EM fields can be approximately replaced by dipole fields. Previous works dealt mainly with two dimensional (2D) scenarios, i.e., characterizing the effective electromagnetic response for light propagation perpendicular to the cylinder axis.

In this work, we generalize this treatment to three dimensions (3D), i.e., we characterize the effective electromagnetic response for light propagation at any angle, and find that the resulting electromagnetic response is non-local, i.e., it depends on the wavevector component parallel to the cylinder axis. We retrieve analytically, the full polarizability tensor and show that it has different contributions for different polarized incoming EM waves (transverse electric and transverse magnetic with respect to the cylindrical axis), i.e.,

$$\begin{pmatrix} \mathbf{p} \\ \mathbf{m} \end{pmatrix} = \overleftrightarrow{\alpha}^{TM} \begin{pmatrix} \mathbf{E}_{TM} \\ \mathbf{H}_{TM} \end{pmatrix} + \overleftrightarrow{\alpha}^{TE} \begin{pmatrix} \mathbf{E}_{TE} \\ \mathbf{H}_{TE} \end{pmatrix}. \tag{1}$$

It is also diagonal, i.e., it contains no magneto-electric coupling, showing that claims in previous studies were incorrect. Having closed form expressions for polarizability allows us to use effective medium approximation methods, and tailor the spectral response for both electric and magnetic dipolar contributions. It is important to emphasize that for the first time, this gives a fully systematic way to characterize the magnetism (for example, see Fig. 1) of wire media.

Our analysis holds for additional structures based on cylindrical geometry, such as hole arrays, all-dielectric metamaterials, and multi-layer cylinders. It can be used to explain the electromagnetic response of wire media attributed with a negative refractive index, effective magnetism and hyperbolic dispersion relations. In addition, this approach can be applied to more complex unit cells e.g., consisting of clusters of parallel cylinders.

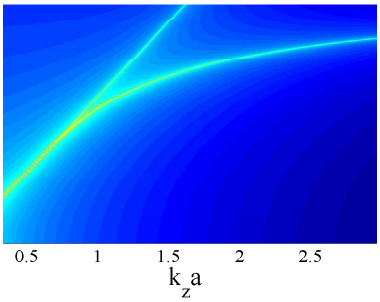

Figure 1: Intensity in log-scale, of the normalized transverse TE magnetic polarizability of a single, metallic cylinder placed in vacuum. The permittivity inside the cylinder is modeled using the dispersive Drude model, i.e., $\varepsilon_1 = 1 - \frac{\omega_p^2}{\omega^2+\gamma^2} + i\frac{\gamma\omega_p^2}{\omega^3+\omega\gamma^2}$, where $\omega_p = 13.7 \times 10^{15}$ Hz, and $\gamma = 32 \times 10^{12}$ Hz. The intensity shown in the figure, resonates near the (straight) light-line and the dispersion relation of surface modes along the cylinder surface. Additional important parameters: the cylinder radius $a = 50$ nm; the surface plasmon frequency $\omega_s = \omega_p/\sqrt{2}$, and k_z the wavevector component parallel to the cylinder axis.

Abstract— Modern simulation applications that carry out large scale iterative processes, such as Monte-Carlo simulations, or manipulate large data structures, tend to be extremely time-consuming due to the shortage of computational resources or the inherent nature of the simulation itself. Typical simulations can take up to several days to complete on conventional systems, while high-end supercomputers can be cost-prohibitive. Therefore, the need for effective parallelization of software execution and resource management is more imperative.

The goal of thus paper is to present a fully-distributed platform that enables software simulations to be executed within user-acceptable time periods, by predicting the resource requirements of each simulation. In this context, the platform analyzes user-defined simulation parameters as well as files that contain historical data about past executions of the particular simulation. Processor and memory utilization, overall execution time, level of parallelization and distributed execution are some of the information collected and used by an efficient training algorithm, in order to determine the optimal amount of resources to be allocated in a particular simulation. The training algorithm applies several machine-learning techniques such as multi-feature linear regression in order to efficiently predict the resource vector that will satisfy the user requirements.

The proposed architecture has been thoroughly tested for a variety of computationally and time intensive software applications, such as the eigenanalysis of electromagnetic structures using a series of numerical techniques (FEM, FDFD, MoM) as well as Monte-Carlo simulations for capacity calculations in 3G networks employing multiple antennas at both transmission ends. Moreover, parallelization techniques such as shared-memory parallel frameworks (OpenMP) as well as distributed-memory models have been utilized as well, that allow distributed execution (MPI) of the studied problems. Finally, for effective resource management, the described platform has been deployed on a medium-scale Cloud Infrastructure that is capable of spanning multiple Virtual Machines (VMs), which in turn will host the simulation software.

Two-dimensional Spatial Frequency Technique for Calculating Electromagnetic Scattering from Large Objects

Dayalan Kasilingam and Anthony Fascia
Department of Electrical & Computer Engineering, University of Massachusetts Dartmouth, USA

Abstract— In computational electromagnetics, there is a need for fast and accurate methods for calculating electromagnetic scattering from large objects and surfaces. Typically, in scattering problems an integral equation (IE) is defined and solved for calculating the fields or the currents on a scattering structure. In numerical solution methods such as the method of moments (MoM), the IE is discretized and solved by the inversion of a matrix. However, since the matrices in the MoM method are generally dense, for large scattering objects, matrix inversion is not computationally efficient. More efficient iterative methods such as the conjugate gradient method have since been developed to handle the numerical complexity of inverting large matrices. These iterative methods have significantly reduced the computational demands of solving the IE for scattering and radiation problems.

Another important technique which has shown great potential for reducing the computational demands of large matrix inversion problems, is the use of the spatial frequency technique. In the spatial frequency technique, the matrix equation is transformed into the spatial frequency domain by the use of the computationally efficient, FFT algorithm. Generally, the IE represents a set of boundary conditions which are the result of a convolution of a Green's function and surface currents or fields. Using the property of the Fourier transform, a convolution in space is converted to a product in the spatial frequency domain. The dense matrix multiplication in the spatial domain representation of the IE is thereby transformed into a multiplication by a diagonal matrix.

In addition, another significant advantage of the spatial frequency method is that it converts derivatives of fields or currents into simple multiplication by the appropriate spatial frequency component. In many scattering or radiation problems, the effective Green's function is derived by taking the derivatives of an original Green's function. In all of these cases, the modified Green's functions for different polarizations can be derived easily from one original Green's function by utilizing this property of the spatial frequency method.

Most of the previous work using the spatial frequency approach for analyzing scattering has focused on one-dimensional surfaces. In this study, the spatial frequency method is extended to scattering from two-dimensional, conducting objects, such as metallic cylinders of arbitrary cross-sections. In discrete processing, only Green's functions represented by circulant Toeplitz matrices can be converted to diagonal matrices in the spatial frequency domain. However, in practice, the Green's function matrices are generally Toeplitz matrices and not circulant Toeplitz matrices. A method for converting the Toeplitz matrix to a circulant Toeplitz matrix without altering the problem and increasing the computer storage requirements is developed and used in this technique. An expression for the induced currents are obtained in terms of a diagonal Green's function matrix in the spatial domain and the spatial frequency transform of the incident fields. A Taylor series expansion is used to avoid the need for matrix inversion. By truncating the Taylor series, one is able to generate results with different degrees of accuracy. Simulation results for scattering from cylinders of different sizes and cross-sections are generated and compared with other fast algorithms such as the conjugate gradient method for speed and accuracy. In addition to the analysis of electromagnetic scattering, this technique also lends itself well to the synthesis of scattering patterns. Several examples of how the spatial frequency technique is applied to the synthesis of two-dimensional targets with prescribed scattering patterns are also given.

A Conformal FDTD Model for Anisotropic Dielectric Interfaces in the GPU-accelerated PIC Code Neptune

S. J. Cooke[1], **G. M. Stantchev**[1], **and T. M. Antonsen, Jr.**[2]

[1]US Naval Research Laboratory, Washington, DC, USA
[2]Leidos Inc., Herndon, VA, USA

Abstract— The 3D Electromagnetic FDTD algorithm provides a practical and powerful technique to solve Maxwell's equations based on known device geometry and material properties. To obtain accurate simulations with this technique it is necessary to discretize the problem geometry onto the Cartesian FDTD grid using conformal (cut-cell) techniques. For metal boundaries these account for geometry at the sub-cell level to improve the order of accuracy of the field boundary conditions, and for smooth conducting geometries may provide 2nd-order convergence of electromagnetic eigenmode frequencies with respect to the grid cell size. For dielectric interfaces, sub-cell schemes have been demonstrated to obtain convergence initially 2nd-order, but for high resolution grids or high permittivity ratios it is observed that lower-order error terms dominate, and convergence revert to 1st-order [1].

In this paper we present a novel sub-cell averaging scheme to discretize material parameters on a Cartesian 3D FDTD grid for cells at the interfaces between regions of isotropic or anisotropic dielectric material. For cells intercepted by a dielectric interface we obtained a tensor expression for the average dielectric permittivity tensor in the cell, as a function of the two local permittivity tensors and the interface normal vector, assumed to be constant in the cell. For the particular case of two isotropic material tensors the resulting effective tensor is anisotropic due to the in fluence of the normal vector. In all cases, the method explicitly preserves the tensor symmetry and therefore is expected to provide stable evolution for time domain simulations.

We have implmented the new scheme in the electromagnetic model of the *Neptune* code [2], a FDTD particle-in-cell (PIC) code developed at the US Naval Research Laboratory since 2010 to model electromagnetic interactions with charged-particle beams. *Neptune* has an accurate conformal representation for metal surfaces, including loss [3], and is optimized for both multicore CPU and NVIDIA GPU hardware.

To illustrate the new scheme we solved for the lowest 97 eigenmodes of an isotropic dielectric sphere ($r = 0.5$) inside a concentric, spherical, perfectly conducting metal cavity ($r = 1.0$) using the new discretization model. The computed eigenmode frequencies were observed to converge to analytical solutions according to the 2nd-order relation,

$$\frac{\Delta f}{f} < \left(\frac{h}{\lambda_0}\right)^2 \varepsilon_r \tag{1}$$

where h is the grid cell size, and $\lambda_0 = c/f$ is the free-space wavelength. This was verified for $\varepsilon_r = 8$, 30 and 100, with cell sizes as low as $h \approx \lambda_0 = 100$.

ACKNOWLEDGMENT

Energy Distribution of Waveguides with Air-hole Dielectric Cylinder Outside of the Defect Layers

Ryosuke Ozaki and Tsuneki Yamasaki
Department of Electrical Engineering, College of Science and Technology
Nihon University, Japan

Abstract— Guiding and scattering problems of electromagnetic waves with periodic structures are very interesting in many areas of physics and engineering such as metamaterials or photonic crystal. Metamaterials are well known as technology which can be controlled mutual coupling of antennas with EBG (Electromagnetic Band Gap) structures and noise of circuit substrate. Also, EBG is the periodic array structure which consists of dielectric and perfect conductor. On the other hand, photonic crystals such as optical nanostructures with periodically permittivity distribution are known as technology which can be controlled the light in the periodic structure by interaction of both the wave nature of light and periodicity. Therefore, in the design of photonic crystals or metamaterials with periodic array or as much as optical wavelength, it is very important to investigate the stop band region or photonic band gaps. Though it is not analyzed the stop band area in Bragg region in detailed, several numerical results are shown only fields distribution by utilizing the FDTD method, FEM method based on variational method, and another numerical techniques.

In recent papers [1–3], we have proposed the periodic dielectric waveguide composed of dielectric circular cylinder and air-hole circular cylinder array, and investigated the influence of energy distribution in the defect area and complex propagation constants at the first stop band region by utilizing the combination of improved Fourier series expansion method and multilayer method for TE mode.

In this paper, we have analyzed the energy distribution of waveguide with air-hole dielectric cylinder outside of the defects layer as shown in Fig. 1. Consequently, the aim of this paper is to obtain optimum dielectric waveguide structure to concentrate the energy into the defect area for TE and TM mode. Numerical results indicate for the complex propagation constants at the first stop band region and the energy distribution for TE mode compared with TM mode.

Development of ADI-FDTD Methods with Dispersion-Relation-Preserving Features

T. T. Zygiridis[1], **N. V. Kantartzis**[2], **and T. D. Tsiboukis**[2]

[1]Department of Informatics & Telecommunications Engineering, University of Western Macedonia, Greece
[2]Department of Electrical & Computer Engineering, Aristotle University of Thessaloniki, Greece

Abstract— The incorporation of dispersion-optimized finite-difference expressions, instead of standard Taylor-based approximations, has been proposed in various publications for the construction of explicit finite-difference time-domain methodologies with upgraded reliability [1]. On the other hand, this practice has not been pursued extensively in the case of unconditionally-stable FDTD methods, with the most common one being the alternating-direction-implicit (ADI) FDTD scheme [2]. A rather popular approach that targets the accuracy improvement of such methods is the direct incorporation of high-order derivative approximations [3]. Although these may ensure milder anisotropy and smaller spatial errors, they do not constitute the most suitable choice for performance enhancement. This becomes clear, if one takes into account the nature and the practical applications of unconditionally-stable methods: the latter are deemed appropriate discretization strategies mainly in cases of densely-sampled spaces, where explicit FDTD schemes require excessive number of iterations, due to their restricted stability range. Furthermore, if we consider the fact that time-steps larger than the common stability limits are selected in the context of unconditionally-stable methods (hence, significant temporal errors emerge), we naturally conclude that a proper error amendment calls for the efficient treatment of the combined space-time errors, rather than the spatial ones only.

The ADI-FDTD method is a perturbation of the Crank-Nicolson scheme and is realized as a two-stage process with implicit update equations:

$$\left(\mathbf{I}-\frac{\Delta t}{2}\mathbf{A}\right)\mathbf{u}^{n+1/2}=\left(\mathbf{I}+\frac{\Delta t}{2}\mathbf{B}\right)\mathbf{u}^{n},\quad \left(\mathbf{I}-\frac{\Delta t}{2}\mathbf{B}\right)\mathbf{u}^{n+1}=\left(\mathbf{I}+\frac{\Delta t}{2}\mathbf{A}\right)\mathbf{u}^{n+1/2} \tag{1}$$

where $\mathbf{A}$, $\mathbf{B}$ are derivative matrices, $\mathbf{I}$ is the identity matrix, and u is the vector of all field components. Our goal is to modify only the derivative matrices, yet derive an algorithm with lowered space-time errors. As in most FDTD methods, pursuing the correction of accuracy on a single-frequency basis is usually simpler than performing wideband amendments. In our case, we first introduce three-cell spatial operators,

$$D_u f|_i=\frac{1}{\Delta u}\left[C_1\left(f|_{i+\frac{1}{2}}-f|_{i-\frac{1}{2}}\right)+C_2\left(f|_{i+\frac{3}{2}}-f|_{i-\frac{3}{2}}\right)\right] \tag{2}$$

which are designed to minimize the corresponding spatial flaws at a selected frequency point. This is accomplished by treating plane-wave expressions as trial functions, and defining suitable error estimators, whose minimization leads to optimized values of the C_1, C_2 coefficients. Then, the algorithm's overall performance is further controlled by proceeding with an artificial modification of the speed of light, which is equivalent to altering the properties of the background medium. This approach rectifies the error pertinent to the numerical phase velocity (which is calculated from the corresponding dispersion relation), by ensuring a vanishing mean value.

Apart from the aforementioned methodology, we also discuss the possibility of exploiting the scheme's dispersion relation for the construction of optimized ADI-FDTD techniques, when different orders of space and time discretizations are considered. A power-series based approximation of the dispersion relation and the matching of terms with equal order can produce new spatial operators with attractive error-balancing properties. Therefore, this paper accomplishes the construction of more reliable unconditionally-stable computational models, by exploiting alternative ways for the definition of improved spatial approximations.

Polarimetric and Phased Array Weather Radar Observations Using Optimized Pulse Compression Waveforms

James M. Kurdzo, **Robert D. Palmer**, **and Boon Leng Cheong**
Advanced Radar Research Center, University of Oklahoma, Norman, OK, USA

Abstract— The meteorological community has traditionally utilized single-frequency pulsed Doppler radar observations for the detection, surveillance, and forecasting of severe convective thunderstorms, flash floods, winter storms, and other potentially life-threatening weather events. Despite the widespread use of pulse compression waveforms in other radar disciplines, meteorological radars have yet to embrace this technology. With numerous studies exploring the potential for both phased array and low-power/low-cost dish platforms for weather observations, the necessity for extremely high-sensitivity waveforms has become a major issue for the weather radar community. Recently, the Advanced Radar Research Center (ARRC) at the University of Oklahoma has been developing pulse compression waveform optimization, design, and real-world system implementation techniques, and has been using these waveforms on a series of weather radar platforms. The use of pulse compression has provided good sensitivity while significantly lowering the cost of complex systems, and provides the potential for spatial resolutions nearly an order of magnitude higher than typically seen in operational weather radar. This paper presents a series of comparative weather observations using pulse compression waveforms on the ARRC's PX-1000 100 W, X-band, transportable solid-state radar, as well as the ARRC's Atmospheric Imaging Radar (AIR), a 3.5 kW, X-band, mobile digital beamforming tornado radar. PX-1000 case examples including the 20 May 2013 Moore, Oklahoma EF5 tornado will be shown, with a focus on multi-lag processing for high quality polarimetric estimates that captured unique debris ejection signatures. AIR case examples including the 19 May 2013 Shawnee, Oklahoma EF4 tornado, the 31 May 2013 El Reno, Oklahoma EF3 tornado, and the 21 May 2014 Denver, Colorado tornadoes will be presented. The AIR cases focus on a combination of extremely high spatial and temporal resolution, with native range resolutions as high as $1^\circ \times 1^\circ \times 37.5$ meters, and $90^\circ \times 20^\circ$ volumetric updates as fast as 5 seconds. Examples of unique meteorological phenomena only observable with the combination of extremely high temporal resolution and pulse compression waveforms are presented, including simultaneous volumetric vortex tilt structures, horizontal hook echo convective lines, and 3-dimensional debris trajectories.

Transparent Cathode Virtual Cathode Oscillator

Seyed Morad Ali Hashemi[1], **Erfan Zabeh**[2], **and Ali Pirmoradi**[2]

[1]Electromagnetics Research Laboratory, Sharif University of Technology, Tehran, Iran
[2]Department of Electrical Engineering, Sharif University of Technology, Tehran, Iran

Abstract— This paper reports structural considerations on virtual cathode oscillator (VCO) resulting in a new cathode structure that increase final efficiency while decreasing system chaotic behavior. Nonlinear phenomena are the most important sources of the complexity of the electron beam dynamics and microwave generation process in VCO. Chaos, maybe the most important nonlinear phenomenon appearing in VCO considered as a dynamical system is studied. Small changes in the oscillator parameters, such as input voltage or structural parameters values, could make undesirable variations in output parameters, meaning potential instability, causing difficulties getting enough close to the forbidden limits of those parameters. At these conditions final efficiency will be reduced considerably.

A novel structural optimization is introduced by the authors that controlling chaotic behavior of the system, allows the input voltage to increase without any notable distractive effects on the microwave beam. We found that if we divide-cathode to several separate concentric annular parts located apart from each other on a plane surface with designed distances, chaotic behavior of the system will decrease considerably in large anode-cathode distances. The novel cathode, called transparent cathode, was simulated with PIC-code method to study the chaotic behavior of the new structure. It was shown that increasing input voltages pushes the system towards the chaos, as is usual in the VCOs but with some considerable differences regarding those with conventional cathodes: in the novel design, the chaotic behavior appears at much higher input voltages letting higher microwave powers and higher efficiencies to be achieved.

Optimization of General Microwave Passive Circuits Based on Zero-pole Technique

N. Leszczynska, **A. Lamecki**, **and M. Mrozowski**
Gdansk University of Technology, Poland

Abstract— Passive circuits such as directional couplers and power dividers are key building blocks in various microwave and millimeter-wave systems, since they are used in almost every high frequency component including power amplifiers, mixers, multipliers and antenna feeding networks. General techniques for designing of those circuits are well known in the literature, but at a final design stage, electromagnetic solvers are commonly used to perform the final verification and numerical optimization. Usually large computational resources are involved at this stage. As a result, the full-wave design-by optimization is usually very time consuming.

In this submission a novel approach for numerical tuning of the design is shown. In this approach, the circuits are optimized using cost function involving zeros and poles of the rational function approximating scattering parameters. Such a formulation of a cost function has been utilized to design microwave filters, and it was found that this function yields very rapid convergence. The extension of the zero-pole technique to other types of passive circuit is non-obvious since reference (target) zeros and poles have to be known. In the case of filters the reference zeros and poles are known form the circuit synthesis. For other types of circuits, the synthesis procedure does not directly lead to a rational function so the reference zeros and poles are not known. To overcome this limitation, in this submission the reference zeros and poles for arbitrary structures are extracted from simulated response of a low-fidelity model. Since the low-fidelity model should be easy to compute, a good choice for this purpose is a device's equivalent circuit or a simplified low resolution numerical model.

Such a model can be easily tuned and optimized to meet the design requirements. Then the zeros and poles extracted from optimized response are used as a reference to perform a numerical tuning of original, complex design. The effectiveness and robustness of the proposed technique is presented in illustrative examples.

Large Scale Characteristic Mode Analysis with Multilevel Fast Multipole Algorithm

Q. I. Dai, H. Gan, and W. C. Chew
University of Illinois at Urbana-Champaign, USA

Abstract— After a humble beginning in the early 1970s, theory of characteristic mode (TCM) has gained a recent resurgence of interest in the field of antenna design and optimization. Although use of characteristic mode (CM) analysis shows success in systematic antenna designs, relatively little effort has been devoted to the numerical computation of such modes. Conventional TCM based on the electric field integral equation (EFIE) can only deal with small scale problems where the matrix pair in a dense generalized eigenvalue problem (GEP) is explicitly generated. However, such a scheme fails in applications where in multimode excitation, a large platform such as the entire vehicle chassis works as an antenna, or in multi-scale modeling, the object contains fine structures which lead to a dense mesh and a large number of unknowns.

Large scale characteristic mode computation poses challenges in computational electromagnetics (CEM) as it calls for efficient solutions of large dense GEPs. Multilevel fast multipole algorithm (MLFMA) can greatly reduce the computational complexity and memory cost for matrix-vector multiplications (MVMs), which is powerful in iteratively solving large scattering problems. In this work, we demonstrate that MLFMA can be easily incorporated into the implicit restarted Arnoldi method for CM computation after simple modifications. For the large platform application, we propose a combined integral equation (CFIE) based TCM, where the mid-frequency MLFMA is employed to speed up the required MVMs. A radiating characteristic mode of a NASA almond which has a length of 15 wavelengths is obtained with the proposed scheme and demonstrated in Fig. 1, where around 54,000 unknowns are involved. For the multi-scale modeling, we propose an augmented electric field integral equation (AEFIE) based TCM, where the mixed-form MLFMA is adopted to accelerate the required MVMs.

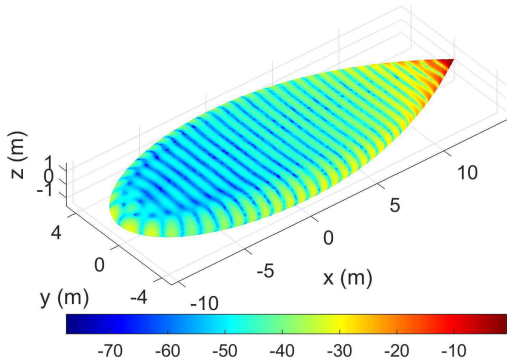

Figure 1: A radiating characteristic mode of a NASA almond computed with CFIE based TCM and MLFMA.

Efficient Calculating the High Frequency Scattered Fields from the Fock Currents of 3-D Convex Scatterers with the Incremental Length Diffraction Coefficients Technique

Abstract— In this work, the efficient algorithms for the high frequency scattered fields from 3-D convex scatterers are studied in detail. We propose the Fock current and the incremental length diffraction coefficient (ILDC) technique to efficiently calculate the high frequency scattered fields.

As is known, the physical optics (PO) current makes use of the local tangential plane approximation technique and usually loses accuracy, especially when the observation point lies around the transition regions and in the deep shadow regions. In order to remedy this limitation, we comprehensively study and adopt the Fock currents from the convex scatterers. Next, to capture the high frequency wave physics phenomenon from convex scatters, the Fock current is separated into the classical physical optics (PO) current and the non-uniform (NU)-Fock current along the shadow boundary and in the deep shadow region. Due to the highly oscillatory nature of the Fock currents, we propose the numerical contour deformation technique to efficiently evaluate the Fock currents. On invoking the ILDC technique, the high frequency scattered fields are clearly formulated in the lit, shadow and transition regions of the 3-D convex scatterers. Compared to the PO scattered fields from the 3-D convex sphere, numerical results demonstrate the significant accuracy enhancement of the scattered field in terms of the Fock current, especially for the large bistatic angle case. Finally, the work offers the high frequency wave physics picture from the 3-D convex scatterers, including the Fock current behaviors around the transition regions and the creeping wave fields.

A Variational Method to Solve Maxwell's Equations in Singular Axisymmetric Domains with Arbitrary Data

F. Assous[1] **and I. Raichik**[2]

[1]Ariel University, Israel
[2]Bar-Ilan University, Israel

Abstract— We propose a new variational method to compute 3D Maxwell's equations in an axisymmetric singular 3D domain, generated by the rotation of a singular polygon around one of its sides, namely containing reentrant corner or edges. We consider the equations written in $(r,\ \theta,\ z)$ and use a Fourier transform in θ to reduce 3D Maxwell's equations to a series of 2D Maxwell's equations, depending on the Fourier variable k. The principle is to compute the 3D solution by solving several 2D problems, each one depending on k.

Let us denote by $(\mathbf{E}_k,\ \mathbf{B}_k)$ the electromagnetic field for each mode k. Following [1, 2], it can be proved that this solution can be decomposed into a regular and a singular part. The regular part can be computed with a classical finite element method. The singular part is more difficult to compute: it belongs to a finite-dimensional subspace. Its dimension is equal to the number of reentrant corners and edges of the 2D polygon that generates the 3D domain. We will propose a new variational approach, based on a decomposition of the computational domain into subdomains, and we will derive an ad hoc variational formulation, in which the interface conditions are imposed with a method deduced from a Nitsche approach.

We will first consider the case $k = 0$, corresponding to the full axisymmetric case. We will show how to compute $\mathbf{w}_0^s$, the singular part of the electric field solution $\mathbf{B}_0$. We will then derive the non stationary variational formulation to compute the total part of the solution. After, we will consider the computation of the case $k \neq 0$. Following [2], this will require first to derive the system of equations solved by the singular parts for each k. Then to derive and solve the time-dependent variational formulation depending on k, for each mode. Finally to reconstruct the approximate 3D electromagnetic fields from each mode k.

Abstract— The electromagnetic characterization of dielectric media is a major issue in many industrial fields such as civil engineering, oil, food or agriculture industries as well as medicine. The radiofrequency (RF) inductive techniques are non-contact and therefore well suited for the non-invasive evaluation and monitoring of dielectric media [1], so they appear to be quite promising compared with the capacitive techniques. In order to foresee the sensitivity of such inductive RF sensors as well as to carry out quantitative evaluation of dielectric media, a versatile and computationally efficient modeling tool is required. To do so, analytical models have been developed [2] but they are limited to simple configurations. Numerical modeling techniques such as finite element computations are more versatile but they require heavy computational resources when three dimensional computations of complex configurations are required. In this paper, we investigated the relevance of a mesh-free semi-analytical modeling technique, so-called distributed point source method (DPSM) [3] to model the interactions of a RF sensor with a dielectric media. The basic principle of DPSM is based on the use of i) active equivalent source densities (ESD) used to model the actives sources in the workspace (here the current flowing in the RF antenna) and ii) virtual ESD used to take account of the boundaries between the different material included within the workspace. The distributed ESD radiate as Green's functions in the considered media so the variables of interest at any point of the workspace (e.g., magnetic field...) can then be determined as the sum of the contribution of all radiating ESD. The main advantage of the DPSM is that it is a "mesh-free" method. It just discretizes the active sources and the boundary, so the objects of any geometry may be modeled with no theoretical limitations on the shape and on the number of objects. As a result, the DPSM can be considered as a computationally efficient and versatile 3D modeling tool. In this paper, the configuration of a single RF loop interacting with a dielectric media including a buried object (e.g., a tumor in a biological tissue) is considered. The DPSM modeling is implemented and a parametric study of the sensitivity of the RF antenna to the changes of material conductivity is studied according to sensor position and used frequency. The computation results are validated by experiments involving a 2 cm diameter single loop RF sensor operated in the 1–100 MHz bandwidth. In addition, a simple system of two RF single loop antennas is also considered to locate the position of the inclusion. The first computation results show that it is possible to locate a buried dielectric inclusion thanks to the variations of the ratio of current intensities feeding the two antennas. The obtained results enable the DPSM to be considered in further works for the modeling of complex inductive sensors, such as transmission-line resonators [5], or for antennas arrays dedicated to dielectric imaging.

Quasi-modes in Segmented Waveguides

G. Demésy, A. Nicolet, and F. Zolla
Institut Fresnel, Aix-Marseille Université, CNRS, ECM, France

Abstract— In the present paper, we show that it is possible to use a periodic structure of disconnected elements to guide electromagnetic waves. To study such structures, we use the concept of quasi-modes associated to complex frequencies (also named quasi-normal modes or leaky modes).

In the present paper, we show that it is possible to use a periodic structure of disconnected elements (segmented waveguides [1]) to guide electromagnetic waves, **in the direction of the periodicity**, on significant distances with very limited losses. To study such structures, we use the concept of quasi-modes associated to complex frequencies [2]. The numerical determination of quasi-modes is based on a finite element formulation completed with Perfectly Matched Layers (PMLs) [3]. These PMLs lead to non Hermitian matrices whose complex eigenvalues correspond to quasi-mode frequencies. Using Floquet-Bloch theory [4], a numerical model is set up that allows the spectral study of structures that are both open and periodic. With this model, we explain how light can be guided on significant distances and with very limited losses through disconnected elements.

Figure 1 shows the real part of the electric field in the xy plane for a finite chain of finite length cylinders with a dipole source at 750 nm.

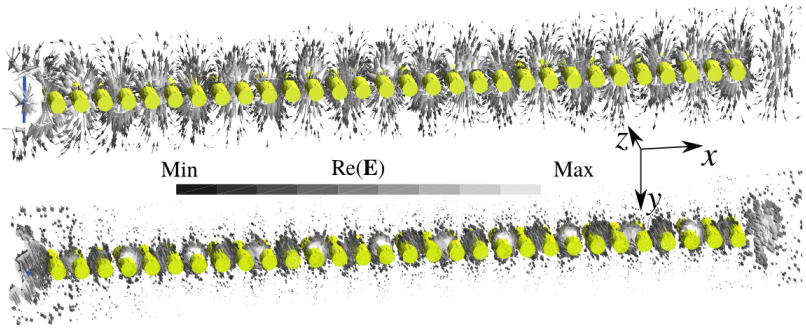

Figure 1: Finite chain of 30 cylinders of finite length $l = 6r$, with $d = 300\,\text{nm}$, $r = 125\,\text{nm}$ and $\epsilon_c = 2.25$ enlighten by a dipole antenna at 750 nm. Real part of the electric field in the xz plane. Two possible orientations — along (a) y or (b) z — of the dipole antenna leads to the excitation of one of the two quasi-modes with $\text{Re}\{w\} = 2.5 \times 10^{15}\,\text{rad/s}$.

Chaos Control in Virtual Cathode Oscillator by Cathode Structural Optimization

Seyed Morad Ali Hashemi[1], **Ali Pirmoradi**[2], **and Erfan Zabeh**[2]

[1]Electromagnetics Research Laboratory, Sharif University of Technology, Tehran, Iran
[2]Department of Electrical Engineering, Sharif University of Technology, Tehran, Iran

Abstract— Virtual cathode oscillator (VCO), as one of the simplest vacuum tube microwave generators considering its geometrical and constructional simplicity, has one of the most complex dynamical behaviors.

Nonlinear phenomena, present in the microwave-plasma interaction in the active region of the VCO, are the most important sources of the complexity of the electron beam dynamics and microwave generation process in the device.

Chaos, as one of the most important phenomena appearing in the nonlinear dynamical systems, has been studied in the VCO performance. The microwave generation process, considered as the overall dynamical operation of a complicated system of nonlinear partial differential equations (PDE) with boundary values as given by the geometry, materials and other structural properties of the tube and initial conditions defined by the input driving pulses, is an appropriate start point for the chaos to appear.

It has been shown that input anode-cathode voltage is one of the most important parameters in the formation of the chaotic solutions of the considered system of nonlinear boundary value PDEs. PIC-code simulation of the system has been widely used to study the various aspects of the chaotic behavior of the designed VCO. It has been shown that increasing input voltage pushes the system towards the appearance of more and more periodic oscillations with different periods leading finally to a completely chaotic performance. Bifurcation diagram showing this procedure has been derived via numerical processing of the PIC-code results and has confirmed the results of the time and frequency domain diagrams showing the deeply chaotic behavior of the system.

The same has been done applying the PIC-code simulation of VCO for studying the effects of the cathode radius on the chaotic behavior of the system and it has been shown that this parameter deeply affects the chaotic performance of the designed system. Increasing cathode radius results in increased disorder in the output microwave parameters. Bifurcation diagram has been extracted considering the variations of the system output via changing cathode radius. This diagram elegantly shows the chaos formation process through the cathode radius variations.

Analyzing the simulation results, authors suggest design optimization of the cathode structure to improve the system performance and control the undesirable chaotic behavior of the system. It has been shown that the new cathode structure is capable of delivering higher current flows and beam powers to the interaction region of the vacuum tube avoiding the chaos occurrence compared to the conventional cathodes used in the similar systems.

Rigorous Optimizations of Three-dimensional Antenna Arrays Using Full-wave Simulations

C. Önol[1, 2], Ö. Gökçe[1], H. Boyacı[1], and Ö. Ergül[1]

[1]Department of Electrical and Electronics Engineering, Middle East Technical University, Ankara, Turkey
[2]ASELSAN Inc., Ankara, Turkey

Abstract— Optimizations of antenna arrays for required values of the directive gain, side-lobe level, beamwidth, and in general, for the characterization of the overall radiation pattern, are popular problems in antenna design and engineering [1–3]. Given an array of antennas, the aim is to find the optimal set of excitations of its elements for desired radiation characteristics. For rapid optimizations, simple approaches based on the array factor are very suitable, leading to very efficient designs of excitations. Unfortunately, using these approaches, mutual couplings between antennas are neglected or simplified, leading to significant deviations of the optimization results from real-life measurements when the antennas are strongly coupled [4, 5]. For realistic optimizations, antennas need to be modeled accurately, and if possible, via full-wave solvers; but, using highly accurate solutions for the purpose of optimizations may not be trivial [6].

In this work, we consider rigorous optimizations of antenna arrays using heuristic algorithms, such as the genetic algorithms and particle swarm optimization methods, which are employed on simulation results obtained with the multilevel fast multipole algorithm (MLFMA). MLFMA allows for accurate simulations of antenna arrays, without any periodicity, infinity, and similarity assumptions, and by taking into account all mutual couplings between the antennas. For the optimizations of an M-element array at a single frequency, the number of full-wave simulations is only M, since complex current densities and radiation patterns can be combined via superposition without omitting mutual couplings. For a given array of static elements, these simulations also have common computations, which can be used to accelerate the overall solution phase. The results of M full-wave simulations are used by the heuristic algorithms in order to perform the optimizations, e.g., for increasing the directive gain at desired directions, minimizing radiations at given locations, and shaping the main beam by controlling the excitations.

The proposed mechanism that is based on MLFMA and heuristic algorithms is very flexible and applicable to arrays of nonidentical elements with arbitrary positions and orientations. In addition to arrays with fully excited elements, for which phase optimizations is more critical, we consider arrays with parasitic elements, especially when large antennas are used as reflectors. As an important advantage, the developed optimization environment allows for multi-band optimizations, where radiation characteristics at multiple frequencies are considered and optimized simultaneously for multi-band applications.

On the Electric-current-driven Microstructural Evolution

R. S. Qin
Department of Engineering and Innovation, The Open University, UK

Abstract— Application of an electric field to the conductive heterogeneous media causes the non-uniform current distribution. The magnetic energy associated to the current distribution can be calculated using a numerical method [1]. Different microstructural configurations of the heterogeneous media cause different current distributions, and hence associate to the different magnetic energies of the electrically discontinuous media. The magnetic energy is a type of free energy.

The irreversible thermodynamic law predicts the system evolution trajectory. This indicates the heterogeneous media to evolve toward an optimum configuration with least magnetic free energy. The evolution is driven by the irreversible thermodynamics. An equivalent electromagnetic force can be constructed to drive the electrical neutral suspension particles to propagate [2]. This provides kinetic understanding of electromagnetic-driven microstructure evolution.

We present in this report our systematic calculation of the microstructure evolution driven by the applied electric potential and the associate magnetic field. Some new results on the have been revealed for the conductive media containing multiple, deformable and splitable inclusions. This provides some theoretical understandings to the experimental observation on the electropulse-induced nanostructured materials synthesis [3]. The phase with low electric conductivity can change from a laminar plate to many small particles by the applied electric current. The electrical neutral particles in a conductive media can be manipulated to move toward desirable directions by the electric field.

Abstract— Several procedures for the accurate polarimetric characterization of the speckle pattern of light scattered from disordered media were recently proposed [1, 2]. Those characterizations were driven at an angular scale much smaller than the speckle grain size in order to avoid spurious spatial coherence effects. Inhomogeneous bulks and rough surfaces were analysed, with both polarized and unpolarized laser sources [3]. With the degree of polarization (DoP) histogram accurately estimated from data, enpolarization and depolarization phenomena were evidenced. For unpolarized illumination, the speckle pattern shows partial polarization, with a DoP rising up to an average of 0.75 for the most strongly scattering media. The opposite behaviour appears for polarized illumination, where the speckle pattern can present a DoP distributed around values significantly smaller than unity.

The enpolarization effect was first successfully and quantitatively predicted for bulk scattering of unpolarized light using the sum of random phasors model for fully developed speckle. Note that the scattering medium is here considered as disordered but deterministic rather than random: for simulation purpose, the medium is described by a single realization of a random process. This simple theory however fails to modelize depolarization in the case of polarized illumination. The model was thus extended in [4] to take into account the scattering coefficients dependency to frequency. This dependency is generally neglected according to the quasi-monochromatic assumption. This spectrally extended model now outputs the complete speckle DoP histogram for two inputs: the incident light DoP and the ratio of the incident light bandwidth to the characteristic scale of scattering coefficients frequency variation.

In this talk, we present comparisons between measured [1–3] and simulated speckle DoP histograms for non-absorbing bulks. Rough surfaces and absorbing bulks speckle patterns experimentally present lower levels of enpolarization/depolarization. We discuss how the spectral model can be extended anew to modelize this class of intermediate scatterers.

Abstract— Advances in plasmonics research and its ever-increasing practical applications have necessitated the development of accurate and efficient computational tools for simulating the electromagnetic response of plasmonic nanostructures. To this end, various numerical methods have been developed which are suitable for simulating different structures, and have their own advantages and limitations.

Surface integral equation (SIE) formulation is an integral method to simulate the optical response of nanostructures in the frequency domain. This method is based on the Green's tensor formalism, and can be used to simulate nanostructures in homogeneous as well as periodic backgrounds. The SIE requirement of having to discretise only the surfaces of the scatterers reduces the computational costs and avoids complications such as the requirement of truncating the background medium artificially. Also, the triangular meshing used in this scheme can approximate irregular particle surfaces very well, allowing the simulation of realistic plasmonic structures. Surface electric and magnetic currents which are the natural output of SIE simulations also enable direct and efficient computation of physically relevant quantities.

Here, we utilise SIE to compute the optical response of complex and realistic systems encountered in plasmonics. Various near-field properties such as intensity enhancement, lifetime modification and surface charges, as well as far-field quantities such as optical cross sections and second harmonic scattering are analysed. In addition, we also demonstrate the extension of SIE to compute the resultant optical forces and torques.

Furthermore, we discuss how the implementation and use of SIE can be optimised. We present a tailored recipe for the computation of SIE matrix integrals which improves the calculation accuracy without a significant overhead in computational costs. The use of this recipe permits the SIE simulation of more complicated geometries requiring less surface discretisation in the process. We also talk about the constraints to adhere to while building meshes to describe the simulation geometry. Besides choosing the correct size for the mesh elements, we show how it is necessary to enforce the correct symmetry on the meshes for accurate computation of quantities such as second harmonic scattering.

Numerical Modeling of Light/Matter Interaction at the Nanoscale with a High Order Finite Element Type Time-domain Solver

S. Lanteri[1], **C. Scheid**[1,2], **and J. Viquerat**[1]

[1]Inria Sophia Antipolis-Méditerranée Research Center, France
[2]University of Nice-Sophia Antipolis, France

Abstract— The numerical modeling of light interaction with metallic nanostructures requires to solve the system of time-domain Maxwell equations coupled to appropriate models of physical dispersion in the metal such as the Drude and Drude-Lorentz models. In the computational nanophotonics literature, a large number of studies are devoted to Finite Difference Time-Domain (FDTD) type discretization methods based on Yee's scheme [1]. As a matter of fact, the FDTD [2] method is a widely used approach for solving the systems of partial differential equations modeling nanophotonic applications. In this method, the whole computational domain is discretized using a structured (cartesian) grid. However, in spite of its exibility and second-order accuracy in a homogeneous medium, the Yee scheme suffers from serious accuracy degradation when used to model curved objects or when treating material interfaces.

During the last twenty years, numerical methods formulated on unstructured meshes have drawn a lot of attention in computational electromagnetics with the aim of dealing with irregularly shaped structures and heterogeneous media. In this talk, we will report on our recent efforts aiming at the development of a family of high order finite element type time-domain solvers for the numerical treatment of nanophotonics/plasmonics applications in the linear regime. The basic ingredient is a discretization method which relies on a compact stencil high order interpolation of the electromagnetic field components within each cell of an unstructured tetrahedral mesh. This piecewise polynomial numerical approximation is allowed to be discontinuous from one mesh cell to another, and the consistency of the global approximation is obtained thanks to the definition of appropriate numerical traces of the fields on a face shared by two neighboring cells. Time integration is achieved using an explicit scheme and no global mass matrix inversion is required to advance the solution at each time step. Moreover, the resulting time-domain solver is particularly well adapted to parallel computing. The proposed method is an extension of the so-called DGTD (Discontinuous Galerkin Time-Domain) method that we initially proposed in [3] for the simulation of electromagnetic wave propagation in non-dispersive heterogeneous media at microwave frequencies. For the numerical treatment of dispersion models in metals, we have adopted an Auxiliary Differential Equation (ADE) technique that has already proven its effectiveness in the FDTD framework. From the mathematical point of view, this amounts to solve the time-domain Maxwell equations coupled to a system of *ordinary differential equations*. The resulting ADE-based DGTD method is detailed in [4] and is part of a larger initiative aiming at the development of a software suite dedicated to nanophotonics/nanoplasmonics.

Homogenization of Periodic Electromagnetic Structures: An Uncertainty Principle

Igor Tsukerman[1] and Vadim A. Markel[2]

[1]Department of Electrical and Computer Engineering, The University of Akron, USA
[2]Departments of Radiology and Bioengineering and the Graduate Group in Applied Mathematics and Computational Science, University of Pennsylvania, USA

Abstract— The analytical and numerical results of the paper show that effective magnetic response of periodic intrinsically nonmagnetic structures has limitations: strong response is unavoidably accompanied by a commensurate loss of accuracy in the effective medium representation of the material. This can be viewed as an uncertainty principle for homogenization of electromagnetic metamaterials.

One of the most intriguing features of periodic structures composed of intrinsically nonmagnetic constituents is their nontrivial magnetic response, which can be particularly strong under electromagnetic resonance conditions. It is often tacitly assumed that this response is limited only by the characteristics of the constituent materials (most notably, their losses). However, we demonstrate that this artificial magnetism has a more fundamental limitation: the stronger the magnetic response, the less accurate ("certain") predictions of the effective medium theory are. We view this as an uncertainty principle for homogenization of electromagnetic metamaterials.

Our analysis is based on the recently developed non-asymptotic homogenization theory [1] and on the comparison of fields around a metamaterial slab and an (approximately) equivalent homogeneous slab. In addition to analytical derivation, we consider, as an instructive example, a triangular lattice of cylindrical air holes in a dielectric host [2]. Despite the high level of isotropy around the Γ-point in the second photonic band, the uncertainty principle holds. First, isotropy with respect to the Bloch wavenumber is not accompanied by isotropy of the Bloch impedance; second, surface waves [3, 4] play a significant role at shorter wavelengths.

High-order Trefftz Absorbing Conditions for Wave Problems

Igor Tsukerman[1] **and Ralf Hiptmair**[2]

[2]Seminar of Applied Mathematics
ETHZ, CH-8092, Zürich, Switzerland

Abstract— For scalar frequency-domain wave equations in 2D or 3D, we propose a "Trefftz generator" of local nonreflecting conditions — a critical part of finite difference (FD) and finite element solution of wave problems in unbounded domains. Trefftz approximations are, by definition, provided by functions that satisfy the wave equation exactly. At the exterior boundary, these are outgoing plane/cylindrical/spherical waves or some of their derivatives. The second component of the Trefftz generator is a set of degrees of freedom — linear functionals such as the value of the solution and some of its derivatives at boundary points. We show that the proposed generator reproduces classical nonreflecting conditions (Engquist-Majda and Bayliss-Turkel) and generates a variety of new high-order conditions.

This paper is a substantial further development of finite difference (FD)-Trefftz absorbing conditions [1–4]. For scalar frequency-domain wave equations in 2D or 3D, we propose a "Trefftz generator" of such conditions. Two key ingredients of this generator are (i) a set of local Trefftz functions [1–6] — outgoing waves satisfying the wave equation and approximating the solution near a given point on the exterior boundary, and (ii) a set of degrees of freedom — linear functionals such as the value of the solution and some of its derivatives at boundary points. The ultimate result is a sparse linear FD system.

Our Trefftz machine reproduces classical Engquist-Majda [7] and Bayliss-Turkel [8] conditions and generates a variety of new conditions. For canonical problems of scattering from dielectric or perfectly conducting cylinders, convergence of order six on 9-point stencils is demonstrated, with the relative solution error $\sim 10^{-5}$–10^{-8} with 10–20 grid points per wavelength. We are not aware of alternative methods yielding a similar level of accuracy on comparable grids. Extensions to 3D and vectorial problems are possible.

Modeling of a Slab Photonic Crystal with a One-dimensional Multilayer Mirror with Given Dispersive and Spectral Characteristics

Mikhail Libman[1, 2] **and Nikita Kondratiev**[2]

[1]Moscow State University, Moscow 119991, Russia
[2]Russian Quantum Center, Moscow 143025, Russia

Abstract— Many photonics applications need devices with special spectral and dispersive properties. Generating optical signals of a given form such as ultra-short laser pulses or supercontinuum are among those tasks. Photonic crystals which spectral and dispersive properties are set by their design can be employed for that purpose. A simple model of such one-dimensional photonic crystal is a Bragg mirror, consisting of alternating dielectric layers with high and low refractive indices. This simple model enables us to understand the way of engineering optical properties. It is possible to achieve required dispersion law and to extend the bandwidth of the mirror at the same time by chirping width of the layers. The same method should be applicable for the photonic crystal.

In our work we justify the applicability of a dielectric mirror model to the description of a real photonic crystal. A slab waveguide with periodically changing width is considered and it is shown that this width change can be recalculated to the effective refraction index modulation. The applicability of transfer-matrix method of transmission properties calculation was demonstrated. Two methods of deriving of the expressions for the photonic bandgap were considered and proved to be consistent, while emphasizing different aspects of the propagation process. The position and width of the bandgap as a function of waveguide's width was investigated. Finally, modeling of one-dimensional chirped Bragg mirror was performed with respect to the material and waveguide dispersion. Numerical optimization method and analytical method were realized to calculate the chirp law for the desired dispersive characteristics.

Nonlinear Standing Waves on a Periodic Array of Circular Cylinders

Lijun Yuan[1] and Ya Yan Lu[2]

[1]College of Mathematics and Statistics, Chongqing Technology and Business University, China
[2]Department of Mathematics, City University of Hong Kong, Hong Kong, China

Abstract— For periodic array of circular dielectric cylinders surrounded by air, where the cylinders are made of linear medium, it is well known that standing waves that are periodic along the array and decay exponentially away from the array could exist at discrete set of frequencies [1], corresponding to the non-uniqueness of related diffraction problem. In this paper, we consider periodic array of nonlinear cylinders with Kerr nonlinearity, and show numerically that standing waves exist continuously with the frequency. These standing waves are periodic along the array and decay exponentially away from the array. Their amplitudes depend on the frequency. As the frequency decreases, their amplitudes increases. It appears that there are infinite number of nonlinear standing waves at each frequency.

To compute the nonlinear standing waves, we solve the nonlinear Helmholtz equation as an eigenvalue problem with frequency as the eigenvalue. Assuming that the period of the array is L and the radius of the cylinders is $a < L/2$. In the Cartesian coordinate system (x, y, z), we assume the cylinders are parallel to the z axis and their centers (in the xy plane) are located on the y axis at $y = mL$ for integers m. Due to the periodicity of the array and the solution, the problem can be considered in unit cell $S = \{(x, y) : |x| < L/2, |y| < L/2\}$ containing one cylinder, with periodic boundary condition in the y direction and transparent boundary conditions at $x = \pm L/2$. In the domain Ω outside the cylinder and inside the unit cell, the Helmholtz equation is linear and its solution can be expanded in cylindrical waves. This allows us to find the Dirichlet-to-Neumann (DtN) map (which depends on frequency) for the Hemlholtz equation on Ω. Combining these conditions, we can find boundary condition on the boundary of disk D given for $r < a$. With this condition, it is only necessary to solve the nonlinear Helmholtz equation on D. In earlier works, similar techniques have been used to analyze optical bistability [2] and symmetry breaking [3] in structures with nonlinear circular cylinders. To solve this problem, we discretize the nonlinear Hemlholtz equation by mixed Fourier-Chebyshev pseudospectral method [4], with Fourier and Chebyshev methods for θ and r respectively, where is the polar angle, and use an iterative method.

A Space-time Discontinuous Galerkin Trefftz Method

F. Kretzschmar[1,2], **S. M. Schnepp**[3], **H. Egger**[1], **I. Tsukerman**[4], **and T. Weiland**[1,2]

[1]Graduate School of Computational Engineering, TU Darmstadt, Germany

[3]Institute of Geophysics, Department of Earth Sciences, ETH Zurich, Switzerland
[4]Department of Electrical & Computer Engineering, The University of Akron, USA

Abstract— We present a space-time discontinuous Galerkin method for time-domain Maxwell's equations that employs polynomial Trefftz basis functions [1], i.e., polynomials that solve Maxwell's equations exactly in an element-wise fashion. This reduces the number of degrees of freedom from $\mathcal{O}(p^4)$ in the method with all polynomials of order p to $\leq \mathcal{O}(p^3)$, while preserving the approximation accuracy. The new method retains the exibility of the discontinuous Galerkin framework [2] while improving the dispersion behavior. New features such as inhomogeneous media and optimized transparent boundary conditions can be applied.

Maxwell's Equations: We consider propagations of electromagnetic waves in the absence of sources; For problems of this kind time-dependent Maxwell's equations

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \quad \text{and} \quad \nabla \times \mathbf{H} = \mu \frac{\partial \mathbf{E}}{\partial t} \tag{1}$$

form the set of governing equations. Here, $\mathbf{E} = (E_x, E_y, E_z)^{\mathbf{T}}$ denotes the electric field, $\mathbf{H} = (H_x, H_y, H_z)^{\mathbf{T}}$ is the magnetic field whereas ϵ and μ are the permittivity and the permeability, respectively. We assume the fields to be divergence free $\nabla \cdot \mathbf{E}_0 = 0$ and $\nabla \cdot \mathbf{H}_0 = 0$.

Polynomial Trefftz Functions: The considered system of Maxwell's Equation (1) can be solved by 6-dimensional Trefftz functions of the form $\mathbf{F} = (\mathbf{E}, \mathbf{H})^{\mathbf{T}}$. One particular choice of Trefftz basis functions are polynomial Trefftz functions of order p which are a desired choice for numerical integrations. General properties such as dimension and stability as well as different construction procedures are described in [4]. Following [3, 4], a polynomial Trefftz basis can for instance be composed of Transport polynomials

$$\mathbf{F}_i^p = \begin{pmatrix} \mathbf{E}_i \\ Z^{-1}\mathbf{H}_i \end{pmatrix} \cdot (\mathbf{d}_i \cdot \mathbf{r} - \mathrm{v}t)^p, \tag{2}$$

with $\mathrm{v} = 1/\sqrt{\epsilon\mu}$ being the local speed of light and $Z^{-1} = \sqrt{\mu/\epsilon}$ the intrinsic impedance, that describe a plane wave traveling in direction $\mathbf{d}_i$.

Conclusion: We have outlined a discontinuous Galerkin Trefftz method for Maxwell's equations. Our numerical results demonstrate the spectral convergence of the method; Consequently, small sets of basis functions can result in a very high accuracy. Excellent dispersion behavior has been obtained. In addition a transparent boundary conditions of arbitrary order can be (easily) implemented.

The Sommerfeld Halfspace Problem Redux: Alternative Field Representations, Role of Zenneck and Surface Plasmon Waves

K. A. Michalski[1] and J. R. Mosig[2]

[1]Department of Electrical and Computer Engineering
Texas A&M University, College Station, Texas 77843-3128, USA
[2]Laboratory of Electromagnetics and Acoustics
École Polytechnique Fédérale de Lausanne, Lausanne CH-1015, Switzerland

Abstract— The problem of a vertical Hertzian dipole (time-harmonic current element of infinitesimal length) radiating in the presence of a lossy conducting halfspace was first rigorously solved by Sommerfeld in 1909 and other dipole configurations were treated in his later works. Sommerfeld's solution was expressed in terms of improper integrals with Bessel function kernels, which cannot be evaluated in closed form. A major finding of the original Sommerfeld paper was that the integrands exhibit a pole, whose residue he identified as a cylindrical form of the surface wave postulated earlier by Zenneck. Sommerfeld's work was motivated by the desire to explain the radio wave propagation along the surface of the earth, before it was realized that re ections from the ionosphere were in fact the decisive factor, making the still recurring discussions of the importance of the Zenneck wave rather immaterial. However, since the end of the last century, there has been a resurgence of interest in the Sommerfeld halfspace problem and the Sommerfeld surface wave in particular, in the context of THz applications, near-field optics, plasmonics and nanophotonics. The Zenneck wave becomes a surface plasmon polariton in the case of noble metals at optical wavelengths. In this paper, a complete *ab initio* solution is presented for the problem of an arbitrarily oriented Hertzian dipole radiating in the presence of a material halfspace. The solution method combines a vector potential approach with a transmission line analogue of the medium, which is a convenient means of scalarizing the Maxwell equations and it facilitates the inclusion of any number of layers in the analysis. Following Sommerfeld, the solution is first expressed in terms of Fourier-Bessel transforms, also known as Sommerfeld integrals. The analytical properties of the integrands in the complex plane are investigated. In particular, a proof of the existence of the Sommerfeld-Zenneck pole on the proper Riemann sheet is given and the relation of the Zenenck wave and the surface plasmon polariton is confirmed. Alternative integral representations of the vector potential Green functions are derived by contour deformation and analytic continuation of the integrands into the complex plane. Closed-form asymptotic expressions for the fields at the interface are also derived and the role of the Zenneck wave and the surface plasmon is discussed.

Propagation of Electromagnetic Wave Packet in a Dispersive Anisotropic Metamaterial

Jie-Luen Wu[1] and Pi-Gang Luan[2]

[1]System Development Center, National Chung-Shan Institute of Science and Technology
Longtan Township, Taoyuan County 325, Taiwan
[2]Department of Optics and Photonics, National Central University
Jhongli City, Taoyuan County 320, Taiwan

Abstract— A metamaterial consisting of subwavelength dielectric and metallic layers can be treated as a homogeneous anisotropic medium having indefinite permittivity tensor and hyperbolic dispersion relation in some frequency ranges. Recently, interests have been raised about the issues concerning the propagation of wave energy in dispersive media, and contradicted results about the possibility of superluminal propagation of electromagnetic wave packets in hyperbolic metamaterials were claimed by different authors [1, 2]. Since special relativity puts absolute speed limitation on any kind of signal or energy propagation, and this is related to the notion of causality, we thus believe to clarify this issue as clear as possible is very important.

In this work, we study the propagation behaviors of a wave packet in a dispersive anisotropic medium. The medium is assumed to be the effective medium corresponding to the structure consisting of dielectric and metallic layers. The two principal values of the permittivity tensor thus have the Drude and Lorentz type dispersions if the dielectric and metallic layers are assumed to be having constant and Drude type permittivity, respectively. We derive the energy density for this medium and show that for a propagating mode the energy velocity is equal to the group velocity, and examine the propagating behaviors of a wave packet, assuming all the plane waves composing this packet have frequencies far from the absorption band.

Many plane waves having proper frequencies and wave vectors satisfying the dispersion relation of the medium were chosen so as to compose the wave packet [3]. In order to trace the motion of the wave packet, the idea like 'center of mass distribution' is used. The center position of a Gaussian-wave packet is defined by evaluating the 'weighted sum' of the position vectors, using the energy density as the weight function. The packet velocity can be calculated numerically by tracing the packet center position at every time step. We compare the predicted group velocities of single-frequency propagating modes with the wave packet velocities for different frequency widths and angular widths for the k-vectors, and find they fit very well if the frequency and angular widths were chosen appropriately. Most importantly, according to our results we find that neither the energy velocity for a propagating mode nor the packet velocity for a wave packet can exceed the speed of light in vacuum if the dispersion of the medium were carefully taken into account. We also discuss the possible origins of the contradicted predictions made by previous researches.

Electromagnetic Field Distributions in Stratified Structures

Huai-Yu Wang[1] and Chao Li[2]

[1]Department of Physics, Tsinghua University, Beijing 100084, China
[2]School of Physics and Engineering, Sun Yat-sen University, Guangzhou 510275, China

Abstract— In studying dipole radiation, the near field and far field should be treated separately. In a vacuum background, it has been well known that the near field/far field (NFFF) boundary L is about the light wavelength λ_0, $L \sim \lambda_0$. Stratified structures are often encountered in practice. A typical situation is the air-sea-earth trilayer structure. The NFFF boundary in such backgrounds has not been well studied yet. In this work, we carefully study how to determine the NFFF boundaries in stratified structures.

The general model is depicted in Fig. 1. There can be Q layers and $Q-1$ interfaces between them. The region between the top and bottom layers are called intermediate region. A vertical electric dipole (VED) is located on the origin of the cylindrical coordinates (ρ, z, φ). The VED can be in either the top layer or the intermediate region. Each layer has its own refraction index (RI). In each RI configuration, the largest and smallest RI's are denoted as $n_{\max}$ and $n_{\min}$, respectively.

We carefully evaluated the field distribution in bilayer, trilayer and multilayer structures with various possible RI configurations. Two kinds of far-field expression of the electric field were derived. It was proved that the approximation methods obeyed reciprocal theorem. The results of far-field approximations were compared to those of precise numerical calculation to determine the NFFF boundaries.

In stratified structures, two factors severely influenced the field distribution. One was that if $Q \geq 3$ in Fig. 1, multi-reflection happened in the intermediate region wherever the VED is. The other was that the lateral waves moved along the interfaces which mainly existed in the layer with higher RI and exponential decayed in the lower RI layer. These two factors complicated the field distribution in space and made the NFFF boundary much farther than that in vacuum background.

Through the detailed investigation, the NFFF boundary was proposed to be

$$L \sim 1000 \max\{D, 0.1\lambda_0\} n_{\max}/n_{\min}.$$

This expression is valid for any stratified structure with any RI configuration. In a bilayer structure, $D \sim |d_1|$, while in a structure with more layers, D is the thickness of the intermediate region, $D \sim d_1 - d_{Q-1}$. The structural parameters reasonably entered the expression of the boundary.

Transmission of EM Waves through Very Dry Reinforced Concrete

Thierry Gilles and Ghilkrist Afomasse
Ecole Royale Militaire, Laboratoire d'Electromagnétisme Appliqué (LEMA)
Avenue de la Renaissance 30, Bruxelles 1000, Belgium

Abstract— Considering realistic frequency and moisture content dependant electromagnetic characteristics of concrete [1] simulations with FEKO in the frequency domain show that at some frequencies and at normal incidence, reinforced concrete exhibits a very high transmission loss at some frequencies. This phenomenon is very weak for lossy concrete but ranges 10 to 20 dB for very dry concrete, indicating that the transmission loss is not due to absorption in the concrete but results from destructive interactions.

To better understand the origin of this transmission loss, reflection and diffraction ray tracing theory could be called for, but there are numerous combinations of reflections and diffractions inside reinforced concrete. To figure out which of those are the main contributors to the high transmission loss, one can resort to time domain simulations with CST. The very short time duration of the pulses must be set to allow discrimination of the individual pulses following the various reflection and diffraction paths.

CST also allows to derive by FFT the transmission loss caused by the pulses received at a given location past the structure. Without time gating, retaining all pulses occurring after arrival of the first one, a transmission loss pattern similar to the one obtained with FEKO through an inifinite slab is obtained. Using timegating to retain less and less of those pulses, CST allows to identify how many among the first pulses are necessary to generate the resonant high transmission losses.

Very few reflection and/or transmission measurements through reinforced concrete have been published [2, 3], and none of them exhibits a resonant high transmission loss. To perform measurements reproducing the behavior of an infinite slab, special care must be taken to efficiently eliminate unwanted reflections and diffractions, either by using appropriate absorbing material everywhere needed or with a time gating technique. For time gating technique it is important to properly dimension the reinforced concrete slab sample in conjunction with the transmit and receive antenna positions to make sure that all pulses contributing significantly to the transmission loss will be retained before the appearance of the first unwanted pulse due to edge diffraction on the sample edges.

Combining various simulations and measurements, it has been possible to explain the high transmission losses observed at specific frequencies through dry reinforced concrete.

A Dynamic Transmission Line, Temporal Photonic Crystals, and Wave Vector Gaps

J. R. Reyes-Ayona and P. Halevi
Instituto Nacional de Astrofísica, Óptica y Electrónica, Tonantzintla, Puebla 72840, México

Abstract— Frequency or energy gaps are ubiquitous in physics and electronic engineering. On the other hand, wave vector- or k-gaps are hard to come by, if at all. Here we report what is likely the first measurement of a genuine k-gap. This has been achieved by propagating microwaves in a specially modulated transmission line (TL). The measurements have been confirmed by a calculation based on realistic modeling.

In our low-pass TL of eight cells the capacitors have been replaced by varactors that — unlike the situation in traveling wave amplifiers — are modulated externally at some frequency $\Omega/2\pi$ by the same time-periodic voltage. The dispersion relation $\omega = \omega(k)$ has been determined by a method similar to the differential phase-shift method of fiber optics engineering. This resulted in a photonic band structure of two k-bands separated by a k-gap, corresponding to forbidden values of the wave vector for any ω. This gap Δk is determined at the waist of the two k-bands, that occurs at the frequency $\Omega/2$. We get a very good fit between the experimental points and the realistic calculation, which shows that the gap Δk increases with the strength of modulation m of the voltage.

It is well known that a static low-pass TL can be represented by an effective medium in the long wavelength limit $ka \ll 1$, where a is the period or size of the unit L-C cell. We have generalized this equivalence to the dynamic case: at every instant of time the permittivity and permeability must satisfy the relations $\varepsilon(t) = C(t)/a$ and $\mu(t) = L(t)/a$. We find that, as long as $ka \ll 1$, the mean-field theory also fits well the experimental and theoretical results for the TL.

In general, the effective medium is characterized by time-periodic $\varepsilon(t)$ and $\mu(t)$, namely, it is a *temporal* photonic crystal [1]. We expect that the periodically modulated transmission line described above will exhibit all the features predicted by our group for the temporal photonic crystals: frequency comb in the reflectivity and transmittivity [1], parametric resonances that depend on a geometric condition [2], and faster-than-light transmission of the peaks of some harmonics of pulses that are traversing a slab [3]. Much higher frequencies should be feasible if the capacitances and inductances are replaced by split-ring resonators.

So, transmission lines and temporal photonic crystals — here's "Where Microwave and Lightwave Communities Meet", as the PIERS *motto* goes!

Abstract— Recent advances in light harvesting using micro- and nano-structured materials have demonstrated the possibility to achieve striking increase of the efficiency of photovoltaics systems [1, 2]. Several proposed strategies achieved really interesting results but their implementation in photovoltaic market is questionable due to the high technological fabrication steps required that sensibly increase the fabrication costs.

Light harvesting photovoltaics are often based on porous materials because they give the possibility to carefully tune optical properties by reducing the reflectivity, while maximizing the absorption of light across large portions of the visible spectra [3–5].

Despite the majority of the studies on light harvesting were focused on the visible part of the spectra, the near infrared region contains a substantial amount of the energy density (about 25% in the range 1 to 3 µm).

Here we proposed a strategy to exploit the long photon lifetime, achievable in random structure, to enhance optical absorption in the sub bandgap spectral region.

We model a 2D random system composed by anisotropic pores elongated along a preferential axis and we analyse the role played by the rough-surface in the enhancement of the absorption through multiple scattering processes. The roughness is modelled by decomposing the pore onto short section with different radii.

The results show that rough-pores induce a large enhancement in the near-IR absorption compared to flat-pores, yet the backscattering from the top interface increases considerably also the reflection.

We show that reflection can be kept at low value if a bilayer structure is employed: the first layer (the one that face the incoming radiation) is made of flat pores, while the underlying one has a large roughness. In this case, simulations show that the integrated absorption increases by 50% compared to bulk silicon and of about 20% compared to flat pores. Interestingly the enhancement shows a flat response over the entire near-IR regime.

Our study suggests a scheme to realize photovoltaics systems with optimized absorption response for the near-IR range. The proposed structure can be implemented as back reflector in 3rd generation PV to increase cell's performances exploiting the sub-bandgap incident radiation. Finally the structure is compatible with silicon technologies and does not necessitate of complex nanofabrication techniques.

Effect of Material Properties on Transmission through Metallic Hole Arrays at Terahertz Frequencies

Renu Bhadresha, **Nisha Sarwade**, **Arnab Pattanayak**, **and S. P. Duttagupta**
Veermata Jijabai Technological Institute, India

Abstract— Ebbesen demonstrated enhanced transmission through subwavelength hole arrays for a metal dielectric interface at optical frequencies in [1]. This was in contrast to the previous studies [2] that associated subwavelength arrays with weak transmission. While there is no consensus about the exact transmission mechanism, it is most widely accepted that this enhancement at optical frequencies is due to the generation of surface plasmon polaritons due to the complex dielectric constant exhibited by metals exhibited by metals with value $|\epsilon_r/\epsilon_i| > 1$ (where ϵ_r is the real part and ϵ_i is the imaginary part of the compex dielectric constant). At terahertz, the large conductivity of metals is usually considered a hindrance in the generation of SPPs. However it was shown that bulk plasma frequencies are can propagate along the interface for a range of frequencies from $\omega = 0$ to $\omega = \omega_p/2$, where ω_p [3] is the bulk plasmon frequency. In this paper, the material properties were modeled using these plasma frequencies for Au, Ag and Al.

As seen by Krishnan et al. [4], for maximum enhancement in transmission, the two materials on both sides of the metal should have the same dielectric constant. Keeping this in mind, a free-standing structure is designed where the material properties of the metal become the deciding factor in the transmission characteristics. The advantage of a free-standing design is that there is drastic reduction in fabrication steps because modern micro-fabrication techniques such as micro-machining can be used for design. Another advantage is that the dielectric is essentially taken as air and this simplifies the theoretical transmission calculations. In this paper, for the design, the plasma frequency for each metal is calculated from experimental values. These values were taken from [5] and the plasma and collision frequencies were calculated using the Drude Model equations. The design of the array is for operation in the 0.5 to 2.5 Thz range.

The geometric parameters were kept constant and the effect of variation of material for the same design was studied. The array was designed as a periodic array with a hole dimension d and a periodicity of a and a normal incidence. The design was analysed using CST Microwave Studio and each array was designed as a unit cell and simulated as a periodic array of these unit cells. The transmission characteristics show that there is a distinct peak related to the enhanced transmission due to generation of SPPs.

The results show that the enhanced transmission is due to the generation of surface plasmons. The thickness variation also affects each metal differently which is also analysed. This work gives a comparative study that can be used for efficient material and design parameter selection for different applications such as THz imaging, short distance indoor communication, etc..

Terahertz Generation from DAST Depending on Chirp of Pump Pulses Amplified by Double-clad Yb-doped Fiber Amplifier

Junichi Hamazaki, Norihiko Sekine, Akifumi Kasamatsu, and Iwao Hosako
National Institute of Information and Communications Technology, Japan

Abstract— High-power broadband terahertz (THz) generation has attracted much attention for various THz applications such as THz spectroscopy. To generate highpower broadband THz pulse, optical rectification effect is generally used, by using an ultra-short high-power pump pulse and a nonlinear crystal. Regarding pump pulse, pulse is characterized by wavelength, pulse energy, pulse width but also its chirp. It is known that dechirped pump pulse is the most suitable condition for THz generation. However, this is the case when a crystal is thin enough When a crystal is thick, it is non-trivial owing to material dispersion Effects of the pump pulse chirp in THz generation have not been well investigated.

To obtain chirp-controlled high-power femtosecond pump pulses, we used double-clad Yb-doped fiber (DC-YDF) amplifier. Since YDF has large gain and broad gain spectrum (1.0–1.1 μm). Furthermore, DC-YDF has extremely larger gain than usual YDF. Output power over 1 W is easily expected by using DC-YDF. Thus, DC-YDF amplifier is suitable for high-power ultra-short pulse generation. From the amplifier, average output power > 3.1 W with a pulse width of 110 fs at high repetition ration of 100 MHz is obtained. Chirp is controlled by varying distance of grating pair for pulse compression.

In this paper, we report the effects of the pump pulse chirp in THz generation. We generated THz pulse using DAST crystal and chirp-controlled femtosecond high-power pump pulses amplified by DC-YDF amplifier. By using THz time domain spectroscopy technique, we investigated THz spectra as a function of the chirp parameter. We found positive-chirp pump pulse can generate higher power and broader-band THz pulse, compared with dechirped pulse.

Photonic-based Millimeter Wave Wireless Link

Abstract— Nowadays, millimeter (mm)-wave frequency bands have become important as a candidate frequency band for wireless links of 5 G networks. This is because wide bandwidths to increase data rates up to several Gbps can be gotten in the mm-wave frequency bands with minimizing interference to allocation frequency bands. In order to check out a feasibility of a high-speed wireless link using the mm-waves, we have presented various photonic-based continuous wave (CW) generation schemes in mm-wave frequency bands. Using a generated mm-wave, a wireless link has demonstrated. Generally, photonic-based mm-wave generation schemes make a CW in the mm-wave frequency bands by beating two optical signals with wavelength differences. A conventional double sideband suppressed carrier (DSB-SC) scheme is very popular scheme to get two correlated optical signals with wavelength differences. We modified the DSB-SC scheme to increase frequency tunability, to overcome electronic dependency, and to reduce evaluation cost. Some achievements are listed in this paper. Especially, based on our results, we have accomplished a CW in the mm-wave frequency bands using a local oscillator with one-sixth frequency of a wanted mm-wave frequency. Using the DSB-SC scheme and some electronics, a high-speed wireless link operating up to 10 Gbps is successfully demonstrated and verified. Consequently, our results can be useful for developing mm-wave wireless link up to several tens Gbps.

50-Gbit/s Wireless Transmission over 20 Meters at 300 GHz

Abstract— There has been a growing interest in the application of terahertz (THz) waves, whose frequencies range from 100 GHz to 1 THz, to ultra-broadband wireless communications. Photonic techniques have been efficiently employed to generate and modulate THz carrier signals. Real-time and error-free transmission experiments have so far been demonstrated at bit rates of 40 Gbit/s using a photonics-based transmitter with an on-off keying (OOK) modulation and a direct detection receiver at 300 GHz [1]. Such a simple configuration offers low-cost, small-size and energy-efficient transceiver modules by future electronic and photonic integration technologies [2].

In this paper, we present our recent results on the increase of bandwidth of the 300-GHz band transmitter and receiver, enabling real-time 50-Gbit/s transmission over the link distance of 20 m.

Abstract— The bandwidth of wireless networks needs to grow exponentially over the next decade, due to an increasingly interconnected and smart environment. By 2020 there will be 50 billion devices connected to the internet. Low-cost, compact and broadband wireless transceivers will be required. The current WiFi frequency bands do not have enough capacity and wireless communication needs to move to the millimeter-wavelength or sub-terahertz range. The use of all-electronic solutions becomes increasingly prohibitive, though, at these higher frequencies. Microwave photonic technology offers the bandwidth and carrier frequencies required for high-capacity wireless networks and remote sensing applications. In this paper, we will introduce our efforts to leverage the advantages of microwave photonics and photonic integrated circuits to develop low-cost and ubiquitous wireless technology enabled by silicon photonics based transceivers.

Abstract— We present a novel Photonic Integrated Dual Wavelength Source with increased functionality and performance for Millimeter and Terahertz wave generation using an on-chip Colliding Pulse Mode Locked Laser Diode (OC-CPMLLD) and Arrayed Waveguide Grating (AWG) optical filter. The on-chip Colliding Pulse Mode Locked Laser Diode is a versatile pulsed source which includes multimode interference reflectors which are on-chip mirrors structures that allows defining the length of the cavity with lithographic precision so the repetition rate can be precise defined. Then the optical frequency comb generated by the pure colliding pulse mode locked condition is addressed to an Arrayed Waveguide Grating (AWG) optical filter which allows selecting two optical modes separated at the desired frequency within the Millimeter and terahertz frequency ranges. The key issue has been to design the pulse repetition rate at a sub-harmonic of the AWG channel spacing so in the dual wavelength source the colliding pulse mode locked repetition rate is 30 GHz and the Channel spacing of the AWG is 90 GHz. if we have the second harmonic repetition rate of 30 GHz provided by the on-chip Colliding Pulse Mode Locked Laser Diode, we can add an AWG filter with a channel spacing setting at a harmonic of the repetition rate within the millimeter and terahertz range like 60 GHz, 90 GHz, 120 GHz, 150 GHz, 180 GHz, etc.. As a result, we are able to design a dual wavelength source that allows choosing the frequency you want within the millimeter and terahertz frequency range based on lithographic precision.

Photonic Integration Solutions Enabling Coherent Millimeter Wave and THz Systems

Cyril C. Renaud
Department of Electronic and Electrical Engineering, University College London, London, UK

Abstract— Photonic technologies are seen as a potential key technology to the development of efficient sources in the millimetre-wave and THz range [1, 2]. This is mostly due to their relatively high power, coherence and tuneability. However, despite offering high-speed modulation and tuneabilty, it is clear that for many application and the development of THz technology a smaller footprint and lower power consumption will also be essential. While photonic solutions using discrete components have shown promising results [3], it remains essential to solve these remaining problems. To do so will require integrated photonic solutions as it will naturally offer smaller footprint while some of the losses within a discrete element system could be better managed thus enabling lower power consumption.

This contribution will concentrate on heterodyne photonic sources. Such sources have achieved emission across the THz range with linewidth lower than 10 Hz when used with locking systems [4]. Furthermore, being based on optical telecommunication technologies, these systems enable fast modulation.

The typical heterodyne coherent system we are envisaging may include an optical frequency comb generator (OFCG) used to lock the heterodyne source on a microwave reference. It is then composed of a dual tuneable laser source that provides the two optical oscillations spaced by the frequency of interest and a photomixer with antenna to generate the millimetre-wave or THz signal. The discussion will thus concentrate on the integration of these different components.

We will first present solutions for the OFCG and present results on three different configurations; mode-locked Fabry-Perot laser, FM-laser and amplified recirculating loop. We then will describe different set of dual laser heterodyne sources including potential locking techniques to enable highly coherent systems. A discussion on the different locking performances will show that linewidth of less than 10 Hz are achievable for frequencies in the THz range. Finally a fully integrated millimetre wave source including the photomixer will be presented including results on locking techniques.

Photonic Integrated Circuits for Generation and Detection of Coherent CW THz Radiation

Thorsten Göbel, Michael Theurer, Dennis Stanze, Francisco Soares, and Martin Schell
Fraunhofer Heinrich-Hertz-Institute, Germany

Abstract— Within the last years, THz technologies became mature and ready for everyday use. Many applications have been demonstrated, but the industrial breakthrough has yet to come, though. In order to make THz technologies available for large scale applications, compact and low cost solutions need to be developed. Photonic THz systems at the optical telecommunication wavelength of 1.5 µm are most suitable to fulfill industry's demand for reliable and reasonable priced systems. Here, cw THz systems profit most from telecom technologies, since all required optical components are available off-the-shelf in high quality and at low price. But even the latest generation of cw THz photomixing systems is based on discrete components and therefore limited in size, flexibility and cost.

In this paper, we present the next evolutionary step for cw THz photomixing systems: The transition from discrete components to Photonic Integrated Circuits (PICs). The Terahertz-PICs are fabricated with an InGaAsP/InP material system and operate in the optical wavelength range of 1550 nm. They comprise DFB-lasers, optical phase modulators and integrated optical waveguides for on-chip signal distribution. A unique bidirectional operation technique allows for driving the THz emitter and the THz detector at the same time and enables full control of the THz signal (amplitude, frequency and phase) via standard electronics, whereas the tuning of the laser wavelength is enabled by integrated heaters.

The performance of different THz-PIC implementations will be discussed on the basis of experimental results. Further, the paper will give an outlook for future PIC implementations and discuss how and where THz-PICs can enable the breakthrough for THz technology from lab applications to real life applications.

Plasmonic Terahertz Emitters and Detectors for Sensing and Wireless Communications

Abstract— This paper reviews recent advances in emission and detection of terahertz radiation using two dimensional (2D) plasmons in semiconductor heterostructure integrated devices and their applications to sensing and high-speed wireless communication systems. The nonlinear dynamics of the 2D plasmons including the plasmon instability and rectification effects is first presented as the operation principle to demonstrate its potentiality of broadband intense emission and sensitive detection of terahertz radiation. The Doppler-shift effect of the plasma wave velocity under an asymmetric plasmon cavity boundary and/or the spatial modulation of electron transit time in a sub-micrometer scaled 2D plasmon system with a non-uniform 2D electron density distribution can promote the plasmon instability, resulting in self-oscillation of plasmons in the terahertz regime. The hydrodynamic nonlinearity of 2D plasmons can rectify the incoming electromagnetic radiation, resulting in photovoltaic detection of terahertz radiation under an asymmetric 2D plasmon cavity boundary. Second, the device structure that can provide practical emission and detection performances are addressed, which is based on a high-electron mobility transistor and incorporates the authors' original asymmetrically interdigitated dual-grating gates (DGGs). Numerical analysis reveals that in comparison with conventional symmetric DGG structure the asymmetric DGG can substantially improve the detection sensitivity as well as the instability (emissivity) by three to four orders of magnitude. Third, excellent terahertz emission and detection performances including coherent, monochromatic emission beyond 1-THz range at relatively low temperatures and the record detection responsivity of 22.7 kV/W (2.2 kV/W) at 200 GHz (1 THz) at 300 K with low noise equivalent power of 0.48 pW/Hz$^{0.5}$ (15 pW/Hz$^{0.5}$) are experimentally demonstrated by using InAlAs/InGaAs/InP heterostructure material systems. The frequency dependence of the responsivity is in good agreement with the theory deduced from the plasmonic drag and ratchet effects. Their arrayed monolithic integration and module assembly/packaging issues are also discussed. Finally their applications to terahertz-imaging-based sensing as well as high-speed wireless communications are demonstrated.

Terahertz-wave Integrated Circuits Based on Photonic Crystals

Abstract— Recently, the frequency band of terahertz electromagnetic waves (from 0.1 to 10 THz) has attracted much attention owing to its unique application possibilities such as in spectroscopic sensing, non-destructive imaging, and ultra-broadband wireless communication [1]. However, building terahertz-wave application systems and devices requires the use of bulky and discrete components, including sources, detectors, waveguides, and lenses. Size reduction of the active devices and development of integration platform are required to build a terahertz-wave integrated circuit.

Resonant tunneling diodes (RTDs) are promising as compact terahertz-wave source [2] and detector [3] because they can operate at room temperature in the terahertz-wave bands. Error-free wireless transmissions have been successfully demonstrated in the 0.3-THz band at bit rates of 2.5 Gbit/s [4] and 10 Gbit/s [5] using an RTD transmitter and a receiver, respectively. As a terahertz integration platform, metal-based structures such as metallic transmission lines and electromagnetic metamaterials are being extensively studied. However, the intrinsic absorption loss of metals in the terahertz-wave frequency region is high and uncontrollable. We have proposed a photonic-crystal slab consisting of a two-dimensional lattice of air holes formed on silicon as an alternative platform (Fig. 1) for terahertz-wave manipulation [6]. In addition, ultralow propagation loss (< 0.2 dB/cm) using terahertz photonic-crystal waveguides have been successfully demonstrated in the 0.3-THz band [7]. We have also achieved 1.5-Gbit/s error-free THz-wave communications and high-definition video transmission in a photonic-crystal waveguide of as long as 47 cm with bends of 28 times [7], a waveguide with a grating coupler [8], and a diplexer [9].

The most critical issue currently is how terahertz waves confined in the dielectric photonic-crystal waveguide can be efficiently coupled to an RTD, which is a tiny electronic device with a small metallic electrode. We have proposed the integration of a photonic-crystal waveguide and RTD chips by hybrid bonding [10]. In this paper, we first theoretically discuss an efficient integration scheme for the photonic-crystal waveguide and RTDs. Then we describe the experiments on the frequency characteristics of an integrated receiver using an RTD detector. Finally, we demonstrate an error-free gigabit transmission using the integrated device at the 0.3-THz band.

Abstract— Terahertz (THz) waves have several interesting features, including strong THz fingerprints, the capability of penetrating those dielectric materials, and no radioactive contamination. Because of those features, THz waves are being investigated for various potential applications in, for instance, quality control, remote gas sensing, and security imaging [1]. In last a couple of decades, the time-domain spectroscopy (TDS) system with a femtosecond pulsed laser have been mainly used. The other approach is to use continuous waves (CW) THz signal, commonly based on commercially available fiber-optic components originally developed for telecommunications in the 1550-nm wavelength region. Recent CW THz spectroscopy systems have exhibited compact feature with fair performance in dynamic range and fast measurement [2, 3]. Moreover, a homodyne detection scheme dramatically improved the signal-to-noise ratio (SNR) of the system [4]. We have reported 100 and 75 dB-Hz maximum dynamic range of the intensity measurement at 300 GHz and 1 THz, respectively [5] with the fiber-optic components. In theory, the homodyne detection scheme enables us to measure phase information, such as relative dielectric constant, of a sample under the test. However, a few meter long pit-tailed fibers work as thermo-optic modulators and therefore we were unable to reconstruct a physically comprehensible dielectric constant or relative permittivity of samples under test from the measured phase information.

In this report, we describe the design of the silicon photonic integrated circuit for the THz homodyne spectroscopy system [6] and present spectroscopic measurements of several materials. To improve the reliability of the measurement, particularly in phase, silicon photonics technologies have been adapted in the homodyne CW THz spectroscopy system. Phase modulators, optical couplers and waveguides were fully integrated in a 2-mm^2 area on silicon-on-insulator substrate and the probe and reference signals was generated form the tiny single chip. With a high speed UTC-PD, PCA, and the silicon photonic circuit, we experimentally demonstrated the homodyne measurement of the complex dielectric property, absorption coefficient, and relative permittivity at a given sample thickness at up to 2 THz with excellent phase stability.

Abstract— In the past decade, integrated photonics on silicon on insulator (SOI) platform has been shown to be promising for many applications of photonics from interconnects to sensing. While the knowledge of mature fabrication processes in CMOS has helped to achieve high optical quality passive and high bandwidth active optoelectronic devices in silicon, the current state of silicon photonics does not exploit the state of the art CMOS infrastructure for low-cost, high-yield manufacturing and fast prototyping in the same fashion that analog and digital electronics do. As a result, the fabrication of silicon photonic devices and systems for research and development or even in some cases for low to medium volume manufacturing is done either in-house or in small-scale foundries customized for specific applications. In this work, we have shown that it is possible to integrate photonic components in IBM's 45 nm SOI CMOS process, which is an open-foundry native electronics CMOS process [1]. There are three components to this effort: 1) understanding the materials and processes in the CMOS process, 2) understanding the design guide rules and proper layout generation techniques, and 3) careful optimization of backend post-processing for substrate release/transfer.

In using a native CMOS process to lay out photonics there are two main issues to tackle; first, there is no direct access to all of the mask layers (some layers are automatically generated from other layers) and considering that the process is mainly designed for MOSFETs this could potentially be problematic (e.g., getting unwanted doping in the device layer) and requires careful understanding of the process design kit (PDK) and devising methods to get around it; and second, there are design guide rules (e.g., minimum gap or width, minimum and maximum density rules) that can potentially constrain our freedom for designing photonic devices. We have shown that for our process of choice (IBM 45 nm SOI CMOS) it is possible to utilize all of the design capabilities to tackle these challenges and to develop parameterized cells for complex photonic devices such as microring modulators and detectors with sufficient flexibility over the design space.

The other major challenge for using electronics SOI platforms for the integration of photonics is that the insulator under the device layer is optically too thin to prevent the leakage of light into the substrate (thickness it kept small for good heat sinking). We have optimized a Xenon Difluoride etching process that enables us to remove the underlying silicon substrate (either selectively under the photonic devices or over the entire die) with excellent optical quality. Using this technique, we have demonstrated optical losses as low as 4 dB/cm and resonator intrinsic quality factors above 100,000 at 1550 nm.

In summary, we have demonstrated that despite numerous material, process and design constraints in a native electronics CMOS process, it is still possible to build photonic components that can approach the performance of their counterparts with custom substrates and processes. We have previously shown high speed optical receivers [2] and transmitters [3] in this platform.

Computation and Analysis of Terahertz Wire Grid Polarizer Self-resonance Using Transmission Line Theory

J. S. Cetnar[1] and E. R. Brown[2]

Wright State University, Dayton, Ohio 45435, USA

Abstract— A terahertz metal wire-grid polarizer on a low-loss dielectric (crystalline quartz) substrate was simulated using High Frequency Structure Simulator (HFSS) and modeled with equivalent-circuit theory. The transmittance of the polarizer was calculated for electromagnetic radiation at normal incidence from 100 to 1000 GHz for both s-polarization (perpendicular to the grid) and p-polarization (parallel to the grid). The phase difference in S_{21} between the HFSS input and output ports was calculated and plotted versus frequency and versus fill-factors of 0.3, 0.5, 0.7, 0.9, and 0.95 for both polarizations. Analysis of the s-polarized S_{21} shows that the phase-angle differences are all negative. This is interpreted as the phase of the current in the wire grid leading the phase of the voltage across the gaps, and thus the electric field across the gaps. This behavior was seen for all fill-factors. Therefore, a capacitive effect is exhibited by the wire-grid polarizer for s-polarization. Analysis of the p-polarization results show the phase angle differences are positive for fill-factors less than or equal to 0.9 and negative at the fill-factor of 0.95. Thus, the wire-grid current lags the gap voltage for p-polarization at fill-factors ≤ 0.90 (an inductive effect) while wire current leads the gap voltage at fill-factor $= 0.95$ (a capacitive effect). This behavior is the spatial analog of a parallel LC circuit.

The self-resonance of the wire-grid polarizer was then modeled using the lumped circuit parameters of specific sheet inductance and specific gap capacitance for the wire grid, and transmission line theory for the substrate, for various fill-factors. Specific sheet inductance, specific gap capacitance, and self-resonant frequency versus fill-factor were calculated and plotted. The results show a monotonic increase in both specific sheet inductance and specific gap capacitance with increasing fill-factor. Meanwhile, the self-resonant frequency decreases monotonically with increasing fill-factor and asymptotically approaches a constant of approximately 125 GHz at very high fill factors.

Analysis for Improving the Radiation Behavior for THz Devices

Abstract—

Introduction: One of the main issues in THz technology (both emitters and receivers) is radiating the energy effectively. It can be split the issue into two topics: on one hand, the well-known concept of matching impedance. The current state of the art for THz devices, typically gives a high input impedance (few kohm) with a strong capacitance behavior [1]. On the other hand, the second issue is having a broadband radiator for covering the ultra wideband capabilities of THz generators devices [2]. Both requirements, as one can imagine, are extremely difficult to accomplish.

In this paper, a theoretical approach will be done, showing a new approach for getting a broadband behavior with high input impedance, based on loading periodically a transmission line conveniently tapered for getting a suitable backfire radiation behavior. These kind of structures are a generalization of the well-known classical topologies log-per or log-spiral antennas. By means of the proposed structure, those classical geometries will improve both their radiation behavior together with a better matching with the THz device. An explanation of such structures based on the Brillouin plot will be firstly exposed. Some examples as potential solutions for covering the THz issues will be treated. Comparisons with array topologies and single elements state of the art topologies will be done.

[4]Department of Physics, University of Hamburg, Hamburg 22761, Germany

Abstract— Experiments of high-field terahertz (THz) generation by intra-pulse difference frequency generation (or optical rectification) deviate significantly from predictions by existing models. We address this problem via a model which considers the spatial and temporal shaping of the optical pump pulse, the coupled nonlinear interaction between THz and optical radiation as well as crystal geometry for the first time.

Existing models either (i) neglect the depletion of the optical pump [1] which drastically overestimates conversion efficiency or (ii) consider only one spatial dimension [2] which cannot account for crystal geometry or terahertz (THz) beam properties. We solve for both THz and optical electric fields via an infinite set of coupled nonlinear wave equations in two spatial dimensions [3]

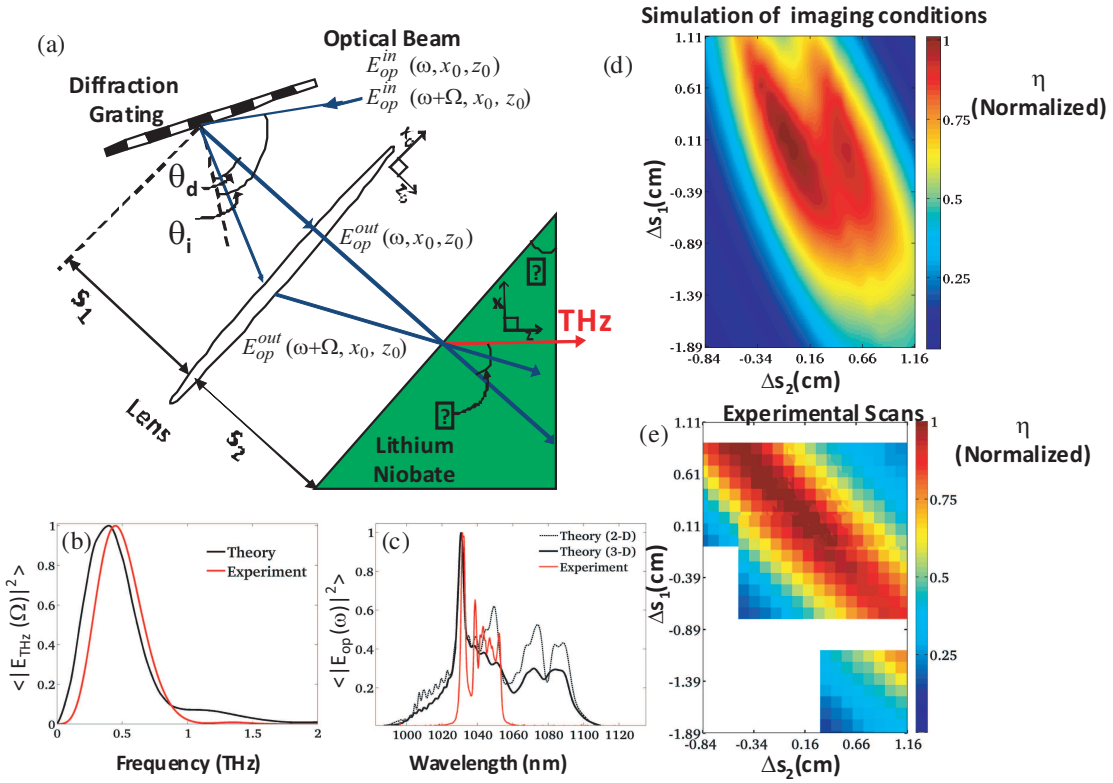

Figure 1: The effects of an arbitrary optical setup such as a tilted-pulse-front setup and prism like crystal geometry can be considered. The simulated (b) THz and (c) optical spectra are in good agreement with experiments. The input Gaussian optical spectrum centered at 1030 nm is predicted to be drastically modified by the THz radiation. (d)–(e) The model provides a one-to-one correspondence between experimental conditions and THz properties as seen in the plots of conversion efficiency Vs imaging distances (s_1, s_2).

as depicted in Eq. (1).

$$\nabla^2 E_{THz}(\Omega,x,z) + k^2(\Omega)E_{THz}(\Omega,x,z) = \frac{-\Omega^2\chi^{(2)}_{eff}(x,z)}{c^2}\int_0^\infty E_{op}(\omega+\Omega,x,z)E_{op}*(\omega,x,z)d\omega$$

$$\nabla^2 E_{op}(\omega,x,z) + k^2(\omega)E_{op}(\omega,x,z) = \frac{-\omega^2\chi^{(2)}_{eff}(x,z)}{c^2}\left[\int_0^\infty E_{op}(\omega+\Omega,x,z)E_{THz}*(\Omega,x,z)d\Omega + \int_0^\infty E_{op}(\omega-\Omega,x,z)E_{THz}(\Omega,x,z)d\Omega\right] \quad (1)$$

A solution for the case of THz generation using tilted-pulse-fronts in lithium niobate is presented. The schematic of the system is depicted in Fig. 1(a). The model accounts for spatio-temporal variations such as angular dispersion, spatial and temporal chirp of the optical pump pulse imparted by the optical setup and geometry of the crystal. The predicted THz and and optical spectra in Figs. 1(b)–(c) are in good agreement with experiments. In Fig. 1(c), the incident Gaussian optical spectrum is drastically reshaped as a consequence of THz generation. In Figs. 1(d)–(e), the conversion efficiency as a function of perturbations to distances s_1, s_2 is plotted. This illustrates the ability of the model to describe effects of system perturbations on various THz properties.

The presented model is thus a highly versatile simulator for understanding the spectral, spatial properties of the generated THz radiation and is an advancement towards optimizing a variety of terahertz generation systems.

Design Challenges for Electro-optic Tuning of Amplitude and Phase in THz Region

Robert Lindquist[1, 2], **Abubaker Tareki**[1], **Daniele Lo Forti**[1], **Wonkyu Kim**[1], **and Junpeng Guo**[1, 2]

[1]Department of Electrical and Computer Engineering, University of Alabama in Huntsville
Huntsville, Alabama 35899, USA
[2]Center for Applied Optics, University of Alabama in Huntsville, Huntsville, Alabama 35899, USA

Abstract— Electro-optic (EO) modulation of the amplitude and phase of an electromagnetic waves in the optical and infrared regions is commonplace and has led to commercially available components used in spectral filtering, polarization management, beam steering, transmitters, displays, etc.. However, electro-optic techniques have had limited success in the THz region due to several practical design challenges. The first barrier for components is the long interaction lengths required to modulate a THz wave. Since the EO modulation depth is directly proportional to the multiplication of the change of permittivity and the ratio of interaction length over wavelength, THz systems with wavelengths ranging from 150 µm to 1 mm pose a challenge. Even a basic tunable half-wave plate using a highly birefringent liquid crystal (LC)with a birefringence of $\Delta n \cong 0.33$ requires an effective film thickness ranging from 225 µm to 1.5 mm. More complicated structures could require interaction lengths of several millimeters. Thick EO films are typically unreliable, require unreasonably large voltages, and tend to be very slow. The second challenge is the selection and design of the electrodes. The material properties of a conductive material in the THz region are significantly different than the infrared and optical region leading to large impedance mismatch at dielectric/electrode interfaces. For instance, the indium tin oxide (ITO) electrodes used in common LC display are practically opaque to the THz wave.

In this paper, the basic EO modulation configuration engineered and fabricated using longitudinal or transverse stratified sub-wavelength structures will presented. By using sub-wavelength layered structures, the thickness limitation of an electro-optic tuning films such as liquid crystals (LC) can be overcome. Consistent with electro-optic modulation convention, the transverse structure will have the applied field and structure periodicity perpendicular to the THz beam propagation. The longitudinal configuration will have the applied field and structure periodicity parallel to the THz beam propagation. Since the transverse configuration allows for long interaction lengths with small apertures and the longitudinal configuration allows for large aperture and short interaction length, the transverse configuration is used primarily in communications application with single beams or within a waveguide while the longitudinal configuration is used in imaging or display applications. The transverse configuration can be designed to provide several practical high transmission, distortion-less, flat top channel filters. Both a novel tunable narrowband notch filter and a tunable transmission filter will be presented. The focus on the longitudinal configuration will be related to the high transmission, polarization independent electrodes. The electrode design is a Frequency Selective Surface consisting of subwavelength periodic structures patterned in continuous gold on a transparent dielectric. The maximum feature size of the structure holes is maintained below a fraction of the thickness of the electro-optic film to allow fringing field to uniformly excite the entire electrode area. Initial experiments have shown polarization independence and transmission peaks that reach as high as 93% in measurements.

Simulation and Design of a Heterogeneously Integrated III-V/Silicon Dual-wavelength Laser

Yingchen Wu and Jian-Jun He
State Key Laboratory of Modern Optical Instrumentation, Centre for Integrated Optoelectronics
Department of Optical Engineering, Zhejiang University, Hangzhou 310027, China

Abstract— THz wireless communication is considered as an excellent candidate to meet the rapidly increasing demand for broadband wireless network, due to its inherently higher bandwidth compared to microwave solutions. Mode-beating dual-wavelength lasers, which can be used for continuous wave (CW) THz carrier signal generation and all-optical clock recovery, have attracted much attention. Monolithically integrated dual-wavelength lasers are more compact, cost-effective than the free-running laser pair as an optical beat source. The dual-wavelength lasers which experience similar environmental fluctuations with the two discrete free-running laser have more stable frequency leading to a smaller drift of the THz signal. Some published multi-section dual-wavelength lasers show potential for tunability. However, these structures need multiple current injections, which lead to a more complicated controlling system and increasing the instability of the generated THz signal. In this paper, we present the design and simulation results of a novel dual-wavelength laser based on III-V/silicon heterogeneously integrated platform. A single-mode symmetric splitting is achieved by embedding shoulder gratings inside a micro-ring resonator. By adjusting the coupling coefficient between the ring and straight waveguide, we can obtain a large SMSR between the two splitting modes and the side mode. The gap between the splitting peaks can vary from 0 to 1 nm by varying the reflection coefficient of the gratings.

Terahertz Metasurface Antireflection Coatings

Hou-Tong Chen[1] and Li Huang[2]

[1]Los Alamos National Laboratory, USA
[2]Harbin Institute of Technology, China

Abstract— Conventional single- or multi-layer antireflection coatings to suppressing the undesirable interface reflection and enhance the transmission have strict requirements in the refractive index and film thickness of the materials being coated. Alternative approaches have been developed, for example, using surface relief structures. However, they pose difficulties and severe restrictions in device fabrication and integration. Taking advantage of the tailored reflection/transmission and their dispersion, metasurfaces consisting of subwavelength planar metallic structures and combining with a dielectric spacer enable ultrathin antireflection coatings without much requirement in the refractive index of the spacer material.

We have developed this concept particularly in the terahertz (THz) frequency range [1, 2]. In our first metamaterial antireflection coating structure, we selectively etch down silicon surface forming an array of silicon cylinders by photolithographic methods and reactive ion etching, which is followed by directional metal (gold) deposition. Eventually we obtain a metal-dielectric-metal structure consisting of metal resonators on top, a hole array at the bottom, and air/silicon cylinders in between as the dielectric spacer. We further find that excellent antireflection performance can be accomplished using much simpler metal-dielectric structures — a combination of a single-layer metallic metasurface and an ultrathin dielectric film, achieving a bandwidth comparable to quarter-wave antireflection. This can be realized by spin-coating of a low refractive index polymer film on top of a high refractive index substrate, and then fabricating an array of metallic resonators. This antireflection approach was also accomplished at mid-infrared wavelengths [3]. In another design we fabricate a metallic mesh on top of the substrate, and then laminating an ultrathin silicon wafer. All of these metamaterial/metasurface antireflection coatings with appropriate design parameters can completely eliminate the reflection at specific frequencies, with a bandwidth approaching quarter-wave antireflection coatings. We emphasize that the metamaterial/metasurface antireflection coatings do not require refractive index matching of the materials being used, and the overall thickness is much less than the traditional quarter-wave antireflection coatings. Further improvement of the bandwidth or achieving multi-band antireflection is possible by using more complex unit cells of the metasurfaces [4]. We will present our numerical and experimental results, together with analytical calculations to elucidate the underlying principles [5].

The Optimisation and Analysis of Multi-moded Feed Horn Structures at Terahertz Frequencies

D. McCarthy, N. Trappe, J. A. Murphy, M. Gradziel, C. O'Sullivan, and S. Doherty
Department of Experimental Physics, Maynooth University, Ireland

Abstract— Carrying out astronomical observations at far-infrared wavelengths is critical in enabling further progress in the fields of cosmology and astrophysics. Such observations will allow additional insight into the birth and evolution of the Universe. To allow progress in these areas, it is necessary to improve the sensitivity and resolution of the instrumentation that is used to carry out these observations.

At the high frequencies in question (terahertz), the instruments typically make use of horn antenna fed detector systems. To achieve the required performance, the horn designs must be highly optimised. Full electromagnetic solvers (CST, HFSS, COMSOL etc.) struggle to predict the performance of horn antennas at such high frequencies in a timely manner due to the large electrical size of the structures. It is therefore very challenging to perform the optimisation using such solvers particularly for multi-mode systems where each mode would have to be considered individually.

In this paper we outline an alternative technique for modelling multi-mode (partially coherent) horn antennas based on the mode-matching technique, which allows electrically large structures to be modelled in a highly efficient manner. This technique returns a set of scattering matrices which gives a full vector definition of the transmission and re ection characteristics of the resulting design at a given frequency. We demonstrate how this can be used to extract field patterns and other figures of merit that are important for evaluating the electromagnetic performance of a horn design.

An efficient genetic algorithm based optimisation technique (using mode-matching) is also presented. The optimisation process is based on a piecewise conical profile horn design and produces a geometry that is optimised with respect to some figure of merit that is of critical importance for the application in question. This allows the instrument to realise the high levels of optical performance that are required for astronomical applications.

Simultaneous Generation of Terahertz and X-ray Radiation with Ultrashort Femtosecond Laser Pulses in Nano-cluster Medium

Abstract— We have studied for the first time the simultaneous generation of terahertz and X-ray radiation from noble gas based nano-cluster supersonic jet under "one-" and "two-color" (fundamental and its second harmonic) excitation with high-power femtosecond laser pulses. It was shown that optimal conditions for effective generation of terahertz and X-ray radiation are different, that makes possible efficient control by ratio between values of terahertz and X-ray signals generated simultaneously from gas based nano-cluster jet by means varying of time delay between laser pulse and cluster jet formation and by varying of laser pulse's chirp.

It has been shown that efficiency of THz generation from cluster jet could be efficiently controlled by varying the ratio between clustered and buffer gases gas mixture; angular distribution of terahertz beam generated near by optical axis under "two-color" laser excitation conditions has been measured as well.

Electromagnetic Properties of Ultrathin Quadrifilar Spirals and Their Complementary Structures

Nina Meinzer, **Alastair P. Hibbins**, **and J. Roy Sambles**
Electromagnetic and Acoustic Materials Group
School of Physics and Astronomy, University of Exeter, United Kingdom

Abstract— Metallic spiral structures have been employed as subwavelength antenna elements in the microwave regime for some time. Recently they also been shown to support localised magnetic spoof plasmons similar to corrugated surfaces or cylinders [1]. Following on from these results we, in this paper, study the electromagnetic properties of ultrathin quadrifilar copper spirals and of their complementary structures, spiral-shaped apertures in an extended copper film. The samples are fabricated by a wet-etching technique using a mask printed onto a thin copper film on top of a mylar substrate. We experimentally map the near-fields of the samples. We further perform numerical finite-element modelling for comparison with our experimental data and to provide further information to aid our understanding of the system.

We start from single spiral elements and compare the electro-magnetic response of a direct copper spiral with that of its complementary (spiral aperture in a copper sheet) structure. From this starting point we move on to an investigation of combinations of small numbers of such spiral elements, both in the direct and inverse case, which exhibit the mode coupling one expects from a system of closely spaced or connected antennas. Depending on the excitation geometry or the arrangement of elements specific eigenstates of the coupled systems can be selectively addressed or suppressed, which adds an additional degree of control over the resonant behavior of these ensembles of a few spiral (spiral aperture) antennas. This latter part of our work is related to previous studies on the channeling of electromagnetic waves.

Optical Frequency-interleaving Full-duplex Technique for Fiber-optic Transmission of Millimeter-wave-band Frequency-modulated Continuous-wave Downlink Signal and 10-Gb/s On-off-keying Uplink Signal

T. Kuri[1], **A. Kanno**[1], **and T. Kawanishi**[2, 1]

[1]National Institute of Information and Communications Technology, Japan
[2]Waseda University, Japan

Abstract— An optical frequency-interleaving full-duplex technique for fiber-optic transmission of millimeter-wave-band frequency-modulated continuous-wave downlink signal and 10-Gb/s on-off-keying uplink signals is newly proposed. The proposed full-duplexing technique with a flexible wavelength channel selector is experimentally demonstrated.

High-precision imaging technology has been in strong demand for safety and security at important facilities. For example, for runway monitoring, several-inch class debris should be detected and removed to ensure safe takeoff and landing [1]. To achieve such high-precision imaging by radio, millimeter-wave (mm-wave) is a promising candidate because of its broad transmission bandwidth. To overcome the large propagation loss and atmospheric attenuation in the mm-wave bands, the introduction of a distributed antenna system (DAS) concept is necessary for large-area surveillance. In the DAS, radio-over-fiber (RoF) technology aids in realizing easy radio signal distribution with a low-loss optical fiber. We have demonstrated the optical generation for highly accurate frequency-modulated continuous-wave (FM-CW) signal, which has high affinity with the RoF technology [2]. We have also demonstrated the distribution of FM-CW signals with three different frequency band in a wavelength division multiplexing (WDM) RoF system [3, 4]. In the demonstrations, although the downlink transmission of FM-CW signals has been verified, an uplink transmission for sending sensed data back to a central control station (CCS) has never been considered.

In this paper, we investigate an optical frequency-interleaving full-duplex technique for fiber-optic transmission of mm-wave-band FM-CW downlink signal and 10-Gb/s on-off-keying (OOK) uplink signals. Their optical duplexing is experimentally demonstrated with a flexible wavelength channel selector for two cases of downlink mm-wave-band, that is, 96-GHz-band and 48-GHz-band. In the demonstration, we show that no serious degradation for both the downlink and the uplink transmission is observed even if our proposed full-duplex technique is introduced in the fiber-optic full-duplex link.

Abstract— Microwave systems, cellular networks and other various personal communications systems require devices that are capable of receiving, converting and processing signals in the millimeter and centimeter wave ranges. A broad palette of devices was developed recently for transferring radio frequency and microwave signals directly to optics. This presents all advantages of optical communication channels, allowing to transmit data securely with high rates, low loss, low power consumption. Electro-optic modulators based on interaction of optical and microwave waves in high-Q nonlinear optical resonators with whispering gallery modes provide a promising platform of that kind.

In our work we present analysis of electro-optic interaction of a fundamental whispering gallery optical mode in a dielectric microdisc and a radio frequency mode of a half-wave microstrip line placed on the disc circumference. 2D and 3D numerical models of the system are developed. Both optical and radio frequency modes are simulated using finite element method with Comsol Multiphysics software. The comparison between the models is presented, and a theory of modulation in the multi-mode system is discussed. The magnitude of electro-optic effect is calculated depending on optical and radio frequency mode numbers. The cases of different polarizations of signal and pump optical field for standing and travelling waves are also considered. It is shown that the modulation in the system exists only for particular sets of mode numbers determined by selection rules. The magnitude of the effect in such system is shown to have an extremal dependence on the microstrip length for a given set of mode numbers.

Optical FM-CW Signal Generation for a Terahertz Radar System by Higher-order Optical Modulation

Abstract— To realize high precision imaging system based on radar technology, high-frequency carrier radio is promising owing to its broadness of available bandwidth. Actually, some radar system for detection of debris with a size of several centimeters on airport runways are being developed for enhancement of civil security using millimeter-wave band such as 77 GHz and 90-GHz bands. However, available bandwidth of the millimeter-wave is limited owing to radio regulations. Therefore, possible range resolution will be several centimeters. Terahertz wave at a frequency greater than 300 GHz is another candidate for high-precision radar system due to its broad available bandwidth. On the other hand, the precise signal generation technology is required for precise ranging. An optical modulation technology can meet the demands by using frequency multiplication configuration in optical domain. Actually, an optical frequency quadrupling based on an optical intensity modulation can provides a frequency-chirp bandwidth of 30 GHz at a carrier frequency of 100 GHz. To expand the frequency with a large number of multiplication factor of the optical multiplier, an optical frequency comb generation technique is indispensable.

We demonstrate an optical frequency-chirped signal generation using higher-order optical modulation technique. An optical frequency comb generator by using optical modulation is utilized as a frequency multiplier with a multiplication factor of 12 to generate 300-GHz-band terahertz radar system. Input signal at a center frequency of 25 GHz with a chirp bandwidth of 1 GHz and 2 GHz provides 6-GHz and 12-GHz-bandwidth optical signals in 6th-order harmonics. Finally, a frequency separation of +6th- and −6th-order components would be 300 GHz with a chirp bandwidth of 12 GHz and 24 GHz. The technique is capable for high-precision imaging system.

Long-life Microwave Lighting

Vladimir Danilychev
Quantum Technologies, Irvine, CA 92612, USA

Abstract— Technology of Multi-Lamp Large Area Lighting Systems, based on Microwave Excitation of new Electrodeless Long-Life Lamps is discussed. Critical parameters of Multi-Mode microwave cavities for uniform excitation of many electrodeless lamps are presented. Limitations on output Intensity, available emission Spectra, applications for Visible Lighting, Surface Treatment and UV Curing, related with use of Large Area Multi-Lamp Sources are analized. Experimental results are presented. Technical characteristics and design of Large Area Long-Life Lighting Systems and Electrodeless Microwave Lamps are shown. Pictures of operating Quantum Multi-Lamp microwave Lighting Systems and Electrodeless Microwave Lamps are presented.

Abstract— Coupling single quantum objects (atoms, ions, quantum dots...) to high-finesse optical resonators is a well-explored route towards strong deterministic photon-photon interactions. Very successful in the microwave regime, this approach is more difficult to implement at optical wavelengths, in particular due to optical losses and to difficulties in obtaining a strong, constant and reproducible light-matter coupling. It has been recently realized that many of these constraints could be lifted by replacing single atoms with strongly interacting atomic ensembles behaving as collective "superatoms" and showing strongly enhanced optical properties. In practice, photons injected in the intracavity atomic gas are converted to atomic polarization waves involving highly excited, strongly polarizable Rydberg atomic states. Their interactions lead to a blockade effect, making atoms located within a $\sim 10\,\mu$m range behave as a single "superatom" which can contain only a single Rydberg excitation but which presents a collectively enhanced coupling to light, allowing to strongly relax the constraints on the cavity geometry and finesse. In this talk I will review the progress accomplished along this line in the last few years in our experiment in Institut d'Optique in Palaiseau. I will then present new research directions we are planning to explore in a new project starting in Collège de France in Paris, which will use specific features of these collective "superatoms", in particular their relatively large spatial extension.

Few-body Physics of Strongly Interacting Photons in a Rydberg Medium

Abstract— Free space photons can be made to strongly interact by dressing the photons with atomic Rydberg states under conditions of electromagnetically induced transparency. Recently a two-photon bound state was experimentally observed in such systems [1]. Here we develop the full scattering theory for two dark state polaritons and explore the various classes of bound states and scattering states that emerge. We identify previously unexplored parameter regimes where polariton-polariton interactions are repulsive. Furthermore, in the regime of attractive interactions, we identify multiple two-polariton bound states, calculate their dispersion, and study the resulting scattering resonances.

We then focus on the regime where the photonic bound states overlap with the continuum of purely atomic two-body bound states. In this continuum, we find the photonic bound states survive as metastable states whose energy spectrum is governed by the Coulomb problem, thus obtaining a photonic analogue of the hydrogen atom. These states eventually decay into bound pairs of Rydberg atoms, but are long-lived, in analogy to the quantum tunneling of a particle trapped by two potential barriers. Furthermore, we find that these states propagate with a negative group velocity. We demonstrate the metastability and backward propagation of these Coulomb bound states with full numerical simulations and discuss the prospects for experimental preparation and observation of these states.

Finally we discuss the experimental implications of this work and explore the possibility of extending these results to the many-body problem.

Strongly Interacting Rydberg Atoms in Hot Vapours

R. Löw
Universität Stuttgart, Germany

Abstract— Strongly interacting Rydberg atoms have proven to serve as an efficient nonlinear medium, even on the single photon level. The drawback is, that most experiments so far have to rely on ultracold atoms in room filling setups. For a better applicability in terms of size, integratability, power consumption and bandwidth we try to adopt the concepts developed for ultracold atoms for atomic vapours at room temperature in microscopic vapour cells. Our approach is twofold: First we have to understand how the interaction mechanisms among Rydberg states influence the optical properties of the gas at room temperature. Here we have already approved that the van-der-Waals interaction, mandatory for any Rydberg blockade, is flawless up to a excitation bandwidth of 1 GHz for a gas of Rubidium atoms. For Cesium the situation is quite different and a large bandwidth excitation results in a rapid aggregation dynamics of Rydberg states, which we also probe optically. The second line of research is dedicated to the miniaturization and furnishing of vapour cells with various functionalities for optimal coupling to the excitation and probing light fields as well for a direct read out of the Rydberg population by an ionization current. Finally I will report on our recent experiments on atom filled hollow core fibres including electrical contacts.

Spontaneous Phase Coherence of a Statistically Flickering Bose-Einstein Condensate of Light

Abstract— Phase transitions are ubiquitous phenomena in nature, which are most often accompanied by a spontaneous breaking of a system's underlying symmetry, as for example a broken rotational invariance in ferromagnets below the Curie temperature due to global spin alignment. For Bose-Einstein condensates, a spontaneously broken $U(1)$ gauge symmetry causes the selection of an arbitrary, yet extensively coherent phase for the ground-state wave function. Interference experiments present valuable tools for the study of spontaneous symmetry breaking and the first-order coherence of such systems. Here we report a time-resolved study of the heterodyne interference of a Bose-Einstein condensate of photons with a narrowband laser source acting as a phase reference. To prepare the optical Bose-Einstein condensate, we trap photons in an optical microcavity filled with a liquid dye solution, where repeated absorption and re-emission processes lead to a thermal equilibration of the transverse motional degrees of freedom of the photon gas. The reservoir of dye molecular excitations serves as both heat bath and particle reservoir, which allows us to realize a regime with large "grand-canonical" number fluctuations of order of the total photon number. Correspondingly, no second-order coherence emerges, as in a thermal (lamp-type) source. The intensity fluctuations lead to phase jumps in the observed interference signal, with a rate reducing for increasing condensate sizes. Further, by engineering different-sized reservoirs, we can relate first to second-order coherence properties, which are determined by the grand-canonical nature of the photon condensate. Our data, when extrapolated to the thermodynamic limit, demonstrates the emergence of persistent phase coherence, while no second-order coherence emerges in the macroscopically populated, fluctuating photon condensate. This outlines the photon Bose-Einstein condensate under grand-canonical statistical conditions as a novel brilliant light source, distinct from both spectrally filtered thermal light and laser sources, which holds prospects for optical imaging techniques.

Strongly Interacting Rydberg Slow Light Polaritons

H. P. Büchler
Institute for Theoretical Physics III, University of Stuttgart, Germany

Abstract— Weak interactions of photons with each other are the basis for many applications of light signals in areas such as optical communication. However, many other applications in classical and quantum communication, computation, and metrology would greatly benefit from tunable photon-photon interactions. Moreover, photon-photon interactions at the level of individual quanta could pave the way to the realization of exotic strongly correlated photonic states. A typical approach to achieve strong two-photon interactions relies on confining photons to high-finesse cavities. An alternative approach towards this goal has recently emerged using Rydberg slow-light polaritons. The key idea is to combine electromagnetically induced transparency (EIT) with the strong interaction between Rydberg atoms. Both phenomena have been well-studied in the past: it has been demonstrated that photons can be slowed down and stored in atomic gases using EIT, while recent experiments on Rydberg atoms have demonstrated the strong interaction and the associated blockade of Rydberg excitations. In the Rydberg-EIT system, a photon entering the atomic gas is converted into a slow-light polariton with a substantial admixture of the Rydberg state. It is the latter admixture that maps the Rydberg-Rydberg interaction onto an effective interaction between slow Rydberg polaritons. Within this approach, a single-photon source and switch was realized, the photon blockade and the formation of bound states of Rydberg polaritons has been demonstrated, and atom-photon entanglement was observed.

Here, we derive the scattering properties and bound-state structure of Rydberg polaritons in one dimension. Our analysis provides a rigorous theoretical framework for analyzing a variety of problems in Rydberg-polariton systems. This framework allows us to analytically derive the effective interaction potential between two Rydberg polaritons and to identify a regime with a purely repulsive interaction. We derive the low-energy scattering length and find the appearance of resonances; we expect the corresponding tunability of the scattering length to play the role that Feshbach resonances play in ultra-cold atomic gases. Moreover, we identify multiple two-polariton bound states for attractive interactions and determine their dispersion relation. In addition, we demonstrate the possibility to design a high fidelity quantum gate between photons, and analytically derive all leading terms reducing the fidelity. A detailed discussion for its experimental realization is provided.

Probing Nanofiber-trapped Atomic Ensembles at the Quantum Level

J. Appel, J.-B. Béguin, H. L. Sørensen, S. L. Christensen, E. Bookjans, K. Kluge, I. Iakoupov, A. Sørensen, J. H. Müller, and E. Polzik
Niels Bohr Institute, University of Copenhagen, Denmark

Abstract— We prepare a mesoscopic ensemble containing a few thousand atoms, trapped in a one-dimensional atomic lattice in the evanescent field of a nanofiber. A dual-color homodyne interferometry method with a pW-power shot noise limited probe is used to measure the atom number. Strong coupling of the evanescent probe guided by the nanofiber allows for a real-time measurement with a precision of 8 atoms on an ensemble of some 10^3 atoms in the one-dimensional trap, we thus demonstrate preparation and detection of an atom number distribution in a one-dimensional atomic lattice with the variance $-14\,\mathrm{dB}$ below the Poissonian noise level. This method is very well suited for generating collective atomic entangled or spin-squeezed states via a quantum non-demolition measurement as well as for tomography of exotic atomic states in a one-dimensional lattice.

We will also present our investigation of reflection off a spatially structured 1-dimensional ensemble: Cesium atoms trapped along the nanofiber are pumped from the $F = 4$ into $F = 3$ hyperfine level by a standing-wave laser pulse, thus generating a Bragg-grating of atoms in different spin states. We coherently probe the reflected field and find coherent reflection from a mirror consisting of only about 100 atoms, well exceeding the incoherent backscattering of a many times bigger ensemble. Using a dual-color Raman field for coherent dark-state preparation of the spatial spin structure, the influence of motional effects can be mitigated.

Cold Atoms Coupled to Photonic Crystals: A Platform for Non-local Non-linear Optics

J. S. Douglas, **T. Caneva**, **and D. E. Chang**
ICFO-Institut de Ciencies Fotoniques, Castelldefels 08860, Spain

Abstract— At optical frequencies photons do not interact with one another in free space. While this facilitates faithful information transfer using photons, it also restricts the possible physics and applications that can be realized using photons alone. To overcome this limitation various systems have been realized where the photons are coupled to atoms, using for example cavities [1] or atomic ensembles [2]. Effective interactions can then be achieved between photons as a result of the particular properties of the atoms. One particularly successful method to induce photonic interactions is to use atomic media that support electromagnetically induced transparency (EIT). In these systems the photonic degrees of freedom can be mapped to atomic ones which may then interact with each other. The photonic interaction is then constrained by the type of interaction that can be achieved between the atoms.

Experiments utilizing EIT media have focused on achieving the required atomic interaction via Rydberg excitation of atoms [2–4]. However, Rydberg interactions typically yield step-like potentials where the strength is coupled to the interaction length scale, limiting the range of phenomena that can be produced. Instead we propose to use the new platform of atoms trapped near photonic crystal waveguides that has been developed in recent experiments [5, 6]. In these systems the presence of an atom near the photonic crystal can induce a cavity mode around the atomic position, and when multiple atoms are trapped the atoms can interact dynamically via these induced cavities. In particular the interactions between the atoms are highly tunable and can be coherent over length scales of the order of one hundred optical wavelengths [7]. Using these systems interactions can then be actively designed between photons allowing, for example, molecular-like bound states of photons.

Single Molecules as Bright & Narrow-band Single Photon Sources

Mohammad Rezai[1], **Wilhelm Kiefer**[1], **Jörg Wrachtrup**[1, 2], **and Ilja Gerhardt**[1, 2]

[1]3. Physics Institute, University of Stuttgart, Pfaffenwaldring 57, Stuttgart 70569, Germany
[2]Max Planck Institute for Solid State Research, Heisenbergstr. 1, Stuttgart 70569, Germany

Abstract— Single photon sources based on single molecules under cryogenic conditions can be extremely bright and narrow-band. We introduce a single photon source based in dibenzanthanthrene which is spectrally matched to atomic sodium.

Introduction: Single organic dye molecules allow to serve as high-brightness single photon sources [1]. Among other candidates, dibenzanthahthrene [2] (DBATT) emits in the yellow/red part of the visible spectrum and shows its optimal properties under cryogenic conditions below $T = 2\,\mathrm{K}$. Under these conditions, the molecules do not bleach or blink and the molecules can be used for an indefinite time. The organic host matrix in conjunction with a solid immersion lens (SIL) allows for an efficient extraction of the photons [3]. Commonly more than 1.000.000 clicks on a normal silicon based avalanche photo diode can be detected.

Not only that a high fraction of the emitted photons can be collected — the emission can also be spectrally narrow-band and corresponds to the lifetime limited value. With the molecule dibenzanthanthrene, we observe spectral linewidths down to 12.5 MHz [2, 4]. Commonly, below 20 MHz emission is detected. The presented single photon source represents a very high spectral brightness, and we detect up to 100.000 clicks per second and Megahertz. We are not aware of other sources which exhibit comparable spectral flux.

Since the center of the molecular inhomogeneous band coincides nicely with the D-lines of atomic sodium ($\approx 589\,\mathrm{nm}$), we are able to spectrally select a single molecule to match with atomic sodium. Experiments with slow single photons in atomic vapor have been performed [5]. If a molecule is bright and well-behaved, but slightly shifted against the sodium transitions, we are able to apply an electric field [6] and detune the emitter by several GHz. This allows to "fine-tune" a molecule to match exactly to a desired sodium transition.

To suppress background emission from the host matrix and other emitters, we are able to filter the photons from the molecule with an atomic filter. These Faraday anomalous dispersion optical filters [7] (FADOFs) allow to discriminate the wanted single photon emission from the background and guarantee that the emission matches the atomic transition. We will outline our current efforts to use Faraday filters in conjunction with single photon sources [8].

We will discuss prospects how to generate higher order Fock-states and triggered photons on demand from our source.

Exciton-polariton Interactions in 0D Confinement

Thomas Fink[1], **Christian Schneider**[2], **Sven Höfling**[1], **and Ataç Imamoğlu**[1]

[1]Institute of Quantum Electronics, ETH Zürich, CH-8093 Zürich, Switzerland
[2]Technische Physik, Universität Würzburg, D-97074 Würzburg, Germany

Abstract— Exciton-polaritons not only exhibit fascinating physical properties such as nonlinearities, superfluidity, and Bose-Einstein condensation at elevated temperatures, but also offer ease of tailoring their potential landscape, which makes them promising candidates for quantum simulation applications. However, all experiments to date can be described using a mean-field approach. Consequently, it has been a long-standing goal to demonstrate single-particle nonlinearities in these systems through the observation of polariton blockade [1].

To do so, one requires long polariton lifetimes τ (i.e., spectrally narrow quantum well excitons and a high-Q cavity), and strong lateral confinement of the photonic mode to achieve a sizable exciton-exciton interaction E_{nl}. For $1/\tau \sim E_{nl}$, one then expects to see a reduction of the probability to find two photons at a time in the cavity, which is heralded by light leaking out of the cavity exhibiting photon antibunching. Introducing high-quality quantum well samples and the latest generation of home-made fibers into our semi-integrated fiber cavity approach [2], we measure photon correlations. The tunability of our semi-integrated system also allows us to investigate biexciton Feshbach resonance [3] which may be used to enhance polariton interactions.

Single-photon Routing in Strongly Interacting Ensembles

Callum Murray
Max Planck Institute for the Physics of Complex Systems, Dresden, Germany

Abstract— The coherent coupling of photons to strongly interacting Rydberg states, via electromagnetically induced transparency, has recently emerged as a promising approach to photon-photon interactions acting on the level of single light quanta. The central idea is to enhance and mediate optical nonlinearities via the long ranged interactions of the matter system. The tuneability in interaction characteristics of this setting in turn renders it pertinent to a broad range of applications in quantum information processing, from realizing quantum phase gates to all-optical transistors. However, the optical nonlinearities typically are reliant on the ability to break EIT conditions, rendering the emergent photonic interactions intrinsically dissipative and imposing substantial limitations on the fidelity of quantum operations.

In this talk, I will describe a new approach to photonic quantum logic based on an interaction induced reflection of light to serve as a quantum router. Our scheme leverages on the modification of EIT conditions, rather than breaking them, to yield a nonlinearity that is well suited to performing high fidelity gate operations or coherent optical switching in strongly interacting atomic ensembles.

Photonic Quantum Gates via Rydberg States of Atoms in Microwave Resonators and Waveguides

David Petrosyan
Institute of Electronic Structure & Laser
Foundation for Research and Technology — Hellas, Heraklion, Crete GR-71110, Greece

Abstract— I will describe several techniques employing electromagnetically induced transparency in cold atomic media and long-range interactions between the highly-excited Rydberg states of atoms to achieve strong interactions and high-fidelity quantum gates between single photon qubits.

Electromagnetically induced transparency [1] is a quantum interference effect in which an application of a coherent control field to a resonant atomic medium dramatically reduces the absorption of a weak probe pulse accompanied by a steep dispersion. The probe pulse, upon entering the medium, is transformed into the so-called dark-state polariton — a superposition of light and matter degrees of freedom — which propagates with greatly reduced group velocity. With the ladder configurations of atomic levels, whereby the control field couples near-resonantly the intermediate excited state of atoms to the Rydberg state, such polaritons contain a large admixture of the Rydberg states. These Rydberg states can exhibit long-range, dipole-dipole interactions [2] which translate into strong absorptive or dispersive interactions between the polaritons.

In this talk, I will describe two schemes realizing dispersive interactions between the Rydberg states of atoms. In the first scheme [3], a pair of quantum fields counter-propagating in a hollow-core waveguide filled with the atoms, undergo a conditional phase shift corresponding to the action of the dipole-dipole interaction between the Rydberg components of the two colliding polaritons.

In the second scheme [4], two or more atomic ensembles are trapped above the surface of a coplanar waveguide resonator whose microwave modes near-resonant with the transitions between the neighboring Rydberg states of atoms can mediate effective ultra-long range resonant (Förster) or non-resonantly (van der Waals) dipole-dipole interactions between any pair of atoms within the resonator mode. The Forster, or blockade, regime can be used to create single photonic excitations within one or more atomic ensemble, while the van der Waals regime can be employed to induce a conditional phase shift upon a pair of single-photon pulses each propagating or stored in a different atomic ensemble.

By properly choosing the group velocities of the polaritons and thereby their interaction time, the conditional phase shift can be made spatially uniform and equal to pi, corresponding to a high-fidelity CPHASE gate between the single-photon qubits.

Abstract— Nonlinear optical processes involving highly-excited Rydberg gases have become a topic of great interest in recent years [1]. Recently, we experimentally demonstrated a nonequilibrium phase transition in a dilute thermal Cs atomic gas [2]. The system was driven strongly with a resonant three-photon excitation scheme [3]. The observed phase transition, between states of low and high Rydberg occupancy, is induced by resonant dipole-dipole interactions between Rydberg atoms and can be observed in both transmission and fluorescence measurements. In the frequency domain, we observe a shift of the Rydberg state which results in intrinsic optical bistability above a critical Rydberg number density. In the time domain, we observe critical slowing down where the recovery time to system perturbations diverges with critical exponent $\alpha = -0.53 \pm 0.10$. The atomic emission spectrum of the phase with high Rydberg occupancy provides evidence for a superradiant cascade.

We create a toy model of the system by investigating the dynamics of a driven-dissipative ensemble of interacting two-level systems with random spatial distribution. Using rate-equation Monte Carlo modelling, we observe the emergence of metastable states, producing a bistable response, as the spatial extent of the long-range pair-wise interactions is increased. The importance of the range of interactions is explored through disappearance of bistability in the 3D to 2D crossover. Mixing within the system, due to atomic motion, stabilises the excited state, increasing overall hysteresis. We explain these observations in terms of long-range insensitivity to shot-noise, corresponding to the mean field used in simplified models. We believe that these results are consistent with other recent Rydberg experiments on cold atoms where bimodal behaviour is observed [4, 5].

Achieving Single-shoton Nonlinearities with an Intracavity Rydberg Medium

I. Usmani[1], **R. Bodedda**[1], **E. Bimbard**[1], **A. Grankin**[1], **E. Brion**[2], **A. Ourjoumtsev**[1], **and P. Grangier**[1]

[2]Laboratoire Aimé-Cotton, CNRS/Universite Paris-Sud/ENS-Cachan, Palaiseau, France

Abstract— The realization of a strong and deterministic photon-photon interaction is a challenging task, but could enable the implementation of a two-photon phase gate or the generation of non-classical states of light. The standard nonlinearities in conventional optical media are however too weak to induce such effects. One approach to create single-photon nonlinearities is to temporally convert the photons into dark-state polaritons involving Rydberg atoms [1]. The principle is that a single Rydberg excitation may modify strongly the susceptibility of a small region, thanks to Rydberg blockade [2].

Recent experiments, implemented in an ultracold cloud of ^{87}Rb atoms held in an optical dipole trap, demonstrated nonlinearities at the quantum level, such as it creates a medium transparent for single-photons, but is absorptive for photon pairs [3, 4]. This effect was used to create an attractive potential between photons [5] and single-photon switches [6, 7].

Here, our atomic cloud is placed into a one-ended low finesse optical cavity which amplifies the nonlinear effects [8]. We are also able to perform second-order correlation measurements and homodyne detections of the outgoing field [9].

We will present our current efforts to observe nonlinear effects at the single-photon level. This includes the implementation of a dipole trap to increase the atomic density, or increasing the cavity finesse and its concentricity. We aim at observing bunching or anti-bunching of light and phase jumps induced by Rybderg excitations in our intracavity cloud.

Strongly Interacting Rydberg Polaritons in Optical Cavities

Ariel Sommer, **Nathan Schine**, **Ningyuan Jia**,
Albert Ryou, **Alex Georgakopoulos**, **and Jonathan Simon**
University of Chicago, USA

Abstract— Quantum materials of strongly-interacting photons will allow novel quantum simulation studies of many-body systems. In particular, photonic materials are well suited to studying long range interactions, strong gauge fields, and driven open quantum systems. We describe a novel platform for realizing a photonic many-body system using Rydberg polaritons in degenerate optical cavities.

Degenerate optical cavities provide a flexible platform to engineer photon dynamics, while electromagnetically induced transparency (EIT) using a Rydberg level induces strong interactions between polaritons. We show that photons in nearly-degenerate optical cavities can be described as massive particles in two dimensions subject to an applied potential. When a Rydberg EIT medium is included in the cavity, the dark polariton modes inherit the properties of the underlying cavity modes, but with an increased effective mass and a reduced effective trapping frequency, analogous to the reduced group velocity in free space EIT. The strong interaction between Rydberg atoms induces a strong interaction between the dark polaritons. At large distances, the polariton-polariton interaction retains the form of the Rydberg-Rydberg interaction, while at short distances the interaction saturates due to detuning from the EIT condition. The long range of the interaction gives access to a quantum phase transition to a crystal, allowing novel studies of quantum crystallization in an open system.

We describe progress on realizing Rydberg EIT and single photon nonlinearity in a high-finesse optical cavity. Additionally, we demonstrate an optical cavity that induces an effective magnetic field for photons and is compatible with the proposed Rydberg EIT setup. Strongly-interacting Rydberg polaritons subject to an effective magnetic field give access to fractional quantum Hall states, which are of great interest for quantum simulation.

Cavity Design and Mode Analysis in Woodpile Based Three-dimensional Photonic Crystals

X. Zheng, Y.-L. D. Ho, L. Chen, M. P. C. Taverne, and J. G. Rarity
Merchant Ventures Building, Department of Electrical and Electronics Engineering
University of Bristol, UK

Abstract— In a three dimensional (3D) photonic crystal (PhC) structure with an embedded defect cavity, the cavity mode is strongly associated with the surrounding environment which results in a variety of mode field distributions [1–3]. Inspired by comparing the woodpile lattice with the diamond lattice, here we present a cavity design which supports well confined Gaussian-like cavity modes in a woodpile based 3D PhC structure. By carefully choosing the position of the defect, we can create a cavity with high symmetry and tune the cavity mode with desired order and frequency by adjusting its size. Defects at this position show clearly defined mode orders simplifying analysis.

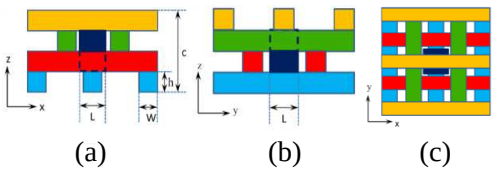

Figure 1: The location of the cavity in one vertical period (four stacking layers in z axis). (a) View of x-z plane, (b) view of y-z plane, and (c) view of the x-y plane (from the top).

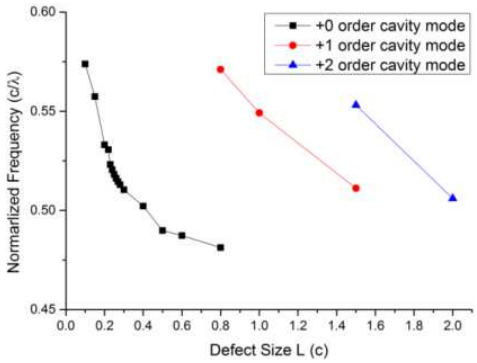

Figure 2: Normalized resonant frequency as a function of cavity size L/c.

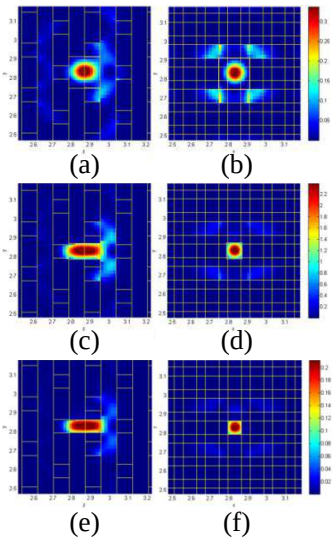

Figure 3: 3. Energy distribution of cavity modes when cavity size (a), (b) $L = 0.5c$, (c), (d) $L = 0.25c$, (e), (f) $L = 0.2c$. (a), (c), (e) View of y-z plane, (b), (d), (f) view of x-y plane. Due to the symmetry of x-z plane and y-z plane, only views of y-z plane and x-y plane are shown.

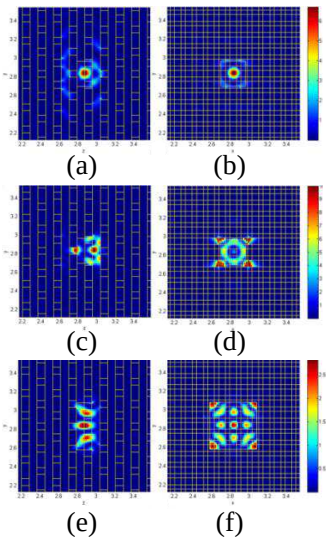

Figure 4: Energy distribution of cavity modes. Resonant mode at (a), (b) normalized frequency 0.48 when $L = 0.8c$; (c), (d) normalized frequency 0.57 when $L = 0.8c$; (e), (f) normalized frequency 0.55 when $L = 1.5c$. (a), (c), (e) View of y-z plane, (b), (d), (f) view of x-y plane

The cavity is formed by introducing a cube defect between two adjacent layers (2nd and 3rd) in one vertical period c (Fig. 1). L is the size of the cavity in x-y plane while the height of cavity is $2h$ (two rod heights) to make it connect with rods in 1st layer and 4th layer. In both 2nd layer and the 3rd layer, the centre of the cavity is also between two adjacent rods in plane. The position of the defect shown in this paper is thus located at the centre of the FCC lattice, the most symmetrical position. The refractive indices of woodpile and cavity are $n = 3.3$, and background material is air.

The calculated cavity modes with resonant frequencies are obtained by using our in house finite-difference time-domain (FDTD) software. When changing the size of the cavity L from $0.1c$–$2c$ (Fig. 2) the resonant frequency traverse the bandgap region. Variation of Q-factor and mode volume will be presented at the conference. The energy distribution in cavity modes can be seen in (Fig. 3) showing Gaussian like modes. Finer confinement and smaller mode volume can be achieved on reducing L from $0.5c$ to $0.2c$. Two resonant modes coexist in the cavity when $L = 0.8c$ and $L = 1.5c$. Energy distributions of each cavity mode are shown (Fig. 4). Due to the symmetry of x-z plane and y-z plane, only views of y-z plane and x-y plane are shown. The corresponding mode numbers 0, 1, 2 can be distinguished.

We will also present preliminary fabrication results towards woodpile photonic crystals with embedded cavities using our direct laser writing (DLW) system [4] and preliminary progress on simulation and fabrication method for introducing emitter inside low-refractive index cavities.

Dynamic Digital Metamaterials for Single Pixel Imaging Systems

Willie J Padilla
Department of Electrical and Computer Engineering, Duke University, Durham, NC, USA

Abstract— Focal plane arrays form the foundation for the vast majority of imaging systems. However, at wavelengths of 10 μm and longer, it becomes difficult, expensive, and/or impractical to form focal plane arrays for imaging. Single pixel cameras are an alternative method for imaging where cost, size or efficiency rule out use of focal plane arrays. A common implementation of the single pixel camera uses a spatial light modulator (SLM) to multiplex various portions of the image. The multiplexed image is sent to a detector and the measurement is repeated a number of times — usually equal to the desired resolution. Commercially available SLMs are based on either liquid crystals or digital mirror devices. Thus these devices may be modulated only to a few kHz and provide little control of the type of modulation available, i.e., usually only phase and amplitude modulation are offered.

Metamaterial spatial light modulators provide advanced functionality compared to commercially available devices. Here we present metamaterial based spatial light modulators which provide the ability to digitally encode images thus permitting high speed high fidelity images. Images are encoded as the coefficients of the Hadamard matrix which provides the best possible signal to noise single pixel imaging system possible. We also explore the related S-matrix for single pixel imaging and additionally utilizes compressive sensing techniques to increase imaging frame rate. Lastly we highlight the ability of metamaterials to realize hyperspectral, polarimetric, and phase sensitive imaging.

Unlocking the Potential of Liquid Crystals as a Functional Component of Active Metamaterials

Abstract— Metamaterials have rapidly advanced over the past decade and are now expected to have major impact across the entire range of technologies where electromagnetic radiation is used. The current effort in the field is being focused on implementing the idea of active and tuneable metamaterials, a generation of artificial photonic media with dynamically controlled optical properties. The latter should enable to dramatically expand the range of the potential applications of the metamaterials making them the fundamental base of future photonic devices.

The control in such metamaterials is commonly achieved by hybridising their fabric with naturally available functional (e.g., nonlinear, phase change or gain) materials. Among such materials, liquid crystals (LCs) possess arguably the strongest and most broadband optical nonlinearity and birefringence, which can be externally controlled by temperature, light, and electric or magnetic fields. That has made liquid crystals one of the first and most popular ingredients of active metamaterial designs.

Although the refractive index changes characteristic to liquid crystals are extraordinarily large, the expected tuneability of the hybrid metamaterial response is still too modest for some of real-world applications, while in practice the efficiency of the tuning is further reduced due to strong surface anchoring of LC-molecules. The latter, in particular, presents a serious challenge for engineering nano-structured LC-loaded metamaterials operating in the visible and near-IR spectral ranges. In this talk we will discuss various strategies that may help to realize the full potential of electrically-controlled liquid crystals, and will illustrate their practical implementation in active metamaterial hybrids.

Voltage-tunable Hybrid Plasmonic Nanostructures

M. V. Gorkunov, S. P. Palto, M. I. Barnik,
V. V. Artemov, N. M. Shtykov, A. R. Geivandov, and S. G. Yudin
A. V. Shubnikov Institute of Crystallography, Russian Academy of Sciences, Moscow 119333, Russia

Abstract— We demonstrate the electro-optical switching of hybrid plasmonic-liquid crystal structures consisting of subwavelength interdigitated aluminum slit gratings covered with a layer of nematic liquid crystal. We report the switching times of 10 ms and switching voltages of 4–8 volts and discuss the possibilities of further functionality improvements.

Optical properties of subwavelength arrays of metal particles, holes and slits are determined by an interplay of various resonant phenomena: surface plasmon resonances (localized and traveling) [1], Fabry-Perot guided mode resonances [2], Rayleigh and Wood anomalies, etc.. Combining plasmonic metal nanostructures with liquid crystals (LC) and semiconductors one can exploit the high sensitivity of the resonances to adjacent environment and create hybrid materials tunable by temperature, irradiation, fields and voltage [3].

We report the results of fabrication and electro-optical characterization of hybrid plasmonic-LC structures consisting of aluminum subwavelength slit gratings (see Fig. 1(a)) used as interdigitated electrodes that reorient the nematic LC upon voltage applied. Gratings with a period of 330 nm and slit widths of 130 nm (G_1) and 165 nm (G_2) were prepared by focused ion beam (FIB) milling of 80 nm thick aluminum layers thermally sputtered on glass substrates. We report the characteristic switching times of the order of 10 ms and demonstrate that voltages of 4–8 V are sufficient for the electro-optical switching (see Figs. 1(b) and 1(c)), which is in line with our theoretical estimates [3]. We discuss the prospects of employing solid state ingredients (e.g., transparent semiconductors) to speed up the switching and improve the performance.

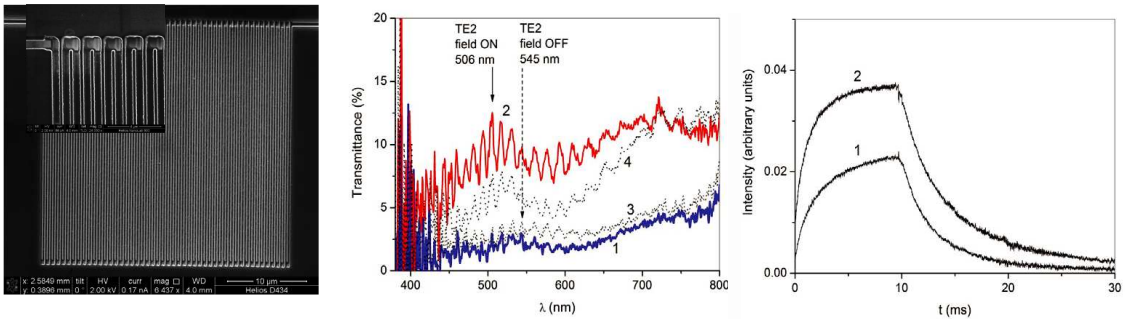

Figure 1: (a) SEM images of interdigitated grating G_2 milled by FIB in Al film; (b) TE transmission spectra of the gratings G_1 (1, 2) and G_2 (3, 4) in nematic LC cell between crossed polarizers in the field-OFF (lines 1, 3) and field-ON (lines 2, 4; $U = 8$ V) states; (c) Time-resolved transmission of the hybrid cell between crossed polarizers for the voltages of 4 V (1) and 8 V (2) applied from 0 to 10 ms.

Multi-stablility and Switching in Superconducting Metamaterials

P. Jung[1], **S. Butz**[1], **and A. V. Ustinov**[1, 2]

[1]Physikalisches Institut, Karlsruhe Institute of Technology, Karlsruhe D-76128, Germany
[2]National University of Science and Technology MISIS, Leninsky prosp. 4, Moscow 119049, Russia

Abstract— We will review our recent experimental studies on ultra-low loss electromagnetic medium comprised of networks of compact superconducting resonators employing SQUIDs as nonlinear tunable meta-atoms.

The design flexibility of superconducting thin-film resonators and circuits allows for utilizing small structures down to the nanoscale while maintaining low loss properties, very strong and well-controlled nonlinearity, and frequency tunability in the microwave and mm-wave frequency range [1]. This approach opens up an opportunity to develop superconducting metamaterials with non-trivially tailored electromagnetic properties, which can be functionalized as ultra-compact resonant magnetic dipole arrays [2, 3], which resonance frequency is widely tunable by varying external dc magnetic field.

Superconducting QUantum Interference Devices (SQUIDs) are implemented as superconducting loops interrupted by Josephson junctions. Recently, we discovered very peculiar multi-stability of SQUIDs in relatively strong ac magnetic fields [4]. In this regime, nonlinear SQUID metamaterials operate as optically switchable microwave propagation media. The nonlinear effects occur in the circuits containing SQUIDs at the high level of the RF-induced current, comparable to the critical current of Josephson junctions. We studied nonlinear properties of SQUIDs integrated into a coplanar waveguide. High microwave currents in the waveguide result in the inductance of the critical current becoming dependent on the instantaneous value of the signal current in the ring. Furthermore, strong microwave driving of a Josephson junction leads to a bifurcation on the lower side of its intrinsic resonance (Josephson plasma resonance). Using a single junction this dynamic bifurcation has been employed to implement a Josephson bifurcation amplifier. The strongly driven Josephson junction enters the bi-stable regime with two stable non-dissipative dynamical states, which differ by both amplitude and phase. The low-amplitude state oscillates nearly in phase with the driving signal, while the high-amplitude state is characterized by the phase shifted approximately by π.

A SQUID-based metamaterial can be operated in a similar multi-stable manner, for which the in-phase response corresponds to positive magnetic permeability χ and the out-of-phase response translates into having χ negative. For properly chosen driving frequency and power, these states are stable and switching between them achieved by changing the driving power or frequency. As these two states with $\chi > 0$ and $\chi < 0$ are both locally stable for a given set of driving signal parameters, they may coexist in a way that some part of meta-atoms oscillate at phase close to π and another part at phase close to 0. Having these groups of meta-atoms mixed together and randomly distributed in the metamaterial should produce kind of birefringence for waves incident on such a metamaterial. Once the two parts are separated by design parameters, they will form an interface between two metamaterials, one with positive and another with negative permeability.

Abstract— Meta-fluidic-materials aim at manipulating light and metal-liquid flow in the microchannel and exploiting their interaction to create highly versatile devices have received significant scientific interests in many areas. The novelties of the integrated meta-fluidic-material are two-fold. First, metal-fluids can be used to carry substances for analysis in highly sensitive optical micro-devices. Second, metal-fluids can also be exploited to control light, making them tunable, reconfigurable and adaptive. In this paper, the state-of-the-art of meta-fluidic-material research is reviewed with breakthrough innovations in optical and photonic devices, including the high potential applications of meta-fluidic-material in biophysical, biochemistry and biomedical studies [1–3].

Meta-fluidic-materials represents a new paradigm for designing light-manipulating devices, such as cloaks, transformation optics and field concentrators, through the engineering of electromagnetic space using materials with spatially variable parameters. Here we report for the first time a proof-of-principle demonstration of a planar metamaterial where resonant properties of every individual metamolecule can be continuously controlled at will. This work provides new insight into the unique optical properties of meta-fluidic devices and their potential applications [4–6].

Meta-fluidic-material is not only to change the material properties through tuning or reconfiguring the unit element structure size or shapes, which is changed by the metal-liquid flow in the microchannel. It is significant breakthrough research for the meta-fluidic-material to demonstrate new materials with new physics phenomena that are never been observed before. In the paper, the different types of meta-fluidic-material will be presented with some future industry applications.

Abstract— We present a fabrication technique for the implementation of ultra-thin, flexible metamaterial membranes with embedded crystalline silicon. The electromagnetic properties of the metamaterial can be optically tuned by an external stimulus. For example, we fabricated a 25 µm thick terahertz bandpass filter whose amplitude transmission could be tuned with a maximal modulation depth of 98% at an operating frequency of 0.67 THz in accordance with the transmission maximum of the bandpass filter. The demonstrated fabrication technique can be universally applied for implementation of more general metamaterial structures and is budget-priced due to the usage of standard silicon.

Introduction: In the last few years metamaterials have gained increasing importance for the implementation of novel adaptive optics in the microwave, terahertz and infrared spectral range. Among various schemes, tuning of the electromagnetic properties of metamaterials by electronic or optical means seem to be the most promising approaches [1, 2]. With respect to optical tuning, the basic methodology relies on the fabrication of plasmonic metamaterial structures on top of thick semiconductor substrates. The drawback of this technique lies in the strong terahertz signal modulation due to etalon effects in the thick substrate and the introduction of artifacts in the measured terahertz spectra. In contrast, ultrathin, optically tunable metamaterials can overcome these limitations due to increased transparency and due to a significantly larger free spectral range that shifts the resonance peaks outside the spectral bandwidth of interest.

Results: Here, we present a methodology for the fabrication of ultrathin adaptively tunable THz metamaterials for the example of an optically tunable bandpass filter. The thickness of the bandpass filter was less than 25 µm and thus sub-wavelength with respect to an operating frequency of 0.67 THz. We obtained a maximal modulation depth of 98% for the amplitude transmission of the filter at the center frequency of 0.67 THz. The maximum amplitude transmission of the filter without photo-excitation was 85%. The fabrication method includes three basic procedures: wet and dry etching of a standard silicon wafer, bonding to a benzocyclobutene polymer and processing and embedding of the metamaterial structure. In the talk, the method will be explained in detail and investigations of the carrier dynamics in a silicon wafer will be presented.

Conclusion: We demonstrate a method for fabrication of ultrathin, sub-wavelength thick metamaterials with embedded silicon as a semiconductor. In general, the presented approach can be applied to a great variety of different metamaterial structures.

Abstract— Extraordinary electromagnetic properties of metamaterials result from the resonant response of constituent elements [1]. At radio frequencies electric and magnetic responses are usually provided by two different types of elements, loop like elements provide for interaction with magnetic field [2] whereas rod like elements govern "dielectric" properties of metamaterials [3]. Lack of suitable materials and fabrication techniques with sufficient precision make radio and microwave metamaterial concepts hardly applicable for optical frequencies. Resent advances in the synthesis of nano-structured particles provide alternative building blocks for optical metamaterials [4]. The desired response can be obtained from the electric and magnetic Mie resonances of nanoparticles. In principle both electric and magnetic resonances can be obtained from a single structure, this being achieved by adjusting the geometry of composite particles to equalize the responses and shift them to the desired frequency. In our contribution we will present an optical metamaterial composed of complex multilayer plasmonic particles with magnetic inclusions. The outer metal-dielectric part of the particle provides for the electromagnetic properties while the magnetic inclusion is introduced to manipulate the particle position in suspensions. In such suspensions particles with intrinsic magnetic moments can arrange into chains under influence of external magnetic field. This property can be used to change the optical response of the suspension by changing the direction of the external magnetic field. For different orientations of the chain axis relative to the light propagation direction and polarization, different structural resonances are excited resulting in different extinction spectra. Optical properties of such magnetically ordered suspensions can be simulated with the help of the superposition T-matrix method [5].

Abstract— Silicon photonics has been of interest for its versatile properties. The silicon bandgap is such that the material is transparent to wavelength commonly used in optical communications (1.28 µm–1.6 µm) and micro-nano-fabrication of structures can rely on large silicon on insulator (SOI) wafers and mature CMOS processes. In order to emphasize the light-matter interactions in this integrated platform, hollow core resonators are needed as well as low interaction volumes, thus meaning large Q/V ratio and small footprint dielectric resonators. Slot photonic crystal cavities are a way to achieve this purpose [1]. Among many candidates, photonic crystal cavities bring a good chance for enhancing photoluminescence of nanomaterials due to their small mode volumes and high quality factors.

We present here the design and fabrication of heterostructure photonic crystal (PhC) cavities on SOI infiltrated by a liquid and with mode volumes of around $0.03(\lambda/n)^3$ [2]. The heterostructure PhC cavities have been reported for achieving very large Q-factors among photonic crystal resonators [3]. We have thus chosen this kind of geometry and have fabricated a series of cavities in order to demonstrate high-Q resonances in a large wavelength window ($1.28\,\mu m \leq \lambda \leq 1.6\,\mu m$). The cavities' design is based on a chirp of the lattice constant in the propagation of light. Fig. 1(a) shows typical scanning electron microscope (SEM) views of the fabricated sample.

Figures 1(b) and 1(c) depict the two cavities in our series of cavities within the resonant wavelength window ranging from 1.3 µm to 1.6 µm. The first cavity is designed with a basic lattic constant $a_0 = 330\,nm$ and presents a resonant wavelength peak at 1284 nm with a Q factor of 10467, and the other one was designed with $a_0 = 400\,nm$ and presents a resonant peak at $\lambda = 1605\,nm$ with a Q factor of 23187. Other fabricated cavities have also proved to have Q factors of around several tens of thousand and (Q/V) values of approximately 800000. The low insertion losses of these devices also prove the quality of the fabrication steps.

We stress that these cavities have been fabricated on silica, i.e., the buried oxide layer of SOI wafers was not removed. In order to properly characterize the samples, we first drop cast an optical liquid on top of the structures ($n_{clad} = 1.46$). Owing to the non free-standing membrane approach explored in this work, these works efficiently demonstrate the potentials of slot photonic crystal cavities relying on a mechanically robust approach to enhance light-matter interactions for silicon photonics nonlinear signal processing and on-chip biosensing.

Abstract— With the data traffic carried over optical-fiber communication systems increasing every year, advanced modulation formats such as QPSK, 16QAM, and advanced parallel transmission technology such as space-division multiplexing are now implemented at baud rates of 25–30 Gbps. Higher-baud-rate optical transmission is very attractive to improve the data rate capacity in long-reach to short-reach communications. Opto-electronic devices are a bottleneck for achieving high-frequency-response performance. For example, in photoreceivers using a transimpedance amplifier (TIA), the 3-dB bandwidth is limited by the TIA's bandwidth of 30 GHz. Using an optical amplifier in place of an electric amplifier (TIA) makes high-baud-rate communication possible because of its wide frequency bandwidth. Very few compact photoreceiver modules operating at high baud rates have been reported. In this report, we present a compact photoreceiver module integrated with a PIN photodiode (PD) and 1.5-μm quantum dot (QD)-based semiconductor optical amplifier (SOA).

We have a developed 60-GHz hybrid integrated photoreceiver, which consists of a 1.5-μm QD-SOA and a high-speed PIN-PD. A maximum responsivity of 25 A/W at a QD-SOA driving current of 400 mA and a 3-dB bandwidth of 62 GHz was achieved. A high sensitivity of −20.5 dBm was obtained through a BER test at 10 Gbps, and a clear eye diagram at 50 Gbps was also obtained. We believe that this design is well suited for high-baud-rate optical-fiber communications. A monolithic integrated device combining the QD-SOA and QD-PD will show higher responsivity. Further, the photoreciever can be used for optical fiber communications including Radio over Fiber communications.

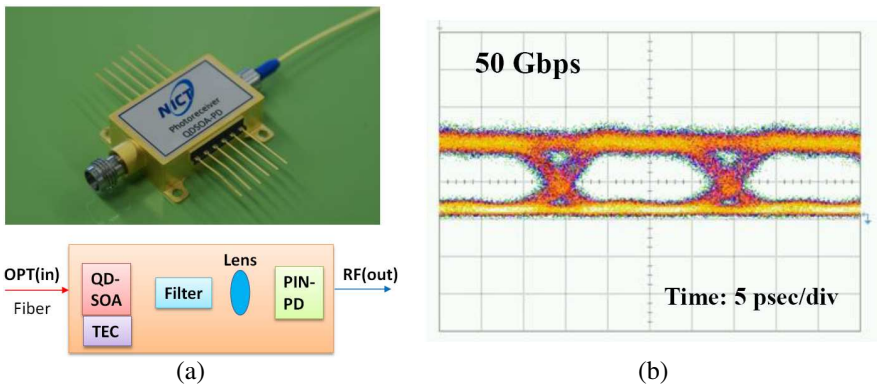

Figure 1: (a) 60-GHz hybrid integrated photoreceiver with a QD-SOA and its schematic diagram, and (b) eye diagram at 50 Gbps, optical input power of −10 dBm, SOA driving current of 290 mA.

Review of Electro-Optic Polymer Nano-Photonic Devices for On-chip Optical Interconnects

Abstract— In the field of optical communication, organic materials and devices are highly complementary to their inorganic counter parts such as silica fibers and semiconductor lasers and detectors. Particularly, organic materials offer large, ultra-fast nonlinear optical (NLO) responses, and broad spectral tunability, and they can be solution processed at low cost onto large-area substrates. NLO organic materials demonstrate superior performance over inorganic NLO materials such as $LiNbO^3$ and silicon. Electro-optic (E-O) polymer materials are second-order nonlinear ($\chi^{(2)}$) organic materials. The refractive indices of E-O polymers can be dynamically changed by an applied electric field, which is known as Pockels Effect. Compared to inorganic E-O crystals, E-O polymers offer intrinsic advantages:

- Large Pockels coefficient with r_{33} values greater than 300 pm/V.
- Ultrafast E-O response time of less than 10 femtoseconds.
- Relatively low dielectric constant ($3 \sim 4$) with small dispersion up to 250 GHz, and very low dielectric loss tangent (10^{-4}).
- Compatibility with virtually any substrate.
- Intrinsic radiation hardness and wide operation temperatures for space communication applications.

During the past 15 years, the E-O coefficient, thermal stability, optical loss, and power handling capability of E-O polymers have been significantly improved by push-pull chromophores, typically consisting of a π-conjugated bridge end-capped with strong electron-donating and accepting groups. E-O polymers have been successfully used for ultra-high-speed E-O modulators, high linearity and high bandwidth RF modulators, hybrid silicon-organic slot waveguide modulators, E-O polymer filled photonic crystal waveguide (PCW) modulators, organic-plasmonic modulators, and polymer ring resonators. This presentation will review the most recent research progress of E-O polymer nano-photonic devices and discuss the applications for on-chip optical interconnects.

Intracellular Molecular Detection by Light Localization Using Graded Plasmonic Nanoapertures

Wonju Lee[1], **Taehwang Son**[1], **Donghyun Kim**[1], **and Eunji Sim**[2]

Abstract— In this study, we explore feasibility of super-resolved axial imaging based on extraordinary light transmission by metallic nanoaperture arrays. Incident light can transmit over several orders of magnitude through subwavelength nanoaperture arrays fabricated at thick metal film due to plasmonic coupling, which is well known as extraordinary transmission (EOT). Many studies based on EOT have generally concentrated on several applications for enhanced sensing techniques. Otherwise, relatively little has been attempted for the resolution enhancement of biomedical imaging based on EOT. For live cell imaging, it is required to observe an axial distance deeper than what is typically done under total internal reflection. Since EOT can be induced to have a much longer penetration depth with a transmission range of a few hundreds of nanometers from surface, sub-diffraction-limited axial sectioning for cellular imaging can be performed. Here, we measured axial information of live cells using subwavelength nanoaperture arrays based on EOT. For axial sectioning of live cells, a linear nanoaperture array was designed to induce a differential penetration depth of EOT formed at apertures of different size. Fluorescent targets were excited up to a different preset distance in the axial direction. Axial distribution of FITC-conjugated ganglioside in mouse macrophage-like cells was analyzed with subdiffraction-limited resolution, 20 nm in the best case, after reconstruction based on signal differences extracted from neighboring nanoapertures. The feasibility of super-resolved axial sampling was extended into gliding bacteria on nanoapertures.

Enhancement of SPR-sensor Sensitivity in Magnetophotonic Plasmonic Heterostructures

D. O. Ignatyeva[1, 2], **S. K. Sekatskii**[3], **A. N. Kalish**[1, 2], **and V. I. Belotelov**[1, 2]

Abstract— We present a novel type of the surface plasmon resonance (SPR) sensor based on the magnetophotonic plasmonic heterostructure and show that utilization of specially designed 1D photonic crystals (PC) along with the magnetic layers (ML) significantly enhances the quality factor and magnitude of the optical and magnetooptical resonances and therefore allows for a several orders of magnitude increase of the SPR-sensor sensitivity.

The sensing heterostructure consists of a plasmonic layer which can be perforated or smooth film of a noble metal (e.g., gold) covered with a dielectric (e.g., bismuth-substituted iron garnet) or metal ML (e.g., cobalt) and coated with 1D PC. ML increases the sensitivity of the SPR-sensor since the magneto-plasmonic resonances are sharper than the plasmonic ones. At the same time 1D PC support ultralong-range propagating modes that enhances the magnitude and sharpens the magneto-plasmonic resonances even more. Although the surface plasmon polaritons (SPPs) can be excited in a magnetic metal directly our analysis shows that the structure where this layer is combined with a film of a noble metal has significantly higher quality factor and is preferable.

We performed the design of the magnetophotonic plasmonic heterostructures and tuned the parameters of the structure in order to enhance the magneto-optical response of the structure via excitation of the ultalong-range propagating SPP mode. The numerical simulations predict extremely narrow plasmonic and magneto-optical resonances and sensitivity enhancement up to 10^{-8} RIU.

Both types of the structures, with dielectric and metal ML were fabricated. The sensing process was performed by two different experimental schemes. Extremely sharp magneto-optical resonance (with a width of about 0.1 degrees) allowed us to detect with a good precision the shift of the magneto-plasmonic resonance position with the variations of the sensor environment. The fabricated spectral sensor sensitivity is 45 deg/RIU (2300 nm/RIU). On the other hand the transverse magneto-optical Kerr effect (TMOKE) is enhanced up to 15% magnitude. Therefore the environment variation can be tracked via the measurement of the absolute value variation of the TMOKE for the fixed wavelength and angle. The sensor magneto-optical response to the refractive index change is 10%/RIU.

Super-period Nanograting Surface Plasmon Resonance Spectrometer Biosensor

Junpeng Guo, **Hong Guo**, **and Xueli Tian**
Department of Electrical and Computer Engineering
University of Alabama in Huntsville, Huntsville, AL 35899, USA

Abstract— Surface plasmon resonance in various metal nanostructures has been extensively investigated for biochemical sensing which detect bonding of biomolecules on metal nanostructure surfaces. Measurement of surface plasmon resonance typically relies on an optical spectrometer that measures the spectrum of transmission, reflection, or scattering light from metallic nanostructures. Here we report a new surface plasmon resonance sensor platform that eliminates the use of optical spectrometers for measuring the surface plasmon resonance. With diffraction grating patterned metal nanostructures, surface plasmon resonance can be measured with a linear photodetector such as a CCD imager in one of the diffraction orders. That way, an optical spectrometer is not needed for measuring the surface plasmon resonance and the shift of resonance due to the bonding of target biochemical. We have demonstrated this new biosensor platform with super-period gold nano-disks, super-period nanoholes, and super-period hybrid metal-dielectric photonics crystal gratings. Our integrated nanophotonics spectrometer biosensor can measure the bonding of bovine serum albumin (BSA) proteins of several nanometers on nanostructure surface. Surface plasmon resonance which cannot be measured in the traditional transmission and reflection modes, can be measured in the diffraction mode with our super-period nano-plasmonics gratings.

Bio-enabled SERS Sensors for Ultra-sensitive Immuno-assay Detection

Abstract— Immunoassay based on specific recognition between an antigen and a complementary antibody has become an essential and reliable tool for clinical diagnoses and diseases detection in recent years. Surface-enhanced Raman scattering (SERS) detection has attracted significant attention due to its narrow spectral bandwidth, immune to photo-bleaching, and fingerprint information of various molecules. Typically, SERS-based immunoassays are implemented on flat glass slides coated with colloidal nanoparticles. These substrates are inexpensive and easy to be functionalized, but the sensitivity is relatively low. Diatoms are photosynthetic microorganisms that create their own skeletal shells of hydrated amorphous silica, called frustules, which naturally possess hierarchical micro- & nano-scale features that are extremely cumbersome and expensive to duplicate by top-down fabrication techniques. In this paper, we present the design, fabrication, and characterization of diatom-based SERS immunoassay by integrating Ag NPs into diatom frustules. The immunoassay was designed according to a standard sandwich protocol of enzyme-linked immunosorbent assay (ELISA). The model antibody, goat-anti-mouse immunoglobulin G (IgG) was first attached to the surface of Ag NPs. The antigen, mouse IgG was then immobilized onto the antibody-functionalized diatom frustules for the specific recognition. To evaluate the specific recognition between the antibody and the antigen, we challenged the immunoassay with a negative control IgG, human IgG. Afterward, the immunoassay was incubated with antibody-functionalized Au NPs, which were initially labeled with Raman reporter, 5,5′-Dithiobis-(2-Nitrobenzoic Acid) (DTNB). We achieved 10 pg/mL detection limit, which is 100× better than conventional colloidal SERS sensors in the comparison group.

Abstract— The design and construction of buildings has historically been driven by structural, functional, and aesthetic considerations. However, the working and home environment is driven increasingly by energy efficiency and electronic communications whether it be the internet, smart energy metering (to be implemented by 2020), telephone, computer data or multimedia exchange and in future by remote patient monitoring (Telecare) and Assisted Living. The wireless performance of building design is not understood and the construction industries do not consider wireless system performance in their designs or specifications despite the rapid employment of metal skins and windows and facades containing metallised layers for energy conservation, both of which are a significant problem for wireless signal propagation. Hence there is a significant need to understand the performance of buildings and construction materials for efficient energy consumption and for the efficient propagation of radio waves.

Security in buildings is also a very important issue. The emergency services require pervasive communications at 400 MHz throughout the built environment. In addition City Managers and built environmental professionals will monitor a range of different aspects of the environment, including factors such as air and water quality, noise and lighting levels as well as human and vehicular movement and behaviour. Most of these services are wireless and they will significantly increase in number and importance in the future. Wireless control is also used in buildings for lighting, heating and energy control systems. The growth of use of these systems into new and demanding applications requires greater efficiency in use of the electromagnetic spectrum and control of wireless interference both within and between adjacent buildings and in the environment itself. Hence, modern buildings must be designed to be wireless radio-friendly and energy efficient whether they are hospitals, schools, offices, prisons or the home.

This paper presents the key findings resulting from the WiFEEB project and addresses how buildings and the built environment can be both energy efficient and wireless friendly. Our objectives have been to develop and verify the new concept of the wireless friendly, energy efficient building. The wireless propagation properties of building and insulation materials have be assessed and are presented. The same properties must be measured for building structures such as walls (internal and external), floors, facades and window systems. These properties have been evaluated from 400 MHz to 20 GHz to include both current and future wireless networks and systems. Results are given resulting from the bespoke optimisation of CAD tools that combine wireless propagation models with energy efficiency models producing a complete model for the built environment. New innovative construction materials such as glass and steel fibre reinforcement are studied and new architectural designs investigated to improve wireless signal propagation while maintaining energy efficiency. Techniques are presented to control wireless propagation within buildings, namely frequency selective surfaces (FSS), smart wall units, adaptive antennas and scattering surfaces. Finally, results of several case studies will be given.

Recycling Radio Waves with Smart Walls

M. Dupré, N. Kaïna, G. Lerosey, and M. Fink
Institut Langevin, ESPCI Paris Tech & CNRS, France

Abstract— We propose to use electronically reconfigurable ultrathin metasurfaces as smart walls to reflect more intelligently the waves in indoor environments. We experimentally prove at 2.47 GHz that it is possible to use these as spatial microwave modulators, using a simple energy feedback. In particular, we show that we can enhance the transmission between two antennas by orders of magnitude or locally conceal a volume from the penetration of waves in a typical office room.

An increasing amount of data is nowadays conveyed wirelessly by radio waves in dense environments such as cities or buildings [1]. While propagating, the electromagnetic waves carrying the information are reflected several times off obstacles such as walls and furnitures, thus causing a spread of the associated electromagnetic energy throughout those complex and reverberating media. This raises health issues and wastes energy. Here we show that part of this seemingly lost energy can be recycled by reflecting more intelligently these multiply scattered waves using smart walls rather than bare ones. To do so we propose to use ultrathin metasurfaces [2] that we design to be electronically reconfigurable in real time as spatial microwave modulators [3]. We show that they can be utilized to cover part of the walls of a typical office room, hence transforming these dumb surfaces into smart ones. We demonstrate that, akin to the spatial light modulators which can focus light through complex media [4, 5], those spatial microwave modulators can passively turn a random electromagnetic field resulting from reverberated and multiply scattered waves into a shaped one using a simple energy feedback and simple optimization algorithms [6]. Specifically, we prove that such smart walls can, in real time, increase by orders of magnitude the energy of a wireless signal received by any antenna or locally conceal a volume from penetration of microwaves [7]. We will present simulation and experimental results as well as a quantitative estimation of the benefits brought by the approach, by introducing and modeling the notion of wavefront shaping in reverberating media.

Our smart walls have applications in green wireless communications and electromagnetic protection. Indeed this approach could be used alongside others [8, 9] to develop energy efficient wireless communication systems. They are also amazing tools for fundamental physics related to the propagation of waves in complex, highly scattering or reverberating media.

An Inductive Frequency Selective Surface for Use in Secure Facilities

Michal Cerveny[1] **and Jonathan M. Rigelsford**[2]

[1]Department of Electromagnetic Field, Czech Technical University
Technická 2, Praha 166 27, Czech Republic

Mappin Street, Sheffield S1 3JD, United Kingdom

Abstract— The use of contraband mobile phones within prisons is an increasing global phenomenon. It enables criminals to continue unlawful activity, including organizing drug deals, assassinations and witness harassment [1, 2]. According to official statistics, 7301 mobile phones or SIM cards were found in UK prisons during 2012 [3]. TETRA (Terrestrial Trunked Radio) is the communications protocol used by emergency services in over 100 countries worldwide and operates between 380 MHz and 420 MHz. It is widely used by Police forces, paramedics, fire brigades, and special response units (including riot police), as well as other government agencies. Historically, cellular mobile phone networks have operated on clearly defined frequency bands. For example, AMPS and D-AMPs was used on systems operating between 806–880 MHz; GSM 900 operates between 880–960 MHz; GSM1800 operates between 1710–1880 MHz; and UMTS 1900–2170 MHz. With the adoption and roll out of LTE and 4G systems cellular network operators have over 40 designated frequency bands which can be used across the existing spectrum allocation and with the addition of newer bands including Band 38 which covers 2570–2620 MHz [4, 5]. Wi-Fi operates in the 2.4 GHz and 5.8 GHz ISM bands and can be used for peer to peer communication on mobile devices.

There are four major issues to consider when designing a system to limit the usability of mobile cellular networks for secure facilities such as prisons. Firstly, mobile phones are capable of sending and receiving messages even when signal strength is low, due to the high sensitivity of the receivers which is typically in the range −110 to −130 dBm. Secondly, the high number of mobile base stations means coverage is vast, so it is probably that many prisons in the UK have good quality signal [7]. Thirdly, to block signals of varying frequencies, a large band stop filter response must be utilised by the FSS, whilst allowing 400 MHz to transmit through. Finally, if the solution such as an FSS, is to be installed into a window frame, optical transparency is essential.

This paper therefore presents an inductive frequency selective surface (FSS) which can be applied to prison cell windows to prevent the transmission of unwanted signals from mobile phones but allows TETRA based systems to operate correctly (as shown in Fig. 1). The performance of the FSS is presented in Fig. 2. In this work it is assumed that the walls of the prison are assumed perfectly isolating and can be achieved using metalized construction materials including

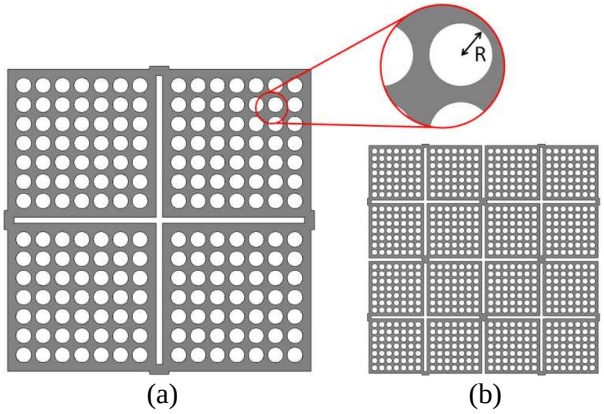

Figure 1: Illustrations of (a) simple inductive cross FSS with better optical transparency by the introduction of an array of holes between the cross arms and (b) an array of 4 unit cells providing 5 interleaved cross elements.

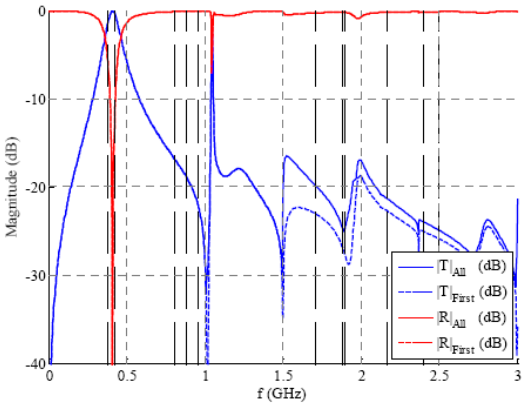

Figure 2: Illustrations of (a) simple inductive cross FSS with better optical transparency by the introduction of an array of holes between the cross arms and (b) an array of 4 unit cells providing 5 interleaved cross elements.

Celotex [8] or Kingspan [9]. Beyond its potential for optical transparency, advantages of the proposed solution over other technologies such as jamming devices or active capacitive FSS [6], are that an inductive FSS is cheap to manufacture as it can be self-supporting and manufactured from a single metallic sheet. Furthermore, it requires no external power supply to correctly run, reducing operating and maintenance costs and is in line with current legislative requirements (i.e., restrictions on jamming overspill for public access areas).

The full paper will provide a detailed description of the FSS design and its performance as well as an assessment of its optical opacity for window applications.

A Simulation Based Distributed MIMO Network Optimisation Using Channel Map

J. Weng, J. M. Rigelsford, and J. Zhang
The University of Sheffield, UK

Abstract— Channel map is an essential tool in network planning and optimisation. In this work, we present an example of MIMO channel map for distributed MIMO network optimisation. Based on the simulation of MIMO channel map, we optimise the MIMO channel capacity and the bit error rate. The results demonstrate that the effectiveness of the MIMO channel map in network optimisation.

An Introduction to Physical-layer Security for Wireless Smart Cities

Matthew A. Bourke, Kenneth L. Ford, Mohammed Benaissa, and Jonathan M. Rigelsford
Department of Electronic & Electrical Engineering, The University of Sheffield
Mappin Street, Sheffield S1 3JD, United Kingdom

Abstract— An overview of physical-layer security theory for wireless communication is presented, along with a discussion of the potential feasibility to smart cities and potential future research directions. For a long time security at the physical-layer has been neglected in favour of computational methods implemented at the upper-layers of the protocol stack. Upper-layer cryptography techniques use encryption with a shared-key to achieve secrecy. This security is invariably achieved using cryptographic methods. Current encryption methods are deemed to be secure because the level of computational power required to crack the keys is not attainable using current technology. Nonetheless, the rise of more powerful technologies such as quantum computing may soon challenge this assumption. The computational complexities required to implement public key encryption prevents low-resource devices from using them. This can have a significant impact on wireless systems for Smart Cities which might be limited in terms of available power or computational overhead.

Cryptography at the physical-layer can be used to complement current upper-layer encryption, or act as an independent security mechanism. This is beneficial for many reasons. It can facilitate upper-layer key exchanges by providing a secure channel and allow independent security mechanisms to be implemented on low-resource devices. The nature of physical-layer cryptography also means that adaptive security measures can be put in place depending on application and classification of the threat. Common types of attacks on wireless systems include:

- **Passive Eavesdropping** — eavesdropping on messages passed between two legitimate parties without actively engaging in any return communications.
- **Denial-of-Service (DoS)** — deny access to legitimate users by exhausting system resources or signal jamming.
- **Spoofing** — masquerading as a legitimate user or system to gain access to privileged resources.
- **Man-in-the-Middle** — relaying messages between two legitimate communication nodes, without knowledge from either user, in an attempt to gain valid authentication.

These attacks can have a big impact on both civilian and military systems. For massively interconnected smart cities these attacks could cause disruptions or damage to smart meters, remote healthcare, transport, and other public services. From a theoretical point of view, information-theoretical secrecy can be achieved at the physical-layer if the signal-to-noise ratio (SNR) of the eavesdropper channel is worse than that of the legitimate receiver; however, problems occur when the eavesdroppers channel is better, or equal to the legitimate receiver. This paper presents a review of current physical-layer security systems and their potential benefits to wireless smart cities.

Selected Aspects of RF Signal Propagation in Buildings

Pavel Valtr[1], **Pavel Pechac**[1], **Ondrej Moravek**[1], **Milan Prihoda**[1], **Lee Ford**[2], **Jonathan M. Rigelsford**[2], **and Richard J. Langley**[2]

[2]Department of Electronic & Electrical Engineering, The University of Sheffield
Mappin Street, Sheffield S1 3JD, United Kingdom

Abstract— Co-existence of various communication services within buildings requires detailed knowledge of behavior of electromagnetic wave propagation in such environment. One of the aspects related to indoor communication is the outdoor-to-indoor penetration. Indoor navigation, for instance, is heavily dependent on indoor signal level due to wall attenuation. Another issue is interference mitigation. This paper addresses several topics related to wave propagation into and within buildings.

The focal point of understanding penetration loss into buildings is the knowledge of electrical properties of building materials. Table 1 shows measured values of relative permittivity and loss tangent of selected building materials. The measurements were done in the frequency range of 5 GHz to 70 GHz and the numbers represent the mean value over the frequency range.

Table 1: Electrical properties of building materials.

Material	Rel. Permittivity	Loss tangent
Plaster board — base	2.14	0.005
Plaster board — wall	2.26	0.005
Plaster board — sound shield	2.78	0.006
Chip board	2.17	0.06
Glass	6.4	0.02

Excess penetration loss due to window blinds and window blind-like structures are usually not taken into account in signal coverage planning. On top of wall attenuation and window attenuation, however, window blinds can impose additional loss which can further downgrade the signal quality from a source located outside the building. Experimental results of window blind insertion loss are presented for frequency range of 5 GHz to 50 GHz, see Fig. 1. The insertion loss is studied depending on frequency, polarization and inclination of the window blind's lamellas. Detailed knowledge of the effects of window blinds on electromagnetic wave propagation can improve existing prediction models.

Realization of a Flexible Technological Demonstrator for HF Sky-wave Data Links

A. L. Saverino[1], **A. Capria**[1], **and F. Berizzi**[1, 2]

[1]Radar and Surveillance Systems (RaSS) National Laboratory, CNIT, Italy
[2]Department of Information Engineering, University of Pisa, Italy

Abstract— Radio frequency range between 3–30 MHz is called high frequency or shortwave radio. For a long time, the high frequency band has been considered as the most important means for communications over long distance. The advent of new technologies, such as satellite and terrestrial communications, made the high frequency systems obsolete. Despite that, a new interest for these systems is growing due to the need of having a relatively cheap and simple system for data and voice exchange, which could be a real alternative to existing system in case of their failure. This paper aims to present an effective and flexible HF digital transceiver demonstrator based on the software defined radio paradigma. The purpose of this demonstrator is to maintain the "essential" information among the authorities in case of the failure of both satellite and Internet communications for critical scenarios (e.g., terroristic attacks, natural disasters).

SC1: Electromagnetic Modelling Methods for EMC Problems

Reciprocity-based Applications of the Time-domain Contour Integral Method

Martin Štumpf
SIX Research Centre, Brno University of Technology, Technická 3082/12, Brno 616 00, The Czech Republic

Abstract— The reciprocity theorem of the time-convolution type is not only the starting point for constructing the time-domain contour integral method (TD-CIM) itself [1], but also it is an efficient means for describing closely related EMC aspects of power-ground structures. This may include, space-time electromagnetic mutual coupling between two power-ground structures [2], pulsed electromagnetic- field radiation characteristics [3], their pulsed radiated susceptibility or even remote sensing of power-ground structure's constitutive parameters, for instance.

In the present contribution it is shown that through the application of the reciprocity theorem with a suitable choice of the 'testing' field state, complex (time-domain) EMC modeling of a power-ground structure is feasible and computationally very efficient. In this analysis, the 'testing' field is found either via the TD-CIM (for arbitrarily-shaped circuits) or using the time-domain 'ray-type' expansion (for rectangular circuits) (see [4], for example).

Systematic applications of the reciprocity theorem related to time-domain modeling of power-ground structures supplemented with the corresponding sample numerical examples will be presented at the 36th PIERS.

Numerical Modeling of Reverberation Chambers: The Cavity Green's Function Boundary Element Method in Comparison to Other State-of-the-art Algorithms

M. E. Gruber and T. F. Eibert
Lehrstuhl für Hochfrequenztechnik, Technische Universität München, Munich, Germany

Abstract— Different cavity Green's function boundary element methods are discussed and compared with other state-of-the-art methods for the numerical modeling of reverberation chambers. The algorithms are compared in terms of accuracy, computing speed and memory requirements. Different scenarios from a reverberation chamber with a single plate stirrer to a chamber with multiple stirrers are considered.

Without acceleration techniques, the use of the cavity Green's function (CGF) boundary element method (BEM) is limited to cavities which contain small, one-dimensional objects [1]. The quadratic complexity in filling the system matrix together with the numerically expensive integral kernel (i.e., the Green's function of the rectangular cavity) impede the modeling of mid- and large-sized objects. To model large objects, different acceleration techniques have been proposed in recent years [2–4]. In 2014, the CGF BEM was accelerated by [2] using the Ewald summation technique together with the adaptive integral method (AIM), where only the near-zone part of the system matrix is computed directly. Far interactions are calculated on-the-fly using AIM during the iterative solution of the matrix-vector equation. In [3], Gruber et al. evaluated the CGF based on the Ewald method. It was observed that the Ewald summation technique can be accelerated with the fast Fourier transform when the Green's function is sampled on an equispaced grid. To calculate values in between the grid, Lagrange interpolation was employed. In [4], the CGF was evaluated with a hybrid approach. The hybrid approach employs the Ewald representation in the near range of the source and a two-dimensional spectral representation in the far range, thereby combining the advantages of both representations. To address the quadratic complexity of the system matrix, a fast group spectral domain approach (FGSDA) was proposed: the system matrix is evaluated in the reciprocal instead of the real-space domain. Although the FGSDA does not reduce the complexity of the system matrix, the constant factor is drastically reduced (over three orders of magnitude) as the integration over test and source domain is not needed in the reciprocal domain.

Besides the CGF BEMs, a hybrid discrete singular convolution (DSC)-method of moments (MoM) was presented in [5]. The electrically large, rectangular cavity is considered in the DSC method while the geometrically more complex objects within the reverberation chamber are modeled with the more flexible MoM. Last bot not least, the specialized methods are also compared to a standard method, namely a multilevel fast multipole method (MLFMM) accelerated free-space Green's function BEM [6].

To analyze the strengths and shortcomings of the different approaches, various scenarios from a reverberation chamber with a single object to a chamber with multiple objects are considered at different frequencies. The algorithms from [3, 4] are, in particular, advantageous when few objects are within the cavity. The AIM accelerated CGF BEM and the standard BEM are favorable when reverberation chambers with many objects are considered.

A Hybrid Computational-statistical Approach to Calculating Electromagnetic Coupling in Complex Environments

T. M. Antonsen, Jr.[1], **G. Gradoni**[2], **E. Ott**[1], **and S. Anlage**[1]

[1]IREAP, University of Maryland, College Park, MD, USA
[2]Nottingham University, University Park, Nottingham NG7 2RD, UK

Abstract— The coupling of electromagnetic radiation into enclosures or cavities through apertures and by circuit elements both electrically small and large has attracted the interest of electromagnetic community for many years. Full solutions of this problem are particularly complicated because of the mathematical complexity in the solution of the boundary-value problem and because of the sensitivity of the solution to details of the enclosure's dimensions, content, and the frequency spectrum of the excitation. These difficulties have motivated the formulation of a statistical description (known as the random coupling model, RCM [1, 2]) of the excitation of cavities, in particular the linear relation between voltages and currents at ports in the cavity, when the ports are treated as electrically small antennas. The RCM has also recently been extended to the case of apertures [3] of arbitrary size. The issue addressed here is the methodology needed to take the results of computational electromagnetic solutions for manageable parts of the system; such as an aperture, an antenna, or a configuration of conducting wires, and integrate these results with astatistical model for the interaction of these parts. The approach will be based on our previous work with rectangular apertures in conducting planes [3]. The key element will be the identification of an appropriate set of fields, far from the system part under consideration, for which an admittance or impedance matrix can be defined and computed. Once this matrix is determined it can be modified according to the RCM prescription to describe the behavior of the part in an enclosing electromagnetic environment.

GPU-accelerated Stochastic-FDTD Study of Lightning-induced EM Fields over Non-deterministic Terrains

G. G. Pyrialakos[1], **T. T. Zygiridis**[2], **N. V. Kantartzis**[1], **and T. D. Tsiboukis**[1]

[1]Department of Electrical & Computer Engineering, Aristotle University of Thessaloniki, Greece
[2]Department of Informatics & Telecommunications Engineering, University of Western Macedonia, Greece

Abstract— A non-trivial number of engineering problems are pertinent, either directly or implicitly, to the electromagnetic (EM) fields produced by lightning strike. This fact has motivated the development of several methodologies, analytical as well as computational, aiming at the precise and efficient prediction of lightning-induced EM pulses. Unfortunately, existing solutions commonly make simplified assumptions regarding the geometric and/or electromagnetic properties of the problems under study, thus rendering the handling of realistic setups rather questionable.

In this paper, we develop a computational framework based on the finite-difference time-domain (FDTD) method that takes into account the uncertainty inherent in certain aspects of lightning-related problems. Specifically, we investigate the effects that the terrain has on the lightning-induced fields, when its geometry is considered non-flat (i.e., its altitude varies with respect to the horizontal x-y plane). The realistic geometric features are realized with the aid of a random rough surface algorithm, where a length-correlation parameter is introduced as an indicator of the terrain roughness. In order to statistically resolve the problem, we first employ the Monte-Carlo method via repeated simulations, as a means to extract the two basic statistical parameters of the EM fields (their expected value and variance). A representative result in the case of the subsequent lightning stroke is displayed in Fig. 1. We next compare our results with a geometric adaptation of the Stochastic FDTD method, based on a covariant-contravariant formulation, where the statistical variation of suitable curvilinear parameters is considered. An attempt is also made to associate the length correlation with the corresponding correlation parameter inherent to the S-FDTD. In the cases examined herein, an almost linear relationship is found to exist.

To accelerate computations and exploit the capabilities of modern multiprocessor GPUs, the full 3D FDTD codes are developed on the CUDA 6.0 programming platform. This decision is favored from the parallelization potential of the FDTD method, the exploitation of which can ensure substantial reduction of simulation times. To guarantee optimal implementation, various parameters (e.g., the block-grid structure) are optimized, and several programming techniques are adopted, including the use of streams for out-of-kernel parallelization, and atomics for avoiding parallelization errors. Our results indicate up to 50 times decrease in execution time for the S-FDTD method and Monte-Carlo approach.

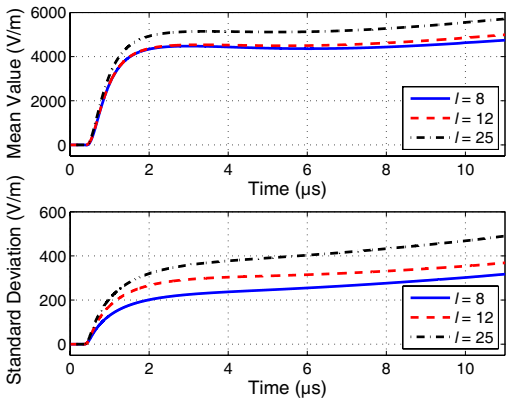

Figure 1: Statistical parameters of the radial electric field, obtained with Monte-Carlo simulations, at position $(r, z) = (100\,\text{m}, 10\,\text{m})$, in the case of non- at terrain. Cases where the correlation length l is set to different values are displayed.

Embedding Anisotropic Carbon Fibre Composite Thin Layers in TLM Simulations

Xuesong Meng, **Phillip Sewell**, **Ana Vukovic**, **and Trevor M. Benson**
The University of Nottingham, UK

Abstract— Carbon fibre composites (CFCs) are widely used in the aerospace and car industries and their electromagnetic properties have been intensively investigated using various experimental and numerical simulation techniques. However, their small thickness and anisotropic properties are still two challenging issues for numerical modelling. We have previously reported a computationally efficient thin layer model [1] for modelling embedded thin isotropic CFC panels with the Transmission Line Modelling (TLM) method. In this contribution, the embedded thin layer model is now extended to the practically important case of anisotropic CFC materials and its role within simulations of more complex 3D geometries are demonstrated.

By definition, the electric and magnetic properties of anisotropic materials vary in different directions. In this paper, CFC thin panels are modelled as anisotropic with respect to the two in plane coordinates (x and y) with the principal directions of the anisotropy assumed orthogonal and aligning with the x and y directions for clarity of presentation. This means that the response of a flat CFC panel to an incident plane wave whose electric field is polarised along one of the coordinate directions can be locally independently modelled using one of two different one-dimensional (1D) thin layer TLM models. In the case of an arbitrary polarisation, $\vec{E}^i = E_x\hat{\mathbf{x}} + E_y\hat{\mathbf{y}} = |E^i|\cos\varphi\cdot\hat{\mathbf{x}} + |E^i|\sin\varphi\cdot\hat{\mathbf{y}}$, where φ is the angle between the electric field $\vec{E}^i$ and the x axis, and $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ are the in plane unit vectors, the incident field is first decomposed into components aligning with the anisotropic principal axes. Each of these components excites a different thin layer model and the net reflection and transmission can be determined by combining the two responses.

As a simple illustration, Fig. 2 shows the comparison of the TLM and theoretical result for (a) reflection and (b) transmission coefficients of an anisotropic CFC thin panel as a function

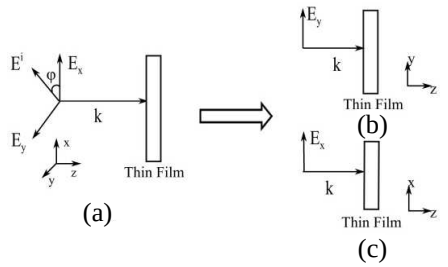

Figure 1: (a) The electric field E^i incident upon an anisotropic thin film can be decomposed into x and y field components. (b) E_y field component incident on a thin film. (c) E_x field component incident on a thin film.

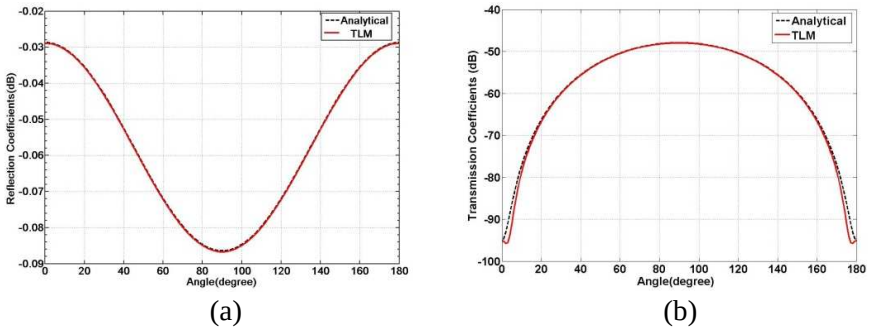

Figure 2: (a) Reflection coefficients and (b) transmission coefficients of an anisotropic CFC thin layer against the angle between the incident field with x axis at 1 GHz. The CFC thin film has the parameters in the x direction $\varepsilon_r = 2$ and $\sigma_e = 10,000\,\mathrm{S/m}$ from [2] and in the y direction assumed $\varepsilon_r = 3$ and $\sigma_e = 1,000\,\mathrm{S/m}$. The thickness of the film is 1 mm.

of the angle between the electric field and the x axis at 1 GHz. It can be seen that excellent agreement between the numerical and the TLM results is obtained. In the presentation, the anisotropic multilayer CFC thin layer model embedded into the three-dimensional examples will also be discussed and more practical examples will be presented.

On the Limits of Numerical Modelling of Electromagnetic Field Coupling through Small Apertures

Gazmend Mavraj and Frank Gronwald
Institute of Electromagnetic Theory, Hamburg University of Technology, Germany

Abstract— The modelling of electromagnetic field coupling through apertures is a classic problem of Electromagnetic Compatibility (EMC). In particular for the case of electrically small apertures a variety of analytic modelling schemes exists [1–4]. In view of numerical modelling it is tempting to apply standard numerical techniques, such as the Finite Integration Technique (FIT) or the Method of Moments (MoM), to this problem as well. However, as a matter of experience, it turns out that a direct application of these standard methods can lead to inaccuracies due to the difficulty of properly discretizing the apertures, see [5, 6] and references therein. In this contribution we want to establish criteria and limits that can be used to estimate whether a standard numerical technique still can be applied to a specific aperture problem. To this end a number of canonical aperture coupling problems is numerically investigated by means of the FIT and MoM and compared to analytical solutions. It is seen that with decreasing aperture size or increasing numbers of apertures the numerical effort becomes impractical and refined hybrid numerical methods are required.

Abstract— The electromagnetic (EM) injection is a technique which has already proved its efficiency for the studies of susceptibility of integrated circuits (IC). Recently, its application in IC cryptographic allowed the generation of significant faults in crypto-system. Near field probes are used to inject EM fault into the circuit. Nevertheless, an understanding of coupling phenomena in term of optimization and efficiency is still lacking. In the context of EM fault injection, probes must be optimized to deliver an intense and localized magnetic field.

Taking into account these optimization criteria, a magnetic loop probe was fabricated and characterized. To concentrate the magnetic field loops are wired around a ferrite-core with a conical cut. The ferrite material is Nickel-Zinc. The diameter of the cylindrical ferrite is about 2 mm, and the ferrite tip ends with a 20 µm diameter size. An electrical model of the probe was established owing to S-parameters measurements. The next step was to understand the EM interaction between the probe and the IC in order to perform an electrical model of the magnetic coupling.

A test chip has been designed by Freescale® in 0.25 µm SMARTMOS 8 technology with 4 metal layers. It allows to study the near-field injection on basic interconnect structures. Voltage sensors was integrated within the chip to measure the local voltage fluctuations induced by EM injection. We conducted this study on 50 Ω micro-strip lines of 1.75 µm × 1 mm deposited on the third layer of metallization. The lines have a 50 Ω termination and are connected to a voltage sensor. The major interest of these sensors is to deliver an accurate measurement of in situ voltage induced by EM injection.

The probe-line coupling is evaluated from measurements results. The basic and intuitive idea of the proposed model is that the system probe-line can be viewed as a transformer. The probe, primary winding, transfers energy to the electrical line, secondary winding, through electromagnetic induction. An equivalent electrical model with lumped elements is proposed. The main advantage is the relative ease of his implementation in SPICE-like electrical simulation software. The most important element to determine is the mutual inductance of the system. We have extracted its using measurements of the voltage coupled under sinusoidal excitation. A good prediction of the interaction between the probe and the IC was obtained on a large frequency range [100 kHz–1 GHz]. Our method has been validated against experiments with a pulse excitation applied to the probe since this kind of excitation signal is frequently used to inject EM faults in IC. Excitation signal is a square at 10 MHz repetition and 10 V peak to peak. Rise and fall times are 10 ns with a pulsewidth of 50 ns. Measurements and calculated results using our model are shown in excellent agreement, thereby validating the model. This procedure will thus be an interesting and useful tool to predict the disruptive effect induced by magnetic probes on secure ICs.

Bound States in the Continuum: Interference Way to Trap Electromagnetic Waves in Open Resonators

Almas F. Sadreev
L. V. Kirensky Institute of Physics, Krasnoyarsk 660036, Russia

Abstract— In 1929, von Neumann and Wigner [1] predicted the existence of discrete solutions of the single-particle Schrödinger equation embedded in the continuum of positive energy states, bound states in the continuum (BSC). Their analysis long time was regarded as mathematical curiosity because of certain spatially oscillating central symmetric potentials. Situation cardinally has changed after Friedrich and Wintgen [2] in framework of two-level Fan-Anderson model formulated the BSC as a resonant state whose width tends to zero as at least one physical parameter varies continuously. Physically a localization of one of resonant states of open system, i.e., the BSC can be interpreted as destructive interference of two resonance states which occurs for crossing of eigen levels of the closed system. That accomplished by avoiding crossing of the resonant states one of which transforms into the trapped state with vanishing width for crossing of the eigen levels of closed system [2]). This simple phenomenon has the same significance as the Aharonov-Bohm effect or the Anderson localization because all of them are manifestation of quantum interference effects.

We propose two layouts for experimental observation of trapping of microwaves inside the open resonator. The first one is the rectangular plane resonator with variable width with two attached waveguides which support propagating TM electromagnetic modes in the first channel [3]. For variation of the resonator's width an accidental degeneracy of two eigenmodes with the same symmetry might occur. A variation of the shape can be achieved by moving well of the resonator or by squeezing of the waveguides. We show that for this process the nearest resonances undergo avoiding crossing during of which one of the resonance widths becomes zero. That is the bound state in the continuum accomplished by intersection of transmission zero with the transmission maximum. That phenomenon was observed by Lepetit et al. [4, 5] in metallic waveguide with dielectric resonator in the THz range. The BSC is trapped mostly inside the open resonator.

The second layout consists of two identical resonators connected by waveguide [6]. Resonators are opened by attaching of waveguide resulting transmission through double resonator's system. Each resonator has multiple transmission zeros at some frequencies and therefore serves as a mirror. Whole system can be interpreted as the Fabry-Perot resonator at these frequencies which supports respectively the bound states [7] for definite quantized distances between the resonators. The double-bent waveguide presents the type of waveguides in which both types of the bound states occur. Each corner is capable to trap electromagnetic waves below the continuum [8, 9]. For definite lengths of bridge between the corners bound states in the continuum occur [10].

We show numerically that the bound states in continuum can be excited for transmission of wave packet if a width of resonator dot is varied linearly in time and reaches those selected values of the width when the BSC arises. Moreover we consider numerically a decay process of different eigen-states in the closed resonator to show that some of them trap in the BSC after the QD is opened [11].

Mode-matching Analysis of TEM Wave Reflection by a Junction of Perfectly Conducting and Impedance Coaxial Waveguides

Ö. Yanaz Çınar[1], **G. Çınar**[1], **and S. Akşimşek**[2]

[1]Eskişehir Osmangazi University, Turkey
[2]İstanbul Kültür University, Turkey

Abstract— In this paper, the reflection of TEM waves by a step discontinuity on the junction of perfectly conducting and impedance coaxial waveguides is analyzed rigorously by applying modematching technique. Such problems may occur on certain microwave measurement systems where the cable on test is coated with a dielectric material. The formulation of the problem is achieved by defining field components at each side of the junction seperately and matching them at the junction by the use of continuity relations (see Fig. 1(a)) as described in [1, 2]. Leontovich boundary conditions are assumed on the coated walls of the cable on test. Finally, the coatings on the inner and outer walls are assumed to be different as shown in Fig. 1(b) and the formulation is repeated accordingly. At the end of the analysis, the effects of the cross-sectional areas of the waveguides and the coatings on the walls of the cable on test are illustrated numerically.

On the Type of Wave-incidence in Multiple-cylinder Diffraction Analysis at 60 and 100 GHz

José-Víctor Rodríguez, **Juan Pascual-García**, **Maria-Teresa Martinez-Ingles**, **Jose-Maria Molina-Garcia-Pardo**, **and Leandro Juan-Llácer**
Universidad Politécnica de Cartagena, Cartagena, Murcia, Spain

Abstract— The analysis of radiowave multiple-diffraction has been carried out through a large number of formulations which, usually, consider a plane-wave incidence over the array of diffracting obstacles. However, when it comes to a transmitter located at a small distance from the series of elements, a spherical-wave incidence assumption could be more appropriate in order to obtain more accurate and realistic results. In this work, a comparison of plane against spherical-wave incidence consideration in multiple-cylinder diffraction analysis is performed, both at 60 and 100 GHz, in order to clarify the margin in which both incidences differ. In this sense, the scheme of the propagation environment considered can be observed in Fig. 1. Moreover, the attenuation due to multiple-cylinder diffraction obtained with the uniform theory of diffraction-physical optics (UTD-PO) formulation proposed in [1], when assuming both plane and spherical-wave incidences, is depicted — as a function of d (distance between the transmitter and the first cylinder) — in Fig. 2, for n =10, $\alpha = 1°$ (with H properly varying with d in the spherical case), $w = 0.232$ m, $r = 0.04$ m, frequencies of 60 and 100 GHz, and *soft* and *hard* polarizations. The relative error between the two solutions ([*Att. Spherical* — *Att. Plane*]/*Att. Plane*) is shown in Fig. 3.

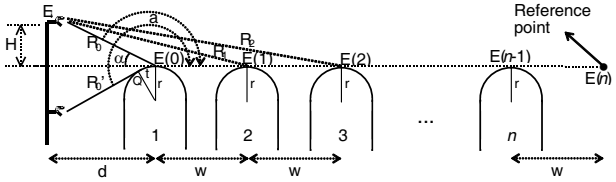

Figure 1: Scheme of the propagation environment under study.

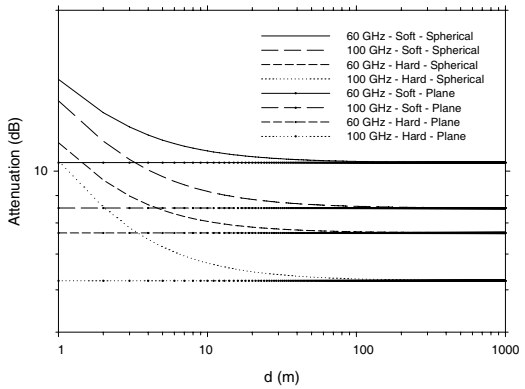

Figure 2: Comparison between both incidences.

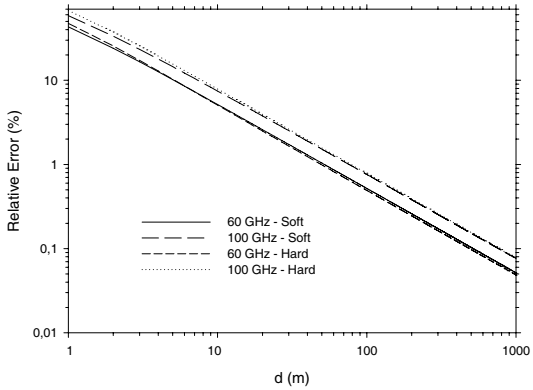

Figure 3: Relative error between both incidences.

As can be observed, it is not until $d = 105$ m that the relative error between the two types of wave incidence is less than 0.5%, for 60 GHz, and 0.75%, for 100 GHz.

On the Importance of Double Bounce Diffuse Scattering in Indoor Wireless Channels

Juan Pascual-García, **José María Molina-García-Pardo**, **José Víctor Rodríguez**, **María Teresa Martínez-Inglés**, **and Leandro Juan-Llácer**
Universidad Politécnica de Cartagena (UPCT), Cartagena, Murcia, Spain

Abstract— The diffuse scattering propagation mechanism accounts for a significant percentage of the received energy, even at high frequencies. One of the most accurate diffuse scattering models is the Lambertian model which is based on the Effective Roughness approach [1]. This model allows the incorporation of diffuse scattering in ray tracing tools and the development of propagation prediction tools based exclusively on diffuse scattering. However, only single bounce diffuse scattering components have been considered so far. Double bounce diffuse scattering must be considered in order to increase the accuracy of the channel analysis. In this work, double bounce diffuse scattering components are considered in a ray tracing (RT) tool allowing a more accurate wireless channel simulation at 60 GHz in an indoor environment. The Lambertian model was selected for both single and double bounce scattering components; both formulations are shown in [1]. The frequency response in the range [57–66 GHz] was simulated and measured in the position depicted in Fig. 1. Subsequently, the complex impulse time response (CIR) was obtained by applying the inverse Fourier transform. As seen in Fig. 2, the double-bounce scattering allows a better agreement between simulations and measurements since single bounce components travel a maximum of 10 meters.

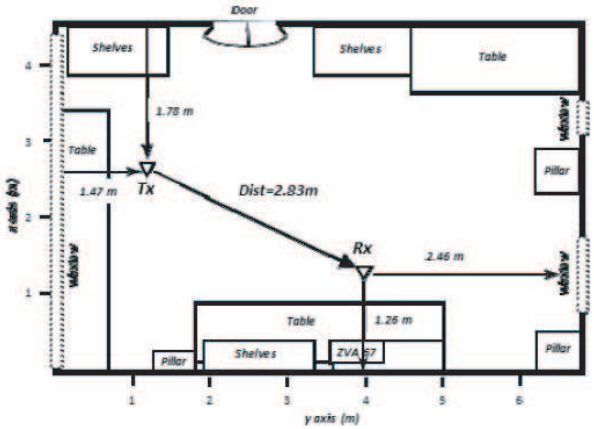

Figure 1: Indoor scenario.

Determination of Optimal Pairs of Radii of Dielectric Samples for Complex Permittivity Measurement of Dispersive Materials

R. Kushnin, **J. Semenjako**, **and T. Solovjova**
Riga Technical University, Latvia

Abstract— The goal of this work is to find the optimum pair of values of radii of two full height cylindrical samples with the same constitutive properties centrally located in a rectangular waveguide for measurements of the complex dielectric constant. A pair of values of radii of samples is called optimal if the value of measurement uncertainty for that pair is smaller than for other pairs of values. One of the problems of this kind was first considered by Paez et al. in [1], where the optimal value of a circular cylindrical post in a cylindrical resonant cavity was found by using the well-known Monte Carlo method. A similar problem was considered in [2], where the optimum value of the radius of a circular dielectric post in a rectangular waveguide was found.

Notwithstanding the advent of powerful computers, the uncertainty analysis still remains a very time consuming task, because the Monte Carlo method requires a very large number of iterations in order for estimation of the measurement uncertainty to be reliable and because in each of these iterations the inverse scattering problem needs to be solved that, in turn, is very time consuming task. Since the computational effort required to solve the inverse scattering problem depends directly on the computational time required by the method for the direct scattering problem one needs to find the fastest approach for solving the direct scattering problem. From many approaches that have been proposed over the last several decades, we have chosen that proposed by Sahalos et al. [3] as it provides reasonably accurate results and at the same time shows very rapid convergence.

Also, in [2] the further reduction in the computation time have been achieved by using piecewise linear interpolation of the reflection and transmission coefficients, but unfortunately this type of interpolation is quite inaccurate in vicinity of resonances. We found that it is more efficient to interpolate the sum and difference of the reflection and transmission coefficients, since for a symmetric obstacle both these quantities have absolute value equal to unity for all real values of the relative dielectric constant that, in turn, means that each pole of this function have the corresponding root such that they are mutually complex conjugate values. Also, these two functions are analytic with respect to the relative complex dielectric constant. Both these properties enable us to use rational approximation involving the roots and poles of theses functions. These pairs can be found successively from the derivative of the phase of the functions. Also, we found that it is more convenient to work with normalized system parameters instead of actual ones, as in the case of a dielectric obstacle two of three parameters take values in limited intervals, since the waveguide is intended to be operated in the single-mode regime. In this study we use the following three normalized quantities, namely, the relative wavelength, relative radius and relative dielectric constant. Numerical studies show that it is sufficient to find only first twenty root-pole pairs. However, for lossy materials such approximation is not accurate, since more poles and roots are required, because the number of root-pole pairs to be taken into account increases as the imaginary part of the complex dielectric constant increases. Fortunately, this issue can be overcome by using asymptotes for root-pole pairs, namely, it is found that for large values of the dielectric constant root-pole pairs can be divided into several groups such that for each of theses groups asymptotic approximation can be found.

Method of Measuring the Dielectric Constant of Grain in Granaries Using Electromagnetic Antennas

Leidong Yang, **Bingfang Wu**, **and Fangming Wu**
Institute of Remote Sensing and Digital Earth, China Academy of Science, China

Abstract— A method is proposed in this paper to calculate the dielectric constant of grain in granaries by measure the speed of electromagnetic wave transforming in the grain.

In granaries, the quantity of the grain is calculated by its volume and density. The grain's standard density can be measured by specific device but cannot be used to calculate the quantity directly. In order to measure grain's storage density, the dielectric constant is used as a middle parameter in this paper. With the same grain sample, the dielectric constant varies with its density which is changed by vibrating [1]. In electromagnetic theory, when electromagnetic wave transfers in medium, its speed depends on the medium's dielectric constant. As to measure the dielectric constant of grain, the transforming speed of electromagnetic wave in it is measured. An experimental device based on electromagnetic wave antenna is designed. The antennas will be input into grains in parallel, and electromagnetic wave will translate between the antennas. The speed of the electromagnetic wave will be measured and the dielectric constant of grain can be calculated.

The largest transmission distance of electromagnetic wave in medium depends on its frequency. The frequency of electromagnetic wave used in these experiments ranged from 10 MHz to 16 MHz. The speed of electromagnetic wave is so fast that some high precision chips were used to measure the tiny difference of phase in the experimental device. Several experiments were done in granaries which have wheat stored in them and the result will be analyzed in the paper.

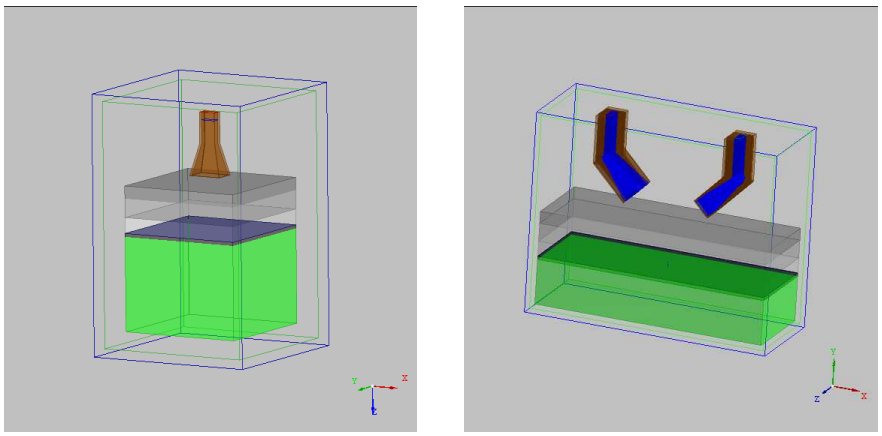
On the Possibility of Water Detection under Asphalt Layer Using Microwave Radar System

A. V. Brovko
Yuri Gagarin State Technical University of Saratov, Russia

Abstract— Detection of water between asphalt and concrete layers is important part of monitoring and maintenance of road quality. For the sake of non-destructive evaluation of the road state, different NDE/NDT technologies can be used. In his paper, possibility of application of microwave radar system for detection of water layer under asphalt is explored.

Two types of radar system is considered: the system with a single antenna (Fig. 1(a)), and the system with two horn antennas (Fig. 1(b)). The performance of the system was estimated numerically with FDTD modeling of wave diffraction on the layers of road.



(a) (b)

Figure 1: Numerical model of (a) single antenna and (b) multiple antennas radar systems for detection of water under asphalt layer.

Numerical analysis allows making the following conclusions:

- Detection of water layer under asphalt with the use of microwave energy is possible.
- System with two horn antennas is more sensitive to the water layer in terms of transmission coefficient S_{21}.
- System with TE polarization of electromagnetic wave is less sensitive to the water layer in terms of transmission coefficient S_{21}, than the system with TM polarization.
- With increasing of water layer thickness from 0 to 1 mm the difference in S_{21} parameter is increasing gradually, but after 1 mm the difference in S_{21} is small.
- Dissipated power in water layer is of the same values as in the first asphalt layer dispite of smaller values in the intermediate layers; this provides potential way of elimination of water from asphalt layer by microwave heating.

Detection of Discontinuities in the Samples of Changing Sizes with ANN-based Technique

A. V. Brovko
Yuri Gagarin State Technical University of Saratov, Russia

Abstract— Detection of discontinuities in dielectric samples using microwave imaging is an important part of non-destructive evaluation and testing technology. Recently, the technique of detection of a spherical inclusion in homogeneous dielectric sample has been proposed [1]. The technique is based on application of artificial neural network (ANN) as numerical inverter, which is trained with numerical modeling data, and after training the ANN may be applied for reconstruction of the inclusion parameters using physical measurement results. Advantages of the approach described in [1] include simple measurement technique and possibility to work with closed measurement waveguide system. However, the technique is limited to the case of constant sizes of dielectric sample. Variations of sizes may destroy completely the procedure and corrupt the results. Moreover, the technique described in [1] requires changing of the positions of sample inside measurement system in the course of measurement, which is not convenient for practical implementation.

In this paper, the attempt to overcome the limitations of technique, described in [1], is undertaken. The sizes of sample are included into a set of parameters which are reconstructed using ANN. In order to provide more input information for ANN to reconstruct the extended set of parameters, different multiport measurement systems are investigated in this paper, namely, turnstile waveguide junction, and junctions of four and five rectangular waveguides.

Numerical experiments with spherical inclusion of changing radius, position, and dielectric permittivity, and changing sizes of rectangular sample of constant homogeneous material show that turnstile junction measurement system permits to reach relative errors 1.5%–3.5% in determination of position of the inclusion, 3%–4% in determination of radius of the sphere, 7%–15% in determination of permittivity. Application of five-port rectangular waveguide junction leads to increasing the relative errors to the following values: 6%–10% in determination of position of the inclusion, 4%–7% in determination of radius of the sphere, 8%–16% in determination of permittivity. Application of four-port waveguide junction seems to be not practical because of too large relative errors in determination of the parameters of inclusion.

Explicit Discretization Schemes for Linear Sampling and Factorization Methods

M. N. Akıncı and M. Çayören
Department of Electronics and Communication Engineering, Istanbul Technical University, Turkey

Abstract— Qualitative inverse scattering consists of various inverse scattering techniques, which aim to recover only the shape of the target rather than the frequency dependent dielectric parameters of the scatterers [1]. These methods have certain advantages over quantitative approaches. Simplicity of implementation and requirement of less computational resources are just two examples of these advantages. Contradictory to this circumstance, such methods are not widely used in engineering applications like subsurface sensing [2, 3], medical imaging [4] and etc.. In particular, finding a mathematical treatment for the derivation of the explicit discretization schemes of such methods is a problematic issue, especially in the near field region [3, 5]. In this context, this work presents a mathematical derivation of the explicit discretization schemes for two famous qualitative inverse scattering methods, which are the linear sampling method (LSM) and the factorization method (FM), for certain near field measurement scenarios. Explicitly, we mathematically derive the discretizations of the well-known "near-field equations" for three different case: measurements taken on a planar surface, measurements taken on a cylindrical surface, measurements taken on a spherical surface. Apart from giving the discretization of the near-field equations for different measurement configurations, we also mention how the discretized equations related with the physical interpretations of LSM [6, 7]. It is important to note that after understanding the mathematical and physical principles which motivate the LSM and the FM, it is straightforward to extend this analysis to another measurement configurations. Lastly, we also give several experimental reconstructions, which are obtained from Fresnel data [8, 9], to prove the accuracy the derived discretization schemes.

Abstract— The scaled gradient projection (SGP) method [1] is a variable metric forward-backward algorithm designed for constrained differentiable optimization problems, as those obtained by reformulating several signal and image processing problems according to standard statistical approaches. The main SGP features are a variable scaling matrix multiplying the gradient direction at each iteration and an adaptive steplength parameter chosen by generalizing the well-known Barzilai-Borwein rules.

An interesting result recently shown by Bonettini [2] is that SGP can be exploited within an alternating minimization approach in order to address optimization problems in which the unknown can be splitted in several blocks, each with a given convex and closed feasible set. Classical examples of applications belonging to this class are the non-negative matrix factorization [3] and the blind deconvolution [4] problems.

In this work we applied this method to the blind deconvolution of multiple images of the same target obtained with different PSFs. In particular, for our experiments we consider the NASA funded Fizeau interferometer LBTI of the Large Binocular Telescope [5], which is already operating on Mount Graham and has provided the first Fizeau images, demonstrating the possibility of reaching the resolution of a 22.8 m telescope. Due to the Poisson nature of the noise affecting the measured images, the resulting optimization problem consists in the minimization of the sum of several Kullback-Leibler divergences, constrained in suitable feasible sets accounting for the different features to be preserved in the object and the PSFs.

Inverse Source in a Multipath Environment

A. Cuccaro, R. Solimene, and R. Pierri
Dipartimento di Ingegneria Industriale e dell' Informazione
Seconda Unviersita' degli Studi di Napoli, via Roma 29, Aversa 81031, Italy

Abstract— Generally, the problem of detecting and localizing small targets can be tackled by adopting a number of different methods. Migration algorithm, time reversal and strategy based on compressive sensing (when the scene under investigation is sparsely populated) are only a few of examples of them. In all inversion techniques, from the scattered field (radiated field if the target is a source) collected over domain, the position of target have to be inferred. However, it often happens that apart from the field due to the target, the fields produced by further object (generally unwanted) are collected as well. This degrades the performance achievable and the detection can be fail.

In this contribution we measure ourselves with this problem, or rather we addressed the detection of point-like sources in multipath environments. This entails dealing with an inverse source problem. More in detail, the scenario of interest includes an ensemble of point-like passive elements (infinitely long PEC cylinders) positioned between investigation domain (containing only the source) and measurement line. A two dimensional scalar framework is set.

From physical point of view, extra in-homogeneities in the environment originates multipath. Multiple scattered waves are often treated as a disturb to be rejected as they give rise to spurious artifacts in the reconstructed images. However, if the in-homogeneous background is someway characterized (i.e., because it is artificially created) these waves can be exploited positively.

In particular, using effectively this spatial diversity and not a priori discard it, we compare two different linear inversion schemes. The first strategy consists in inverting the radiating operator, which rigorously describe the radiation and interaction between the source and passive elements. In the second one, the inversion is achieved by back-projection, which is one of the methods most commonly used in imaging.

We will show how the performance achievable change with the passive structure compared to the free-space, and how the detection system depend on the positions of these extra-scatterers. Finally, we establish which of two different strategies exploits the best the multipath introduced artificially.

Quantitative Imaging in an Aspect-limited/transmission Configuration: Incorporation of Antennas Radiation Pattern

C. Eyraud, **A. Litman**, **S. Nounouh**, **and H. Tortel**
Aix-Marseille Université, CNRS, Centrale Marseille, Institut Fresnel UMR 7249, Marseille 13013, France

Abstract— Electromagnetic wave probing is an interesting tool to obtain the physical features of unknown targets (position, shape, size, complex permittivity). Indeed, these characteristics can be retrieved from scattered fields measurements thanks to the resolution of a non-linear inverse problem. A key point when dealing with quantitative imaging and experimental data is the calibration procedure.

In spherical/circular configurations, when the antennas are sufficiently far away from the target, the calibration can be performed with a single complex coefficient calculated using a reference target. When the antennas are moving closer to the target, even in full-aperture configurations, the impact of the antenna radiation pattern must be investigated, and more complicated calibration procedures might be required. For example, full coefficient matrices can compensate from the fact that, in antenna arrays, the illumination may differ from one antenna to the other. As well, in aspect-limited configurations, the radiation pattern of each antenna greatly influences the target illumination as well as the scattered field collection.

In this work, we consider a transmission configuration, with antennas moving on open-line. This complicated situation forces us to take into account the effective behaviour of the emitters and the receivers. We thus propose to properly model the radiation pattern of the involved antennas by means of a linear combination of electric dipoles and to incorporate it in inversion algorithms. The forward model as well the computation of the various gradients which are involved in the inversion procedure will be affected by such a model. In this talk, we will analyse the influence of these information thanks to reconstructions obtained from measurements performed in an anechoic chamber.

Frequency and Polarization Diversity in through-the-wall Breath Detection

[3]Dipartimento di Ingegneria Industriale e dell'Informazione, Seconda Università di Napoli, Italy

Abstract— In this paper a novel through-the-wall (TTW) breath detection system is studied in terms of different operating frequencies and signal polarization diversity for improved accuracy. The measurement set-up is organized as in Figure 1(a) and includes two sets of circularly-polarized patch antennas (Figure 1(b)) fed by a Vector Network Analyzer (VNA) placed one meter away from a conventional 12-cm thick wall. A subject breathing normally is positioned at a distance of one meter from the other side of the wall with the chest oriented in the direction of maximum radiation of the antenna (1.5 meter from the ground). The return loss of the antenna is acquired at the frequencies 1,575 and 2.575 GHz for vertical, horizontal and Circular-Polarization (CP) of the antenna system, respectively. This large dataset allows a deep investigation on the effects of frequency- and polarization-diversity on the accuracy of the vital sign detection. In particular, measurements taken for different polarizations allow an understanding of the effects of ground bouncing and signal rotation.

The antennas used for the study are CP patches, which offer high gain at minimum complexity. Measurement at 1.575 GHz were conducted using two antennas, located next to each other: one rightand one left-hand circularly polarized. For 2.575 GHz measurement, where the spacing between antennas is more critical due to shorter wavelengths, a dual circularly polarized antenna [1] was used. This allowed to achieve perfect colocation of both polarizations.

As for the breath detection methods, different algorithms are evaluated. In particular, a classical Fourier based method is compared with a novel version of the MUltiple Signal Classification (MUSIC) algorithm.

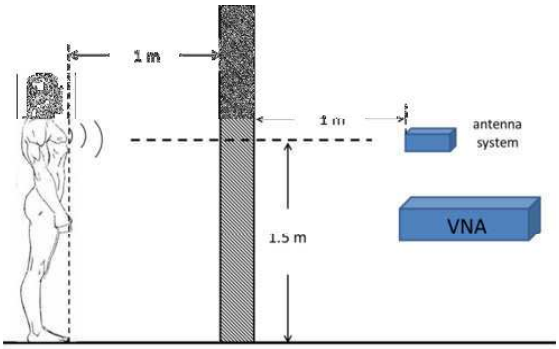

Figure 1: Detail of the measurement set-up.

Waveforms for SAR Imaging in Dispersive Material

N. A. Cartwright
State University of New York at New Paltz, USA

Abstract— Precursor waveforms are derived from the asymptotic analysis of plane waves scattered from an isotropic point scatterer. These waveforms are then used as the transmit waveform for synthetic-aperture radar imaging through dispersive material. Numerical simulations are used to compare these waveforms with "optimal waveforms".

Motivation: As an electromagnetic wave propagates through a dispersive material, those frequencies that lie below the absorption band experience the least amount of attenuation and hence become the dominant contribution to the field for large propagation distances. Asymptotic analysis has shown that in dielectrics, this low-frequency contribution, the so-called Brillouin precursor, has a peak amplitude point that decays algebraically with propagation distance z, as $z^{-1/2}$ [1]. It has been suggested that near-optimal pulse penetration is possible by using the Brillouin precursor as the transmit pulse, which may then have applicability to radar imaging [2].

The question as to which transmit pulse produces an optimal image in synthetic-aperture radar imaging through dispersive media was addressed in [3, 4]. For large signal-to-noise ratios, the optimal waveform "closely resembles the precursor which is generated from a one-cycle sinusoid. This suggests that under certain conditions, precursors may indeed be useful as transmit waveforms in SAR imaging" [4].

Method of Analysis: Here, we derive the low-frequency transmit precursor waveform for imaging isotropic point scatterers embedded in a Debye-type dielectric material indicative of foliage. This "scattering precursor" is obtained by asymptotic analysis of the integral equation for the scattered field using the Born approximation; it is given in terms saddle point locations and modified Weber functions. In comparison to the Brillouin precursor (or the nonscattered precursor), the scattering precursor pulse consists of higher frequencies but it too has a peak amplitude that decays algebraically with propagation distance, now as $z^{-3/2}$.

Numerical Simulations: We compare the propagation characteristics and imaging results obtained for each transmit pulse (both the nonscattered and scattered precursor waveforms, and the optimal waveform given in [4]). Comparison of the bandwidth of each received pulse gives the spatial resolution of each transmit pulse. It is clear from the results that which waveform is "optimal" depends upon the propagation distance from transmitter to scatterer and back, as well as the dispersive properties of the material.

SC2&3: Optoelectronics and Photonics of Graphene and Two-dimensional Materials

Graphene Photonics and Optoelectronics

Andrea C. Ferrari
Cambridge Graphene Centre, University of Cambridge, CB3 OFA, UK

Abstract— Graphene has great potential in photonics and optoelectronics, where the combination of its unique optical and electronic properties can be fully exploited, the absence of a bandgap can be beneficial, and the linear dispersion of the Dirac electrons enables ultra-wideband tunability [1–3]. Despite being a single atom thick, graphene can be optically visualized [4]. The linear dispersion of the Dirac electrons enables broadband applications. Saturable absorption is observed as a consequence of Pauli blocking [5–7] and can be exploited for mode-locking and Q switching of a variety of ultrafast and broadband lasers [1, 5–8]. Chemical and physical treatments enable luminescence [1, 8]. Graphene and other two-dimensional materials are also ideal as photodetection platforms [1–3]. The versatility of these material systems enables their application in areas including ultrafast and ultrasensitive detection of light in the ultraviolet, visible, infrared and terahertz frequency ranges [1–3, 10–13]. These detectors can be integrated with other photonic components based on the same material, as well as with silicon photonic and electronic technologies. By combining graphene with plasmonic nanostructures, the efficiency of graphene-based photodetectors can be increased, because of efficient field concentration in the area of a p-n junction [10]. Light-graphene interaction can be tailored by using microcavities [11].

Graphene Based Optical Modulators

Vito Sorianello[1], **Michele Midrio**[2], **and Marco Romagnoli**[1]

[1]Laboratory of Photonic Networks, CNIT, Via Moruzzi 1, Pisa 56124, Italy
[2]CNIT, Università degli Studi di Udine, Udine 33100, Italy

Abstract— Graphene is shown to allow for the design of an SOI phase modulator with negligible residual amplitude modulation, low insertion loss and record figures of merit with respect to any other technology used so far. In fact graphene based optoelectronics is attracting increasing interest because graphene electro-optical properties can be tuned with a proper gate, as well as because graphene is technologically compatible with other materials, and substantially wavelength independent.

Graphene-assisted electro-absorption modulators, photoconductors and other photodiodes have been demonstrated recently [1, 2]. However, for telecom applications, notably when complex modulation formats are employed to increase the spectral efficiency, availability of phase modulators is of paramount importance too. In this work we show that graphene may allow to realize such a component, with better performance than existing technologies.

A Graphene-Insulator-Graphene capacitor on top of a Si waveguide is used to induce a proper shift of the Fermi potential in graphene. With large enough carrier concentration on the graphene layers, graphene becomes an almost transparent material due to Pauli's blocking principle. Any further change of the carrier concentration only impacts on the graphene dielectric constant. This way, biasing the capacitor and subsequently modulating the applied voltage, phase modulation is achieved [3]. A voltage-length product as low as $V_\pi L = 0.1\,\mathrm{Vcm}$ can be obtained, with an insertion loss of 12 dB/cm. This yields the overall record FOM of 1.2 VdB in a device with driving voltage, footprint and energy per bit consumption in the range of 1 V, $0.5 \div 1$ mm and 0.25–0.01 pJ/bit at 50 Gb/s, depending on the modulator configuration. These figures show that graphene outperforms any other technology used so far for phase modulation. As a matter of fact, modulators based on the plasma-dispersion effect suffer of both residual amplitude modulation and large insertion loss due to the accumulation of carriers. Whereas the footprint of a $LiNbO_3$ modulator is almost an order of magnitude larger than its graphene counterpart.

Abstract— The ability to control the valley degrees of freedom is the foundation of the emerging field of valleytronics [1]. Atomically thin Transition Metal Dichalcogenides (TMDs) are a promising platform for the implementation of new devices exploiting the valley and spin degrees of freedom [2]. Here we measure separately the spin and valley relaxation dynamics of both electrons and holes in the prototypical TMD MoS_2. We disentangle the different processes by the combination of ultrafast optical spectroscopy techniques, i.e., Time Resolved Circular Dichroism (TRCD) and Time Resolved Faraday Rotation (TRFR). TRCD experiments are performed by exciting the sample with an ultrashort circularly polarized pulse, resonant with the optical gap, and measuring the difference between the transient absorption response probed by co- and counter-circularly polarized pulses. The transient absorption is measured on a broad energy range including the A ($\lambda = 650\,\mathrm{nm}$) and B ($\lambda = 605\,\mathrm{nm}$) excitonic transitions at K and K'. These measurements reveal an extremely fast intravalley relaxation of the spin of the photoexcited electrons at the bottom of the conduction band. Furthermore, our data demonstrate that the two non-equivalent valleys K and K' are strongly coupled and the valley polarization is strongly quenched after few ps [3]. In TRFR experiments the pump pulse creates a spin polarized population of electrons/holes in the conduction/valence band, while the rotation angle of the linearly polarized probe pulse is measured by a balanced photodiode bridge technique. We use a two-color TRFR configuration, in which the energy of the probe pulse is tuned well below the absorption gap. In these conditions, the TRFR signal is only sensitive to the helicity-dependent light scattering of the photoexcited electron and hole populations. Since the probe pulse couples with the carrier orbital degree of freedom, the Faraday rotation signal is related to an unbalanced distribution of the photoexcited carrier orbital degrees of freedom. The orbital momentum in MoS_2 single layer is locked with the valley index. Thus, the two color TRFR measurements probe exclusively the intervalley dynamics of electrons and holes. The combination of TRFR and TRCD allows us to disentangle intervalley and intravalley dynamics. Both TRCD and TRFR experiments are quantitatively explained by a set of rate equations which take into account intervalley and intravalley relaxation channels.

Abstract— Recent progress in the exfoliation of layered materials and the nanofabrication of functional structures has revived the interest in two-dimensional materials with properties complementary to graphene, in particular transition metal dichalcogenides such as MoS_2. Their potential for electronics has become evident by the realization of a field effect transistor and a logic circuit device based on a single flake of monolayer MoS_2. Despite its high exciton binding energy, monolayer MoS_2 shows a strong photovoltaic effect and potential for high sensitivity photodetectors. Both these functionalities require efficient charge carrier photogeneration, either via direct excitation of mobile carriers or via exciton dissociation.

Here we use continuous wave photomodulation and femtosecond pump-probe spectroscopy to identify the spectral features of photogenerated charges in an ensemble of few-layer MoS_2 dispersed in a transparent polymer and trace their dynamics, starting with their generation either by direct impulsive excitation into the charge continuum or via exciton dissociation. We find that the primary photoexcitations are excitons which dissociate efficiently with a characteristic time of 700 fs. Thus few-layer MoS_2 displays a behavior which is intermediate between conventional semiconductors on the one hand, and high exciton binding energy materials, such as organic semiconductors, carbon nanotubes, and presumably single-layer MoS_2 on the other. High efficiency photodetectors and photovoltaic elements based on monolayer MoS_2 require additional measures to achieve efficient exciton dissociation, such as a strong built-in field using appropriate electrode materials, engineering a p-n junction, or a heterojunction device. According to our findings, in few-layers, which have the added benefit of absorbing a larger fraction of the incident light, such measures should not be necessary and simpler, more scalable device structures could be used.

Negative Dynamic Conductivity in Pumped Graphene Layers "Decorated" with Quantum Dots

Abstract— The gapless energy spectra of graphene layers, bilayers, and non-Bernal-stacked multilayers enables their applications in different terahertz (THz) devices, in particular, THz lasers with the interband population inversion created by optical pumping or injection [1, 2]. The intraband indirect radiative processes lead to significant THz radiation losses due to the Drude absorption. These processes complicate the realization of the graphene-based THz lasers.

Recently, it was shown that the contribution of the indirect interband transitions to the graphene layer dynamic THz conductivity can compensate or even dominate over that of the intraband radiative transitions, provided that the carrier scattering is primarily associated with long-range scattering potentials (natural or artificial) [3]. The total suppression of the Drude absorption in pumped graphene layers is possible if the size of the scattering clusters is sufficiently large (50–100 nm).

In this work, we evaluated of the role of the indirect interband transitions in pumped hybrid graphene-quantum-dot heterostructures (or graphene layers "decorated" with quantum dots [4, 5]). In these structures, the charged quantum dots (or domes) placed near the graphene layer plane form the spatially fluctuating potential relief providing the carrier scattering with relatively small variations of the electron and hole momenta. We demonstrated that despite a fairly small density of states near the graphene layer band edges, the indirect interband generation of photons can surpass their intraband (Drude) absorption, resulting in rather large absolute values of the negative dynamic conductivity in a wide range of THz frequencies at elevated (room) temperatures. The considered graphene-quantum-dot heterostructures can be perspective for graphene-layer-based THz lasers.

Abstract— Recent experimental and theoretical advances in the study of graphene plasmons have triggered the search for similar phenomena in other materials that are structured down to the atomic-scale, and in particular, alternative 2D crystals, noble-metal monolayers, and polycyclic aromatic hydrocarbons, which can be regarded as molecular versions of graphene. The number of valence electrons that are engaged in the plasmon excitations of these materials is small compared with those of conventional 3D metallic nanostructures, and consequently, the addition or removal of a comparatively small number of electrons produces sizeable changes in their frequencies and near-field distributions. Graphene in particular has been shown to exhibit a large degree of electrical modulation due to its peculiar electronic band structure, which is characterized by a linear dispersion relation and vanishing of the electron density of states at the Fermi level; few electrons are needed to considerably change the Fermi energy. However, plasmons in graphene have only been observed at mid-infrared and lower frequencies, and therefore, small molecular structures and atomically thin metals constitute attractive alternatives to achieve fast electro-optical modulation in the visible and near-infrared (vis-NIR) parts of the spectrum. In this presentation, were view different strategies and recent advances in the achievement of strong optical tunability in the vis-NIR using plasmons of atomic-scale materials, as well as their potential application for quantum optics, light manipulation, and sensing.

Third Harmonic Generation and Saturable Absorption in Graphene

S. A. Mikhailov and N. A. Savostianova
Institute of Physics, University of Augsburg, D-86135 Augsburg, Germany

Abstract— It was theoretically predicted [1] that the linear energy dispersion of graphene electrons leads to a strongly nonlinear electrodynamic response of this material. This fact has been confirmed in a number of experiments, both at microwave [2] and optical [3] frequencies: the nonlinear parameters of graphene were found to be many orders of magnitude larger than those of many other nonlinear materials.

The results of the theory [1] have been obtained within the quasi-classical Boltzmann kinetic theory which is valid at low (microwave/terahertz) frequencies $\hbar\omega \ll 2E_F$; here E_F is the Fermi energy of graphene electrons. In addition, the nonlinear response of graphene was analyzed in [1] in the collisionless approximation $\tau \to \infty$, where τ is the effective scattering time. In this work we will report on the full quantum theory of the third-harmonic response of graphene [4, 5] valid at arbitrary values of the parameter $\hbar\omega/2E_F$. We show that the dependence of the third-harmonic intensity on the frequency ω of the incident wave should demonstrate a huge resonance at the frequency $\omega = 2E_F/\hbar$. corresponding to the inter-band absorption edge in graphene. The third harmonic intensity is calculated both for the case of an isolated graphene sheet and for graphene layer lying on a dielectric substrate like, e.g., SiO_2/Si.

In addition, we will report on results of the quasi-classical theory of the nonlinear response of graphene at arbitrary values of the external ac electric field and arbitrary values of the scattering parameter $\omega\tau$. Such a non-perturbative solution demonstrates, for example, strong absorption saturation at microwave/terahertz frequencies in the ac electric fields of order of 1 kV/cm.

Design and Analysis of Tunable Photonic Devices Based on the Co-integration of Graphene and Dielectric Waveguides

A. Locatelli and C. De Angelis
Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Brescia, Brescia, Italy

Abstract— The peculiar properties of graphene have been attracting the ever increasing interest of the scientific community since the 2010 Nobel Prize in Physics, which was awarded to Novoselov and Geim for their groundbreaking studies. Scientists have already envisaged a plethora of innovative applications in electronics and photonics which exploit the unique characteristics stemming directly from the Dirac dispersion relation of electrons in graphene [1]. In particular, the ultrafast tunability of the electromagnetic parameters of this two-dimensional material can be a key feature for the realization of novel photonic devices. In this context, well-established analytical models are available nowadays to describe both the linear and the nonlinear optical properties of graphene in terms of its 2D complex surface conductivity σ_{2D} [2].

The interaction length between light and graphene is limited by the atomic thickness of the material therefore, following the idea proposed by Liu et al. in a seminal paper [3], several structures based on the co-integration of conventional dielectric waveguides and graphene have been reported, with the goal of perturbing the propagation of a guided mode by means of localized variations of the electromagnetic parameters. This concept allowed to propose, for instance, optical amplitude [3, 4] and phase modulators [5], tunable directional couplers [6, 7] and highly nonlinear waveguides [8]. Most of these structures have been characterized by resorting to full-wave simulations where graphene was modeled as a 3D brick with atomic thickness Δ, and volume conductivity $\sigma_{3D} = \sigma_{2D}/\Delta$. This approach is straightforward but it is characterized by a huge (and often unacceptable) computational burden, thus modeling techniques based on surface current boundary conditions [7, 8] and/or perturbation theory [5, 7, 9] have also been proposed.

In this work we will first review the state-of-the-art of modeling of photonic devices based on the co-integration of conventional dielectric waveguides and graphene. Then, we will systematically study the possibility of applying computationally efficient techniques, such as perturbation theory [9], for the analysis and the design of linear and nonlinear devices for optical processing. We will demonstrate that the effects induced by the tunability of the conductivity of graphene, which can be due to an electrical bias and/or to the Kerr effect, can be accurately predicted by exploiting the "concentrated" nature of the perturbation introduced by the graphene layers.

Abstract— Third-order nonlinear response of monolayer graphene may be significantly magnified by inserting it in properly designed photonic structures, such as defective periodic structures and resonant gratings. Placing graphene within the defect layer of an asymmetric, one-dimensional photonic crystal induces near-perfect absorption in the narrow frequency band associated with the defect mode of the structure. In particular, the enhanced field localization within the defect state amplifies third-harmonic generation efficiency by nearly five orders of magnitude compared with bare monolayer graphene. The role of the structure's asymmetry, the angular and polarization dependence of the linear and nonlinear response will be discussed. The effects of saturation of the third-order susceptibility will be investigated at both the fundamental and third-harmonic frequencies. Finally, we will show the possibility to achieve controllable saturable absorption for the pump signal.

Modeling Graphene Based Couplers and Arrays

Alejandro B. Aceves
Department of Mathematics, Southern Methodist University, Dallas, TX 75275, USA

Abstract— Exploiting the nonlinear properties of graphene layers, we study multi-layer systems for which each layer can be independently modulated. We have shown proof of principle in a 2-layer nonlinear coupler, where small variations of the chemical potential gives wide variations in the beating length, idea for a graphene-based fast switch. Here we will present studies in multi-layer graphene-based systems including nonlinear arrays and the dynamics and properties that can exhibit such systems.

Discrete Solitons in Graphene-based Metamaterials

Abstract— One of the remarkable properties of nonlinear systems is the ability to sustain a localized wavepackets-solitons, which can propagate over long distance without loosing its shape. In the area of plasmonics discrete solitons can be observed in the metal-dielectric multilayers [2]; periodical arrays of nanowires [3] or nanoparticles [4]. Recently it was shown, that a 2D material graphene is strongly nonlinear material [5]. In order to increase the effective nonlinearity of photonic structures with graphene, a natural idea is to use graphene multilayers which, depending on different wavelength regimes, may possess the basic properties of photonic crystals and metamaterials.

In this article, we study nonlinear properties of multilayer metamaterials. created by graphene sheets separated by dielectric layers. We show that this type of metamaterial is essentially nonlinear, and the origin of nonlinearity is the Dirac-cone shape of the charge-carriers spectrum in the graphene. The expression for the graphene's nonlinear conductivity [6] is obtained using the Boltzmann kinetic equation formalism. We demonstrate that such a multilayer structures are described exactly by the stationary discrete nonlinear Schrödinger equation, and, as a result, can support spatially localized nonlinear modes in the form of discrete solitons. We show the existence of two types of solitons. The plasmonic soliton (example is shown in Fig. 1) bifurcates from the low-frequency boundary of the first band (black domain in left panel of Fig. 1), exists in the semi-infinite gap, and is characterized by the evanescent waves in the dielectric between the graphene layers. In the vicinity of the band edge the soliton is delocalized — its electric field is distributed over a large number of graphene layers [panel A]. When frequency is detuned from the band edge, the soliton becomes more localized [panel B]. The *photonic soliton* exist in the upper (finite) gaps of the spectrum, and is characterized by propagating waves in the dielectric between graphene layers.

We also analyze the nonlinear surface modes in truncated graphene metamaterials being a nonlinear analog of surface Tamm states.

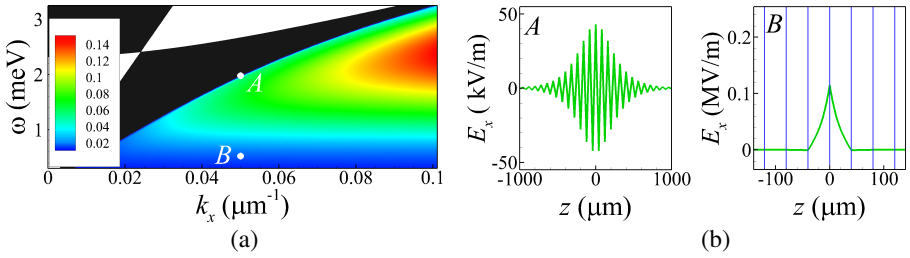

Figure 1: (a) Dependence of soliton norm P (in MV^2/m^2) upon frequency ω and wave vector k_x for the Fermi energy of graphene $E_F = 0.157\,\text{eV}$, interlayer distance $d = 40\,\mu\text{m}$, and dielectic layer permeability $\varepsilon = 3.9$; (b) Soliton spatial profiles for $k_x = 0.05\,\mu\text{m}^{-1}$ and $\omega = 1.98\,\text{meV}$ [panel A], or $\omega = 0.52\,\text{meV}$ [panel B].

Abstract— We study electromagnetic properties of a metasurface formed by array of coupled graphene nanoribbons. We show that surface conductivity tensor has principal components of different sign and the system supports Dyakonov-like plasmonic surface modes.

Introduction: Graphene, two-dimensional lattice of carbon atoms, exhibits a wide range of unique electronic and optical properties [1]. Graphene plasmonics [2] became a rapidly growing research field, both because plasmons in graphene exist in widely demanded THz field and because they can be effectively tuned with an external gate voltage. In [3] it has been shown that a wide range of metasurfaces can be construced based on graphene sheets. In our work we show that nanostructuring the graphene sheet we can tailor the electronic properties directly and as consequence control the conductivity of these metasurfaces.

Conductivity and localized surface waves of the metasurface: We study the system shown in Fig. 1: We calculate the electronic band structure and eigenfunctions for the array of tunnel coupled armchair and zigzag nanoribbons. We show that the coupled edge states of zigzag nanoribbons form the additional electronic band characterizing by the hyperbolic Fermi surface and the band structure of coupled armchair ribbons is characterized by the overlap of electron and hole bands which results in the Fermi surfaces which simultaneously possess electron and hole pockets. Then, using the Kubo formula we calculate the AC conductivity tensors of these structures. We show that for the case of armchair nanoribbons (see Fig. 1) the system can be described by an uniaxial conductivity tensor with principal components of different sign and low loss. We obtain the dispersion equation for the Dyakonov-like surface modes at the anisotropic metasurface. We also study the polarization properties of the localized waves: these modes are linear combination of TM and TE surface plasmon modes appearing in 2 dimensional graphene. Directivity of these plane waves can be controlled with the external voltage which can be used for the creation of graphene-based photonic integrated circuits.

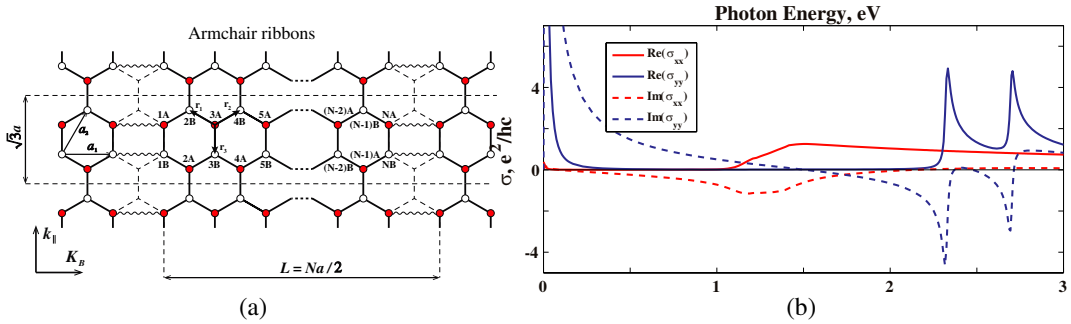

Figure 1: (a) Atomic structure and (b) conductivity of the array of armchair nanoribbons.

Analysis of Graphene Plasmonic Waveguides and Switching Components via a Finite Element Formulation with Surface Conductivity

I. Demirtzioglou and T. V. Yioultsis
Department of Electrical and Computer Engineering, Aristotle University of Thessaloniki
Thessaloniki 54124, Greece

Abstract— We present an efficient finite element formulation for the eigenmode analysis of graphene-based plasmonic waveguides with switching functionalities. The formulation is full-vectorial and addresses graphene as a surface conductivity, as opposed to a bulky material considerations, thus eliminating the need for fine discretizations inside thin graphene models.

Introduction: Graphene is a ground-breaking material, with a multitude of significant properties and effects, including the ability to support surface plasmon propagating modes and switching functionalities [1]. Optical conductivity of graphene has been shown to consist of a Drude intraband term and an interband contribution. These properties may result in either plasmonic modes in THz [2] or enhanced switching in photonic waveguides for the optical communications regime [3].

Finite Element Formulation: The proposed finite element eigenmode formulation starts from a general framework that has been proposed in [4], where the electric field is used as a working variable, with vector finite elements in the transverse plane and a scalar axial component. The quadratic eigenvalue problem is of the form,

$$\left\{ \begin{bmatrix} \mathbf{S}^t - k_0^2 \mathbf{T}^t & 0 \\ 0 & -\mathbf{S}^{z,m} + k_0^2 \mathbf{T}^z \end{bmatrix} + n_{eff} \begin{bmatrix} 0 & -jk_0 \mathbf{P} \\ -jk_0 \mathbf{Q} & 0 \end{bmatrix} + n_{eff}^2 \begin{bmatrix} k_0^2 \mathbf{T}^{t,m} & 0 \\ 0 & 0 \end{bmatrix} \right\} \begin{bmatrix} \mathbf{E}_t \\ \mathbf{E}_z \end{bmatrix} = 0 \quad (1)$$

where the corresponding finite element matrices may involve transverse or axial basis functions or a combination of both. Mass matrices in (1) involve also line integral terms coming from the surface treatment of graphene structures. Perfectly matched layers are used as domain terminating conditions, while linearization of (1) results in positive semidefinite matrices, suitable for sparse eigensolvers.

Plasmonic and Switching Components: The proposed formulation is able to analyze both plasmon graphene ribbon waveguides in the THz regime (Fig. 1(a)) and a switching-capable waveguide structure for telecom applications, based on the CGS waveguide [5], which is properly enhanced by graphene (Fig. 1(b)). Based on the analysis, we have been able to propose a graphene-enhanced plasmonic CGS waveguide with an extinction ratio of 8.6 dB and a 2.15 dB insertion loss for a 10 μm length, which is highly promising for further study.

Propagation of Quasi-TEM Waves in a Graphene Parallel Plate Waveguide Involving Discontinuities

S. Akşimşek
Istanbul Kültür University, Turkey

Abstract— In this paper, propagation of quasi-TEM waves in a 2-D graphene parallel plate waveguide (GPPWG) involving discontinuities [1] is investigated. The purposed waveguide structure involves some certain geometrical and physical discontinuities as illustrated in Figure 1, and the mentioned discontinuity (scattering) mechanisms are: 1) a junction region of thickness b stemming from the latitudinal sudden change between the plates, and 2) different dielectric substrates on each side of the junction region and on this region as well, respectively. The surface of the plates are represented by an anisotropic model of an infinitesimally thin graphene sheet which has a dispersive conductivity term derived from Kubo formula [2].

The Mode-Matching technique, which is the well-known rigorous frequency domain method, is applied to the geometry by determining the guided field terms at the junction region and both sides of this region, and matching them at the junction's boundaries by employing the continuity relations following a similar procedure in [3]. At the end of the analysis the obtained infinite sets of equations are truncated by a truncation number such N. After numerical evaluation of these equations, the scattering coefficients are obtained and solved computationally [4]. The graphical results of the scattering coefficients show the effect of the discontinuities on the propagation of quasi-TEM waves along the purposed waveguide modal, and these results construct a solid knowledge for future applications of nanophotonic devices at sub-THz frequency range.

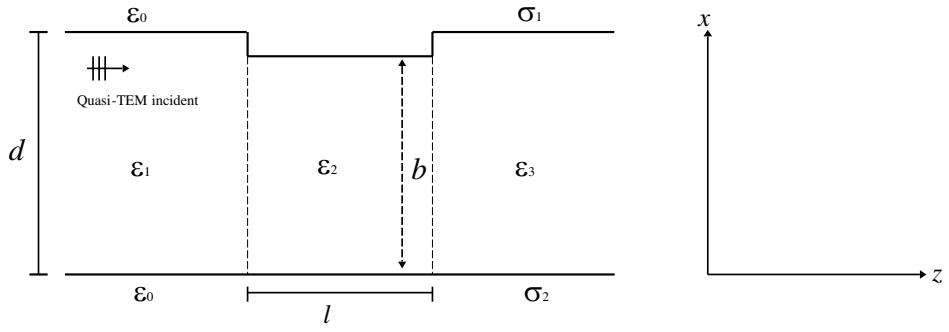

Figure 1: The geometry of 2-D graphene parallel plate waveguide involving discontinuities.

Reconfigurable Antenna Design

Yahya S. H. Khraisat and Ahmad H. N. Qubaia
Electrical and Electronics Department, Al-Balqa' Applied University/Al-Huson University College
P. O. Box 1375, Irbed 21110, Jordan

Abstract— A compact of a reconfigurable rectangular microstrip slot patch antenna of operating frequencies in the range of (2–6) GHz is proposed for Wireless Local Area Network (WLAN) applications. It has one port excited with microstrip line feed mechanism. The proposed antenna consists of a single layer patch antenna with two parallel slots designed that can be controlled via two switches. Two parallel slots are incorporated to perturb the surface current path, introducing local inductive effect that is responsible for the excitation of the second resonant mode. By adjusting the status of the switches state either *on* or *off* mode in simultaneously, the resonance frequencies can be varied, thus achieving frequency reconfigurable.

I represent a fully information and design for reconfigurable antenna to use it in a new hybrid device known Cognitive Radio CR. A cognitive radio CR is a wireless transponder that can sense the environment in which it wishes to operate and can adapt itself to optimize its operation. Sensing the environment may involve the measurement of the communications traffic and interference across a large part of the electromagnetic spectrum. The radio will also have knowledge of the intentions of its user, to enable it to match its searches to the needs of the user. In simple words the operations consist of Sensing and Reconfigurability called a Cognitive Radio CR.

A Utility Maximization Approach to MAC Layer Channel Access and Forwarding

Sunil Kumar[1, 2], **Priya Ranjan**[1], **and Malay Ranjan Tripathy**[1]

Abstract— The directional antenna technology in wireless mesh network is used to improve the spatial reuse of the wireless channel, where nodes communicate simultaneously without interference of each other. Compare to omnidirectional antenna, directional antenna establish links between nodes far away from each other, and reduce the number of routing hops.

Innovative technology is required to meet customer demands and improve the performance in WLAN 802.11. Large number of access point cannot be implemented due to infrastructure limitation like wiring from access point to router or modem. Wireless is a scalable, reliable and cost effective technology which can be used to propose a utility maximization approach to MAC layer channel access and forwarding.

In this paper a nonlinear utility optimization based approach is proposed to share bandwidth channel resources among interfering interfaces both in presence of balanced and unbalanced traffic. We propose a new algorithm to provide channel access information in dynamic network scenario. This work implements nonlinear utility maximization based on data rate and tested indoor IEEE WLAN 802.11n+s. It will hopefully bridge the gap between economic perspective of resource allocation and technological efficiency of WLAN. This can lead to a programmable interface for management and control of physical layer resources in an optimal fashion.

Abstract— The noise in magnetic resonance imaging (MRI) systems is primarily thermal noise generated in the receiver Faraday coil (rf resonator) and in the imaged body. There are two regimes for the thermal noise induced conductive losses in the MRI systems. In the first one, the overall rf loss is body loss dominated, so the SNR is governed by the body loss, in the second instance, loss occurs predominantly in the coil. Therefore in the latter case, reducing the coil resistance or/and temperature can result in significant thermal noise reduction. This can be realized by coils made out of high-temperature superconducting (HTS) materials known for their very low rf surface resistance R_s. Furthermore, relatively high critical temperature of HTS materials allows for cryostat design simplifications, which enables short range distance between the HTS coil and the body.

We report on the design, construction, and validation of receive-only MRI cryo-probe operating at 7 T based on HTS coil integrated with tuning/matching to 50 Ω and de-coupling circuitry. The coil is designed as a double-sided structure, consisting of two split rings, the gaps in each quasiring rotated 180 from each other (Fig. 1). Such structures have been referred to as twin horse-shoe (H-S) resonator and its double-sided configuration introduces not only distributed capacitance, but also reduces capacitive loss by concentrating the electric field within low-loss substrate. HFSS software package (Ansoft) was used to design both copper and HTS coils with dimensions according to the resonant frequency and field-of-view requirements.

The Cu coil and electronic circuit layout was patterned using LPKF PhotoMat C100. Double-sided Cu high frequency laminate ($\varepsilon = 2.2$ and thickness of 0.38 mm) was used for the coil fabrication. Superconducting coils were made of epitaxially grown 0.5 μm thick YBCO superconducting films, which were patterned using optical lithography and wet etching. Two split quasi rings were fabricated on both sides of a 0.33 mm thick Al_2O_3 ($\varepsilon = 10.4$) wafer to create a 300 MHz resonator. A closed cycle pulsed tube cryogenic system (CryoMech HTP10) was used to cool the probe.

Our main interest in this work was the identification of all losses, such as rf coil ($\sim 1/Q_{coil}$), body ($\sim 1/Q_{body}$), cryostat ($\sim 1/Q_{cryostat}$) and tuning/maching/decoupling electronics ($\sim 1/Q_{electronics}$) losses, and assessment of the probe SNR limits. We have measured all loss components of the system. In addition, the influence of magnetic flux (7 T) on the HTS coil was also investigated. YBCO thin film is in the mixed superconducting state at 7 T, which can result in higher losses. The electronic loss ($\sim 1/Q_{electronics}$) increased in 7 T from 1/1600 to $\sim$ 1/900. Most likely such increase is due to magneto-resistive effects in varactors diodes used in the electronic circuit.

From Q measurements (Qcoil, Q_{body}, $Q_{cryostat}$ and $Q_{electronics}$) it was found that for *in-vivo* rat imaging the SNR gain of the system is limited by rf body losses. In such a case, the SNR gain can be adjusted by changing the coil size. For small samples, such as those used for *in-vitro* microscopy imaging, electronics losses turned out to be limiting factors. Further increase of the SNR gain for microscopy will require use of a cryogenic preamplifier and also further reduction of the tuning/matching circuit losses.

SNR gains, tested on phantom and rats at 300 MHz in a few cryogenic configurations, were measured as $\sim$ 6 dB and $\sim$ 8 dB for cooled Cu and HTS coils over room temperature copper, respectively.

Long Range Induction between Josephson Junction Arrays via Microwave Photon Emission and Absorption

Abstract— Strong induction between one-dimensional arrays of Josephson junctions separated with tens of micrometers were observed and analyzed. Arrays have a structure of superconducting quantum interference device (SQUID) connected in series, allowing one to tune Josephson coupling energy by changing the flux threading a SQUID loop. Constituent Josephson junctions were made of $Al/AlO_x/Al$ with a typical size of 100 nm, giving a charging energy of about 50 μeV. A dc current biased in one array may increase the conductance of nearby isolated arrays. Because of large inter-array distance, this mutual induction cannot be explained by capacitive coupling between two arrays [1]. It turns out that the conductance change can be understood under a picture of phase diffusion introduced by microwave excitation [2]. A detail analysis reveals that excitation microwave power is proportional to bias current in the emitter. The induction strength is largest when charging energy is dominant over Josephson coupling energy, a similar trend that an array responds to microwave excitations [3]. In short range, induction strength is inversely proportional to inter-array distance, suggesting a microwave power emission. This induction provides an application of long-range and fast signal coupler.

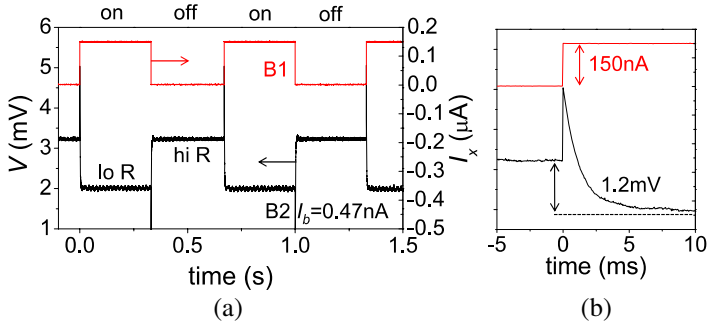

Figure 1: Demonstration of long-range digital signal coupler. (a) Time scan of the output voltage of receiving array under a bias current of 0.47 nA when the emitting array is cyclically switched on and off. When emitter current is switched on, the voltage drops due to a rapid change from high resistance (hi R) state to a low resistance state (lo R). (b) The receiving array responses with a characteristic time smaller than 5 ms, which is limited by our wiring and voltage pre-amplifier.

Abstract— In this paper a new design of meta-fractal antenna is proposed. The dimension of the patch is $40 * 40\,\mathrm{mm}^2$ and the FR4 substrate is used for this. The patch antenna with metamaterial ground plane is shown in Fig. 1(a). The first iterated fractal antenna with the meta-material is shown in Fig. 1(b). The 2nd and 3rd iterated fractal antennas with metamaterial ground plane are shown in Fig. 1(c) and Fig. 1(d).

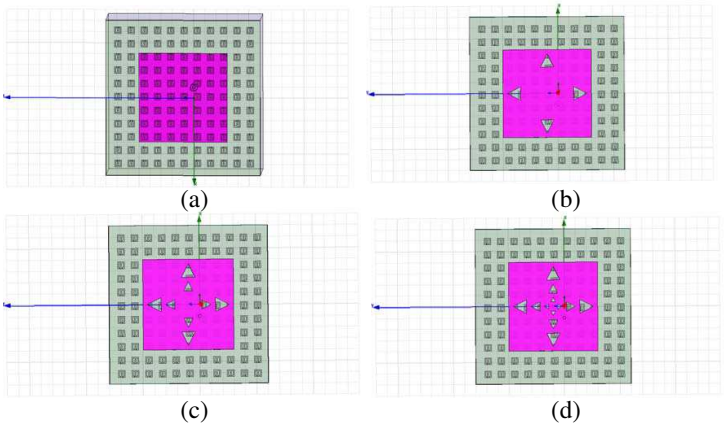

Figure 1: (a) Patch antenna with metamaterial ground plane. (b) 1st iterated meta-fractal antenna. (c) 2nd iterated meta-fractal antenna. (d) 3rd iterated meta-fractal antenna.

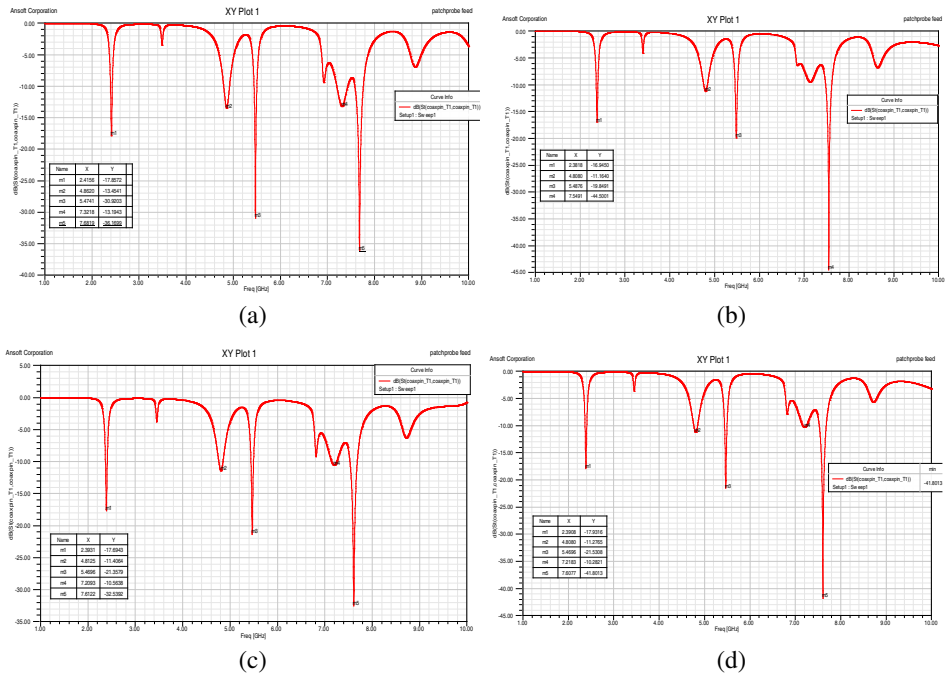

Figure 2: (a) Patch antenna with metamaterial. (b) 1st iterated meta-fractal antenna. (c) 2nd iterated meta-fractal antenna. (d) 3rd iterated meta-fractal antenna.

The results are shown in Figs. 2(a)–(d). As we increase the iterations, different results are seen. The band width used to increase for higher iterations. The return loss results shows better in some of frequency bands for higher iterations and it get degraded for other frequency bands. All these results are analyzed and discussed in detail in the paper.

Abstract— The split ring resonator (SRR) is the key element to obtain left handedness at microwave frequencies [1]. The orientation of the SRR relative to the electromagnetic field is decisive for achieving left handedness (refractive index $n < 0$). It has been suggested that left handedness is sensitive to disorder and that breakdown of left handedness may occur [2]. That would be important for many applications, where manufacturing will cause imperfections, in particular in low cost applications and at high frequencies. We investigate by simulations how the left handedness is affected by rotational disorder of the SRR. The studied structure is shown in Fig. 1.

The structure was designed for left handness in the X-band. The inner, ϕ_1, and outer rings, ϕ_2, rings were rotated, but the position was not changed. The rod position was not changed. In Fig. 2 the refractive index vs. frequency is shown for the case with $\phi = \phi_1 = \phi_2$. ϕ was independent for all SRR and was uniformly distributed between $\pm 0°$, $\pm 15°$, $\pm 45°$, $\pm 90°$. The left handedness ($n < 0$) changes in frequency range and amplitude, but no breakdown of left handedness from orientation disorder is seen. The highest negative refractive index is actually achieved for ϕ between $\pm 45°$. Varying ϕ_1 only had negligible effect and ϕ_2 only similar to the case with $\phi = \phi_1 = \phi_2$.

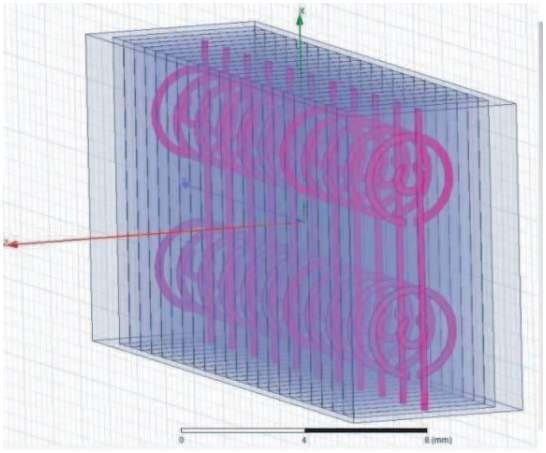

Figure 1: The investigated structure.

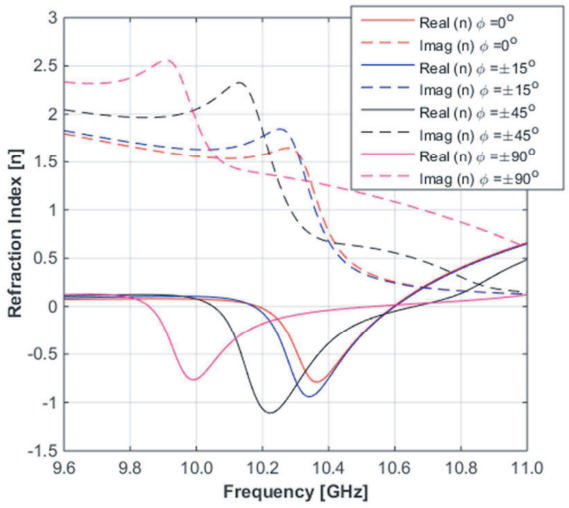

Figure 2: The effect of random SRR rotation ($\phi = \phi_1 = \phi_2$).

Abstract— A microwave switchable filter is one of key circuits in wireless communication systems. A challenging bandpass filter design are tunable, good selectivity characteristics, low insertion loss, and compact size. In this paper, a switchable bandpass to all stopped filter with broad stopband is proposed (Fig. 1). The bandpass filter consists of a hairpin resonator and three capacitors at the ends of resonator with capacitive coupling feed lines. As shown in Fig. 1, two upper capacitances, C_1, are fixed and lower capacitance C_2 is varied The main function of C_1 is used to attenuate the stopband The capacitor C_2 is used to tune the bandpass to all stopped filter by changing DC voltage The proposed filter provides a good selectivity and compact sized. For experimental validation of proposed structure, the bandpass to all stop filter is proposed at an operating frequency of 2.6 GHz The filter is designed on a substrate with a thickness (h) of 31 mil and dielectric constant (ε_r) of 2.2. The fabricated circuit is shown in Fig. 2. The circuit size is $8 \times 25\,\text{mm}^2$ The SMV1233-040LF varactor diode is used for the capacitance variation. The passband is occurred when bias voltage 1.7 V ($C_2 = 3$ pF) From experiment, the passband is shifted to lower frequency compare to EM simulation that is because of the effect of parasitic of the varactor diode and the fabrication error (Figs. 3 and 4). In the simulation, the ideal capacitor C_1 and C_2 are used. The insertion loss in the passband is 1.4 dB and the return loss is better than 15 dB at 2.42 GHz Since transmission zeros near to the passband are obtained at 1.85 GHz and 2.84 GHz it provides a good selectivity characteristic. The 3 dB fractional bandwidth is 6.3%. The upper stopband is suppressed higher than 17 dB from 2.67 GHz to 9 GHz. The lower transmission zero is moved to the passband when bias voltage 3.7 V ($C_2 = 1.55$ pF) providing all attenuated as shown in Fig. 4.

Abstract— In this paper a new design of meta-fractal antenna is proposed. The dimension of the patch is $40 * 40\,\mathrm{mm}^2$ and the FR4 substrate is used for this. The patch antenna with metamaterial ground plane is shown in Fig. 1(a). The first iterated fractal antenna with the meta-material is shown in Fig. 1(b). The 2nd and 3rd iterated fractal antennas with metamaterial ground plane are shown in Fig. 1(c) and Fig. 1(d).

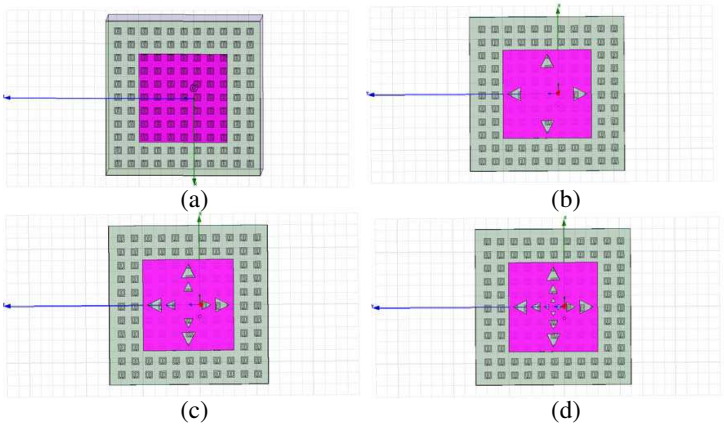

Figure 1: (a) Patch antenna with metamaterial ground plane. (b) 1st iterated meta-fractal antenna. (c) 2nd iterated meta-fractal antenna. (d) 3rd iterated meta-fractal antenna.

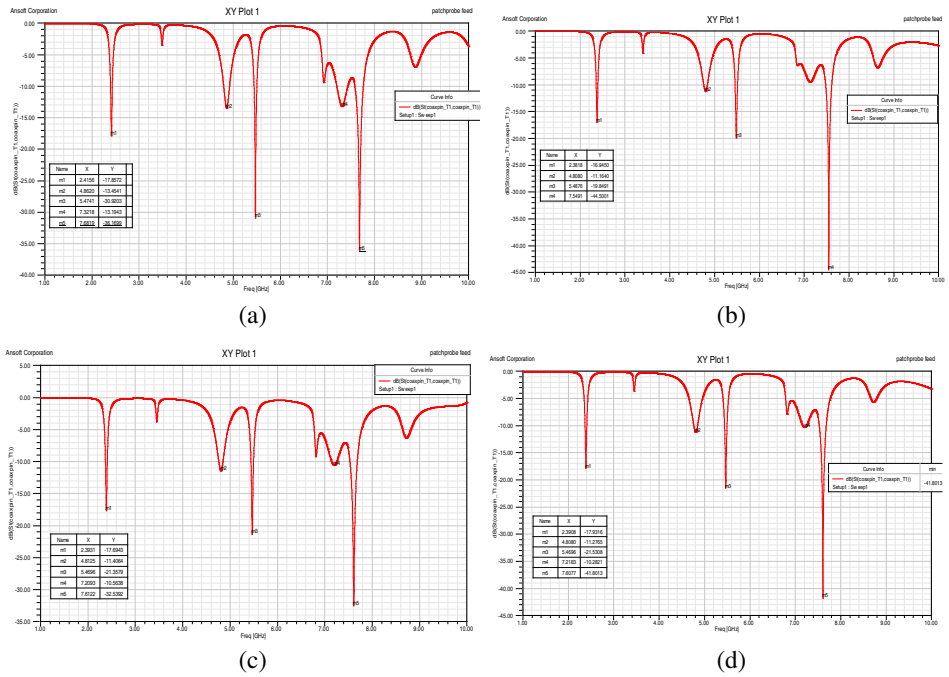

Figure 2: (a) Patch antenna with metamaterial. (b) 1st iterated meta-fractal antenna. (c) 2nd iterated meta-fractal antenna. (d) 3rd iterated meta-fractal antenna.

The results are shown in Figs. 2(a)–(d). As we increase the iterations, different results are seen. The band width used to increase for higher iterations. The return loss results shows better in some of frequency bands for higher iterations and it get degraded for other frequency bands. All these results are analyzed and discussed in detail in the paper.

Abstract— Bangalore is state capital of karnataka, India and also know as IT capital of India. In 1975, total number of lakes in Bangalore was 51 which had reduced down to 17 now because of pollution growth, land encrochment and water pollution. Earlier they were a good source of daily use water for Bangalore but now due to extensive pollution, it cannot be used. We in this paper propose a project based on Low power WSN clubbed with cloud infrastructure to monitor water quality in the lakes in real time during different seasons in a year and see the variation of water quality in different region, i.e., close to human infra, in middle of lake, during rainy season etc.. We want to conduct this experiment simultaneously across the 17 lakes in Bangalore. With the data collected, suitable measures can be suggested to government to take effective actions in order to save the exiting bio-diversity across the lakes. Cloud infrastructure can be useful to see and analyze real time data from anywhere and even archive data which can be further downloaded to see variation in last few year. Similar approach can be implemented to measure real time air quality in Bangalore and some of other major polluted cities like Delhi.

Microwave Characterization of Normal and Superconducting States of Superconducting Flexible Tapes on Metal Substrate; Dielectric Resonator Technique

Abstract— Recent developments in the manufacturing of second-generation (2G) high temperature superconductor (HTS), deposited on buffered flexible metal substrates, have opened more possibilities for application in electric power grid and superconducting magnets. In the current manufacturing process, HTS tapes such as $YBa_2Cu_3O_{7-x}$ on Hastelloy substrate (YBCO/Hastelloy) often have in-situ quality control of surface morphology using high-speed cameras that can detect and flag defects and X-ray diffractometers to access and regulate the tape texture. However, these tools do not provide direct information on the expected critical current performance of the superconductor tape. Since, kilometers long 2G tapes are manufactured by the MOCVD process, an ideal solution would encompass a non-contact and non-destructive technique capable of providing real time information about both the buffer and superconducting layers at each point of the manufacturing process.

We report on development of such method with the aim to use it as a potential room temperature quality control for fabrication of YBCO tapes. The tapes were deposited at different temperatures, what resulted in their different quality, on Hastelloy-supported oxide buffer layers using the MOCVD technique. T_c was about 89.3 K for all three (GdY)BCO tapes and I_c values in zero magnetic field were 165 A, 270 A and 339 A for tapes with measured thickness of 0.84 μm, 1.02 μm and 1.06 μm, respectively. The buffer stack consisted of aluminum oxide (Al_2O_3), yttrium oxide (Y_2O_3), and textured IBAD-MgO and $LaMnO_3$ layers.

Two configurations of dielectric resonators (DR), the single post (SPDR) consisting of highpermittivity barium zirconium titanate (BZT) ceramic operating at 9.4 GHz in quasi $TE_{01\delta}$ and the rod (RDR) consisting of rutile operating at 13 GHz in TE_{011} mode were designed to measure the complex conductivity (σ) of the tapes (12 mm wide) at the normal and superconducting states, respectively. In order to extract complex conductivity (σ) from experimental data of Q-factor and resonant frequency shift, a commercial electromagnetic simulator HFSS, based on finite elements analysis, was used to calculate resonator EM fields. The theoretical Q-factor and resonant frequency shift curves obtained from numerical simulations were matched with the experimental data to determine conductivity of the YBCO tapes in both normal and superconducting states. Three different tapes were fully characterized and correlation between superconducting and normal state properties was investigated.

Discussion of feasibility and limits of using the microwave dielectric resonator technique for measurements of σ on temperature slope in normal YBCO state will be presented.

Coplanar Waveguide Fed Coplanar Patch Antenna for Nanorectifiers at 2.45 GHz

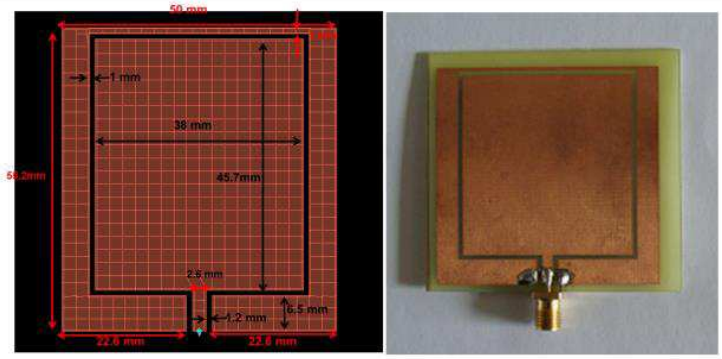
Abstract— The recent developments in semiconductor industry have demonstrated the pervasive use of digital broadband communication handling a huge data to be processed and transmitted at the faster speed. In order to increase the operating speed, the device dimensions have been scaled down following the Moore's Law and reached at the verge of saturation [1]. Therefore, researchers have proposed a wide variety of novel nanoelectronic devices such as Self-Switching Device (SSD) [2] and Ballistic rectifier [3] which can be fabricated in two-dimension electron gas (2-DEG) heterostructures by using standard nanolithography followed by wet chemical or dry etching. Both the devices can be used a rectifier to convert microwave signals into DC signal, however, they don't require any *pn* and/or Schottky barrier when compared to conventional multi-layered rectifiers. Due to their planar device architecture, they have shown very small internal capacitance meaning that their frequency response doesn't have RC charging time limitations as convention electronic devices and can be used for various applications starting from radio frequency (RF) to terahertz (THz) frequencies [2, 3]. Such devices can easily be integrated to outside macroscopic world using coplanar transmission lines and planar antennas which demonstrate very low parasitic capacitances.

Here, we report the design and fabrication of coplanar waveguide (CPW) fed coplanar patch antenna (CPA) to integrate with SSD and ballistic rectifier at Unlicensed Industrial, Scientific and Medical (ISM) band frequency of 2.45 GHz for radio frequency identification (RFID) systems. The custom-built antenna has a similar configuration as loop slot antenna [4] consisting of a patch surrounded by closely spaced ground conductor and a CPW feed line of 50 Ω as shown in Figs. 1(a) and (b). The 1.2 mm thick glass epoxy (FR4) substrate with dielectric constant (ε_r) and loss tangent ($\tan\delta$) of 4.4 and 0.0002, respectively, is used for the fabrication of antenna. The antenna has demonstrated a gain of 3.82 dB and its measured return loss of about 37.24 dB is in reasonable accordance with the simulated values of 47.4 dB as depicted in Fig. 2.



(a) (b)

Figure 1: (a) CPW fed coplanar Patch Antenna with optimized dimensions. (b) Fabricated antenna with a SMA connector.

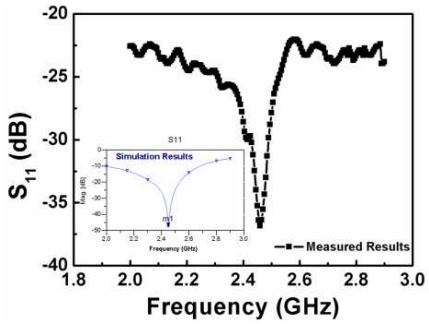


Figure 2: The return loss of 37.24 dB was measured using Agilent's network analyser (model: E 5061B ENA Series) which is in well accordance with the simulated results obtained using ADS software as shown in the inset.

Abstract— This paper presents an UWB antenna with optically controlled frequency notches. Behavior of the photoconductive optical switches under light illumination and in the dark are modeled. The optical signal in turn alters the radiation properties of the antenna structure and consequently changes the notched frequency bands. The photoconductive switches are activated by laser light that is coupled through an optical fiber which extends from the ground plane to just underneath the silicon element (silicon filled gap) placed on the radiating face of the antenna structure. Such a construction allows for easy integration of such antenna designs into conformal packaging for wireless devices [1, 2]. Photoconductive switches are used because of their superior performance as compared to MEMS, p-i-n diodes, and lumped elements. The photoconductive approach does not require the use of bias lines, which typically lie in the plane of the antenna and can interfere with the electromagnetic performance of the antenna. Also, photoconductive switches exhibit extremely fast switching speeds on the order of nanoseconds [2, 3]. The antenna structure is shown in Fig. 1. The four switches S_1, S_2, S_3 and S_4 are controlled using optical signal via optical fiber. Fig. 2 shows the performance of the antenna (return loss S_{11}) for different cases of the optical switches which are either OFF (opened) or ON (closed). Experimentally measured RF performance of the antenna is in good agreement with the numerical simulations.

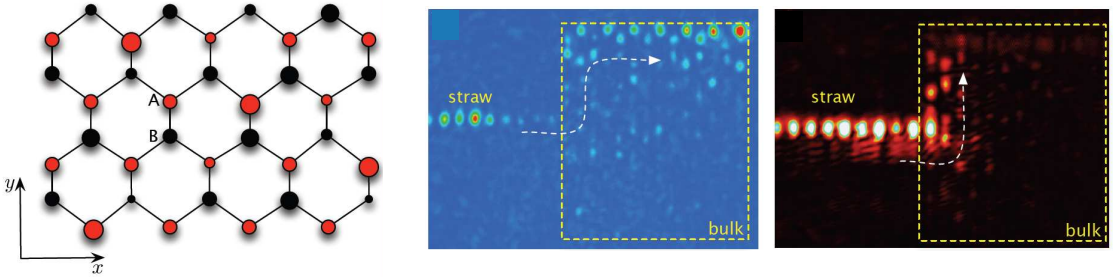
[2]Department of Physics, Technion — Israel Institute of Technology, Haifa 32000, Israel

Abstract— Topological states have emanated a fascination in condensed matter physics and the discovery of topological insulators [1] was one of big successes of recent years. Our team experimentally demonstrated a photonic topological insulator [4] using the so-called Floquet topological insulators (FTI) [2, 3]. This is a 2D lattice where evanescently coupled waveguides are arranged in a honeycomb (graphene-like) geometry and and waveguide is twisted around its axis in a helical fashion.

We now consequentially challenge, how disorder would impact the FTI. In 1958, it was shown that disordered systems exhibit Anderson localization: the suppression of wave transport [5]. In fact, in two-dimensional disordered systems, all eigenstates are localized even for an infinitesimal amount of randomness, without any observable threshold [6, 7]. In contrast, topological systems exhibit a radically different nature which allows them to retain extended states even under the influence of disorder in two dimensions. However, it was still extremely intriguing when the so-called Topological Anderson Insulator was proposed [8]: a system with topological properties — displaying extended edge modes — due to the presence of disorder.

For the first time, we present an experimental demonstration of a Topological Anderson Insulator in any physical system in nature. Our photonic system is similar to that in previous work [4]. In addition, we employ a staggered mass potential, that is, the two sublattices of the honeycomb structure exhibit different refractive indices n_a and n_b (see Fig. 1(a)). When $n_a = n_b$ our system is identical to the FTI in [4] and, hence, exhibits topologically protected edge states (Fig. 1(b)). However, when breaking the inversion symmetry in the transverse plane by detuning the sublattices ($n_a \neq n_b$) a topologically trivial bandgap opens and topological insulation vanishes. In the presence of disorder (helically synchronized with the lattice) this trivial bandgap closes and acquires a nonzero topological invariant when it finally reopens. This is proofed by the formation of a one-way edge state, as shown in Fig. 1(c).

The basic idea of a TAI is as follows. In the periodically driven system with a staggered potential, the drive (the helicity manifested in the gauge $A(z)$) and staggering act as two opponents. While staggering produces a trivial gap with positive effective mass at both Dirac cones, the drive causes a topological gap with opposite masses. When the staggering dominates over the drive, the system has trivial topology. This is where disorder comes in: it effectively reduces the effect of the staggering and, at sufficiently large disorder it closes the trivial gap and the topological phase is restored.



(a) (b) (c)

Figure 1: (a) Schematic representation of the honeycomb lattice with a staggered mass potential composed of two sublattices A (red) and B (black). The uniformly disordered onsite energy is indicated by variable radius of the lattice sites. (b) For $A = B$ and no disorder the wave function at the output clearly travelled along the edge without any scattering. (c) For $A \neq B$ the edge state can be recovered in a disorderd system.

Abstract— The colors shown by several insects often arise from light scattering by very complex photonic structures rather than selective absorption by pigments. Such structures are the result of optical strategies developed during millions of years of evolution. The bright and iridescent colors shown by certain butterflies and beetles, for example, arise from coherent effects which requires ultrathin periodic layers of material [1]. In contrast, a *bright white* coloration is more complicated to achieve, since all colors has to be scattered with the same high efficiency. In this case the wave nature of light is not involved in the appearance of the object, and a bright white is achieved only in presence of multiple scattering, for which thicker, high refractive index contrast systems are usually required. Nevertheless, the extremely brilliant whiteness shown by the *Cyphochilus* beetle is generated by multiple scattering of light inside the *ultra-thin* scales that cover its body. The intra scale structure is characterized by a dense, nanostructured network of chitin filaments, which seems to be optimized (during million of years of evolution) to increase the total reflectance, and thus the bright appearance of the beetle, employing as less material as possible [2, 3].

In this work we analyzed light transport inside the beetle's scales, showing that multiple scattering of light occurs, in spite of its thinness (5–9 µm). We proved, with static and time resolved experiments, that white beetle's scales show the lowest transport mean free path and diffusion coefficient for low-refractive-index systems ($n = 1.5$) reported until now. We found that the crucial aspect of the optimization of light scattering is the structural anisotropy of the chitin network. We indeed demonstrated that light transport inside the scales is anisotropic, and it is engineered to increment the scattering strength in the direction orthogonal to the scale surface, at expense of the in plane scattering, which is not relevant for the total reflectance. With such morphology and geometry of the intra scale structure the beetle succeed achieving a bright white reflectance with a thin, anisotropic, lightweight structure.

Such kind of discoveries can have immediate impact in developing new highly scattering optical systems with applications ranging from thin coatings to LEDs illumination.

Abstract— Recent advances in the engineering of light confinement have demonstrated the ability to fully control the spectral properties of an individual photonic mode in two-dimensional disordered photonic structures paving the way for the creation of open transmission channels in strongly scattering media. The optical confinement and the coupling between modes open new perspectives over the control of the light flow in random media, as well as the possibility to build architectures tuned for efficient light-matter interaction.

Here we propose a novel geometry to achieve coupling between single quantum emitters (Dibenzoterrylene (DBT) molecules, embedded in a thin anthracene crystals), and disordered photonic structures. We investigate the quasi-modes of a disordered pattern to create a chain of hybridized localized modes extended from one end of the sample to the other. Such topology has the advantage of bringing distant molecules to exchange energy, thanks to the shared photonic mode.

In particular the structures that we study are suspended Si_3N_4 membranes in which a triangular lattice of holes is fabricated. The disorder is introduced by shifting the holes by a small normally distributed displacement relative to the position in the perfect periodic lattice. In this way, adding disorder on top of an initial ordered structure, we tune the appearance of Anderson localized modes at the proper frequency, for coupling with DBT molecules FDTD simulations are performed in which several dipoles, that simulate the DBT molecules, are used to excite the photonic structures. In order to detect the appearance of localized or hybridized modes, we have developed a "simulation tool" based on Fourier analysis, phase rigidity, complexity factor, spreading factor, spatial correlation and cross correlation integrals.

A simple case-study platform has been performed as a test bed for the analysis in the disordered case. In particular, two coupled D2 cavities have been analysed. Such system provides an easy model for coupled modes since the modes of the single cavity are well characterized. Considering two adjacent D2 cavities, the coupling strength can be tuned by adjusting the tunnelling rate acting on the radius of the holes shared by the two cavities, while a detuning between the two cavities can be introduced by acting on the non-shared holes. It is therefore relatively easy to study all combinations of coupling and detuning. Combining information about the phase distribution, the field spatial and spectral profile, we anticipate level crossing and anticrossing between modes. The results provide new understanding of the hybridmode nature and define a fingerprint to spot necklace states in two dimensions.

Photonic Band Gaps in Disordered Materials: Stealthy Hyperuniformity Versus Local Ordering

Abstract— Photonic Crystals (PCs) have represented a major driving force for the optical materials community for the last three decades. In analogy with solid-state physics, the goal of photonic crystal science and technology is to understand, engineer and fabricate materials with specific light transport and emission properties. Photonic band engineering is at the heart of virtually any application of PCs. In the early stages of the development of the technological capacities to fabricate photonic bandgap structures, it was realized that fabrication defects inhibit the formation of a gap and thus spoil to a large extent the performance of any practical photonic device, up to a point where commercial applications might be practically precluded.

Recently however the picture of considering disorder as the limiting factor for the fabrication of photonic band gap materials has changed dramatically. Several groups realized that, indeed, certain types of correlated disorder may be beneficial for the creation of a photonic bandgap. Moreover such amorphous bandgap materials would feature a spatially isotropic gap difficult to attain in a truely crystalline structure.

In the pioneering work of M. Florescu and coworkers [1], it was shown that the so called stealthy hyperuniform (HU) disorder can lead the buildup of isotropic photonic bandgaps in two and three [2, 3] dimensions. In contrast with the structures studied in [4], it was suggested that crystalline order is not required to obtain a full band gap but local ordering, uniform topology and, importantly, stealth hyperuniformity.

Stealth HU is a structural property related to the structure factor $S(q)$ of the disordered system: HU patterns present a vanishing $S(q)$ as q tends to zero, while stealthy HU imposes a much more restrictive constrain to $S(q)$: it exhibits vanishing values over a finite range of values from $q = 0$ up to a critical value q_c. Stealthy HU materials can be regarded, to some extent, as the reciprocal space counterpart of the constrains imposed by the hard-sphere (hard-disc in 2D) model in the real space.

In the present paper, we study a system where uniform topology is not relevant as the system is composed of isolated two-dimensional scattering units (circular cylinders). We compare non-polycrystalline disordered samples with different degrees of correlation, showing both stealthy hyperuniformity or only short range ordering due to random packing in real space. We show that an isotropic bandgap emerges in both cases and that the short-range correlated system can present even wider isotropic bandgaps as compared to stealthy hyperunform structures with similar constraints on the degrees of freedom (in q-space or real space respectively). We show how the interplay between different characteristic scattering lengths in the system, namely transport mean free path, correlation distance and pseudo-Bragg length play a role in these systems. We conclude that any constrain imposed in the accessible degree of freedom leads to peaks (at appropriate positions) in the radial distribution function or the structure factor and in promotes the emergence of a photonic bandgap provided the scattering strength of the individual building blocks is sufficiently strong.

Abstract— We study the dynamics of light waves propagation in correlated 2D disordered landscapes. A non-diffracting disorder with adjustable strength V_R and correlation length σ_R is generated in a photorefactive crystal using spatial light modulators (SLM) [1], and tailored wavepackets prepared also using SLM are launched in those photonic disorders. Our disorder, as also in previous similar studies [2], has a well-defined spectral edge $k_{\max,} = 1/\sigma_R$ that causes peculiar propagation patterns. In particular, we observe in real space distributions, a ballistic front of exponential Anderson Localization defined by the ballistic position of waves with $k = k_{\max}$ (Fig. 1(a)), that reminds Bragg plane effects in regular lattices [3]. We compare our observations to simulations using a novel calibration technique for the refractive index [4].

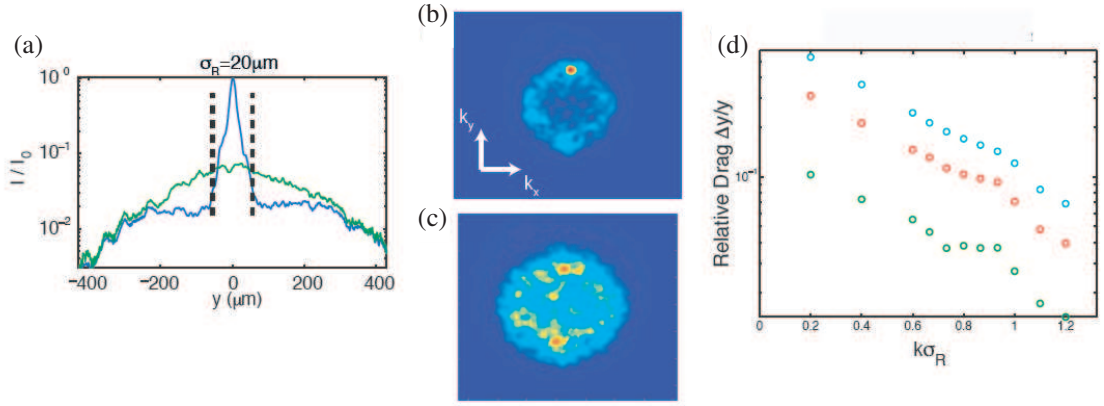

Figure 1: (a) Light intensity at crystal output face for a Gaussian probe beam without (green) and with disorder (blue). Vertical dashed lines show the ballistic positions of components of momentum $k_{\max}$. (c), (d) Fourier space pictures for a plane wave with momentum k with weak (b) and stronger disorder (c). (d) Relative drag (transverse transport reduction) measured at crystal output for plane waves of different transverse momenta k, for 3 disorder strengths.

We also observe intriguing effects in Fourier space. For plane waves with a well-defined transverse momentum k, we observe the formation of elastic diffusion rings (Fig. 1(b)) and a peak of coherent back-scattering (CBS), with contrast close to the ideal maximum of 2 (Fig. 2(c)), which proves the coherence of transport [5]. We study the dynamics of the CBS peak formation by varying V_R: after an increase of the asymmetry in the momentum distribution, we observe a decrease that may be related to the onset on strong localization. Further, measuring the relative stopping ("drag force") of plane waves with different momenta k at the crystal output face, we note a non-monotonous dependence and a maximum close to $k = k_{\max}$ (Fig. 1(d)) that strongly resembles the behaviour predicted for the localization length in a disorder with similar correlation properties [6].

Our work provides a detailed study of light propagation in our correlated disorder, and shows the potential of using wave shaping techniques for the momentum-resolved studies of light propagation in disordered media.

Uni-directional Photonic Modes Due to Strong Random Scattering

Klaus Ziegler
Institut fuer Physik, University of Augsburg, Germany

Abstract— In a photonic medium with a spectral degeneracy, where two orthogonal modes appear with the same wave number, Anderson localization can be avoided in the case of strong random scattering by the formation of uni-directionally propagating modes. This phenomenon was observed previously for strong random scattering of electrons in graphene [1], where electronic states avoid Anderson localization by creating two uni-directionally propagating modes. The reason for this phenomenon are nodes in the spectrum, where the electronic modes have a degeneracy and backscattering is suppressed.

Here we discuss this effect in photonic systems with strong random scattering. The spectral degeneracies can be generated by a randomly deformed photonic crystal. Several examples will be discussed for different structures and different types of random scattering. It will be shown that for weak random scattering we obtain diffusion, whereas for strong random scattering a finite length scale appears which is proportional to the inverse scattering rate. This scale, however, is not the conventional localization length but describes the spatial decay of the photonic mode away from a semi-infinite line. Along this line the electric field is constant. These uni-directional modes are reminiscent of the edge states in quantum Hall systems, where a spectral gap exists rather than a spectral degeneracy. The described effect provides a method for angular localization of a spherical wave by strong random scattering. We derive our results within a convergent perturbation theory and discuss potential applications for focusing light from an isotropic source.

Abstract— Biolasers are laser sources made out of biopolymers and powered by nanophotonic interactions. We will report on biocompatible self-assembled random lasers, made entirely of doped silk, showing clear threshold behaviour and spectral narrowing [1]. We will show that with a simple self-assembly process the porous silk matrix can be incorporated with different dyes and casted in a free-standing inverse photonic glass with designed collective scattering Mie resonances. A diffusive model in which we have included also material dispersion accounts well for the observed lasing curve [2]. The combination of a natural biopolymer and random lasing — a lasing system that uses highly disordered materials to obtain laser action without the need for carefully aligned mirrors — offers the opportunity for integration of a laser within living tissue, opening a new path at the interface between nanophotonic and medicine.

Interpulse and Inrapulse Optical Feedback during Femtosecond Laser Surface Nanostructuring: Experimental Study and Numerical Modeling

S. V. Makarov[1], **A. A. Ionin**[2], **and S. I. Kudryashov**[2, 3]

Abstract— Nonlinear cumulative dynamics of femtosecond laser-induced surface ripples was experimentally studied on silicon and aluminum surfaces, reflecting ultrafast nonlinear dynamics of corresponding optical interference surface patterns. Such dynamics was revealed by detailed electrodynamic modeling to be directly driven by related instantaneous surface optical patterns, which are sensitive not only to cumulative ripples deepening (interpulse feedback), but also to laser-induced instantaneous variation of surface dielectric function (intrapulse feedback), providing either positive, or negative fluence-dependent optical feedbacks. Aluminum and silicon are two typical materials, which represent low and high, respectively, sensitivity of their dielectric function on laser fluence. Therefore we carried out numerical modeling of interpulse feedback for aluminum, and intrapulse feedback modeling for silicon.

The interpulse feedback numerical modeling provides information about the fastest growing relief period at given ripples amplitude. As a result of direct comparison of our experimental data on multishot ripples evolution with corresponding numerical modeling of femtosecond laser energy deposition into growing relief on aluminum, we found out that optical feedback has a maximum value when the ratio $\Lambda/\lambda \sim 0.7$, where Λ is the ripples period and λ is laser wavelength. We show that similar trend should be observed for all materials with high value of imaginary part of dielectric function ($\mathrm{Im}\varepsilon \gg 1$) or high negative value of ε real part ($\mathrm{Re}\varepsilon \ll -1$) [1].

Analysis of the intrapulse optical feedback, basing on modeling of both prompt dielectric function and laser energy deposition into ripples, reveals multiple switching of optical feedback sign during femtosecond laser induced dielectric-to-metal transition. Such behavior of optical feedback causes ripples both degradation and revival during multishot laser irradiation observed in corresponding experiments with silicon [2].

Abstract— At the interface between two media, the properties of Surface Plasmon Polaritons (SPPs) strongly depend on the optical properties of the involved materials. So far, plasmonic effects in noble metals are well described by the widely accepted formulas [1, 2] which are based on the assumption that the imaginary part of the dielectric permittivity is negligible. However, for many materials/systems such an approximation is not valid. This includes interfaces between doped or transiently excited semiconductors and dielectrics with plasmon-active transition metals (such as titanium or platinum), or with organic compounds. An accurate description of such systems requires a refinement of the SPP theory beyond the "perfect metal — perfect dielectric interface" approximation, hence taking into account the neglected imaginary parts [2–5]. In this context, the excitation conditions and properties of SPPs such as the spatial period of the field modulation, the lifetime of the SPP, the SPP decay length and depth strongly deviate from predictions based on the accepted theory.

In this paper, rigorous analytical calculations taking into account the imaginary parts of the dielectric permittivities have been performed which involve the dielectric function terms mostly neglected so far. These refined calculations are presented for various interfacial material combinations. SPPs are found to be excitable on a much wider class of interfaces than just 'noble metal — perfect dielectric' ones. This suggests a possibility to develop plasmon-active photovoltaic cells and new photonic applications based on alternative materials while allowing a wider range of SPP excitation. A list of plasmon-active interfaces is given and supported by near-field modeling using the numerical Finite-Difference Time Domain (FDTD) method. Consequences are detailed for the SPPs in the excitation regimes where the classical approximation is not valid.

Nanostructure Formation by Quasi-1D Plasmon Excitation

Christian Patzek and Ruediger Grunwald
Max-Born-Institute for Nonlinear Optics and Short-Pulse Spectroscopy, Germany

Abstract— Sub-100-nm laser-induced periodic surface structures (LIPSS) can be generated by irradiating materials with intense femtosecond laser pulses. The basic mechanisms of LIPSS are not completely understood because of their high complexity. Compared to lithographic methods which require multistep procedures and cleanroom technologies, the LIPSS approach is easier and cost-effective. By exploiting nonlinear channels for the excitation of surface plasmon-polaritons (SPPs), LIPSS can even be obtained in large-bandgap dielectric materials. The field of applications, however, is limited by the particular tolerance against the residual degree of randomness. For example, random structures can serve as functional surfaces for photocatalysis, anti-icing layers, hydrophobic surfaces or substrates for surface enhanced Raman spectroscopy. Other applications like optical diffraction gratings demand a significantly higher degree of order and require a better control of the laser-material interaction. Important parameters which influence the randomness are the homogeneity of the intensity profile, size and density of defects, the number of laser pulses, the pointing stability of the laser, the polarization orientation and the differential transversal elongation of the translation stage over the path of the substrate. Large areas of material can be structured by scanning methods where the substrate or the laser spot is moved at an optimized speed. Recently we proposed a scanning geometry based on a line focus and a moving substrate. In such a geometry, random defects are statistically changing their relative position along the line focus. Here we report on experimental studies on the formation conditions of coherently linked ripple structures with such a quasi-1D plasmon excitation geometry. The role of nanoscale optical and plasmonic feedback mechanisms is discussed.

Normal and Abnormal Nanoripples Produced on Materials Surfaces by Ultrashort Laser Pulses

Sergey I. Kudryashov[1], **Andrey A. Ionin**[1], **Sergey V. Makarov**[2], **and Wolfgang Husinsky**[3]

[1]P. N. Lebedev Physical Institute, Russian Academy of Sciences, Russia

[3]Institut für Angewandte Physik, Technische Universität Wien, Austria

Abstract— Ultimate (sub-100-nanometer) nanoripples fabricated on different materials surfaces via multi-shot femtosecond (fs) laser exposure are analyzed according to their polarization (ridge orientation) in respect to the laser one — normal (ridges across the laser polarization) or abnormal (ridges along the laser polarization). This polarization aspect is considered in terms of different diffracted EM components on fs-laser photo-excited materials surfaces at photoexcitation conditions, corresponding to their transient optical characteristics, which support excitation of their corresponding surface plasmon resonances. The experimental observation of such normal and abnormal nanoripples is enlightened, invoking the transient optics of fs-laser photo-excited materials experimentally studied by optical pump/probe reflection method, and profound plasmonic description, including plasmon-plasmon interactions, to calculate transient "energy frequency-spatial wavenumber" dispersion relationships for surface plasmon-polaritons in these photoexcited materials.

Waveguiding Metallic Photonic Crystals Produced by Plasmon-driven Self-organization

Abstract— Metallic photonic crystals combined with waveguides are interesting structures that provide a strong interaction between the electronic resonance of a plasmon and the optical resonance of a quasi-guided mode; they can give rise to waveguide-particle-plasmon polaritons with a Rabi splitting. We show here that such structures can result from a plasmon-driven self-organization process [1]. 2D arrays of silver nanoparticles are generated upon laser exposure in a TiO_2 film (Figs. 1(a)–(b)). They exhibit tunable optical properties (Fig. 1(c)) thanks to the control of their size, periodicity, orientation and degree of organization. The physico-chemical mechanisms leading to such a self-organization process are also investigated. Both radiative and non-radiative decays of the localized surface plasmon resonance of silver nanoparticles appear to play an important role in the mechanisms. The non-radiative excitation of hot electrons leads either to charge transfers from metallic nanoparticles to the semiconductor TiO_2 matrix, through the Schottky junction, or to the material heating. These two processes result in two opposite effects that are the shrinkage or the growth of silver nanoparticles through oxidation or reduction reactions, respectively (Fig. 1(d)). Their competition is put to the fore through theoretical and experimental approaches and is shown to control the onset of self-organization [2]. The parameters of the self-organized photonic crystals are however driven through scattering by plasmonic nanoparticles, i.e., through the radiative decay of the plasmon. The latter excites a guided mode of the TiO_2 film, whose interference with the incident field is shown to directly influence the period and the orientation of nanostructures. This novel fabrication method is compatible with large area processing at a realistic cost for technological implementation.

Femtosecond LIPSS Formation on Complex Multilayer Target

Olga Varlamova, **Markus Ratzke**, **and Juergen Reif**
Brandenburg University of Technology, BTU, Cottbus-Senftenberg
Platz der Deutschen Einheit 1, Cottbus 03046, Germany

Abstract— We report on femtosecond LIPSS formation on multilayer targets consisting of a glass substrate, a 100-nm film of a ferromagnetic metallic alloy, covered by a 5-nm protective polymer film. Irradiation with 1 up to 5,000 laser pulses (duration 100 fs, wavelength 800 nm, intensity 2.60 TW/cm^2) results in a peculiar overall ablation pattern, consisting of a system of sharp-edged, flat concentric ring-like terraces, despite the Gaussian beam profile. On each of these terraces, a peculiar LIPSS pattern is developed, with, generally, increasing wavelength towards the spot center. Further, for the inner terraces the LIPSS orientation is parallel with a wavelength of about 700 nm, whereas further out it is perpendicular to the laser polarization. In the latter case, the LIPSS wavelength increases towards the spot center from 100 to 250 nm, despite the flatness of the terrace. This indicates that structure formation is more dependent on local intensity than overall ablation.

Already with the first pulse, the protecting layer is fully removed over the whole spot. After a sufficient irradiation dose, the complete layers are removed at the spot center, and the bare substrate is visible, which does not exhibit LIPSS. So, all structure formation appears to occur in the ferromagnetic alloy film.

Interestingly, the laser-target coupling strongly depends on the laser polarization with respect to the target orientation. This might be an effect of the ferromagnetic film properties.

100-nm-periodic Surface Structures upon Femtosecond Laser Irradiation of Silicon in Water: Experiment and Theory

Abstract— Laser-induced periodic surface structures (LIPSS) are a universal phenomenon upon irradiation of solids with linearly polarized laser radiation [1]. During the last decade remarkable efforts have been made for controlling the LIPSS and for studying their formation dynamics by using ultrashort laser pulses [2–6]. It is generally accepted now that the excitation of surface electromagnetic waves is involved in the formation of near-wavelength sized LIPSS. This may include the excitation of Surface Plasmon Polaritons (SPPs) at the sample surface [7, 8]. For laser processing in air environment, in most cases, both the LIPSS periods and orientations can be successfully explained by taking into consideration transient changes of the optical properties of the laser-excited materials [7]. For laser processing in liquids, usually the LIPSS periods are significantly reduced by up to one order of magnitude. However, only a few studies provide complementing experimental and theoretical analyses of LIPSS formation in different environments [9–11].

In this work, we experimentally study the formation of laser-induced periodic surface structures (LIPSS) upon irradiation of silicon by multiple linearly polarized 30-fs laser pulses (wavelength of $\lambda = 790\,\mathrm{nm}$) in air and water environment. The LIPSS surface morphologies are characterized by scanning electron microscopy and their spatial periods are quantified by two-dimensional Fourier analyses. It is demonstrated that the irradiation environment significantly influences the periodicity of the LIPSS. In air, low-spatial frequency LIPSS (LSFL) were found with periods somewhat smaller than the laser wavelength ($\Lambda \sim 570\,\mathrm{nm} \sim 0.7\lambda$) and an orientation perpendicular to the laser polarization. In contrast, for laser processing in water, a reduced ablation threshold and LIPSS with approximately five times smaller periods ($\Lambda \sim 100\,\mathrm{nm} \sim 0.15\lambda$) were observed in the same direction as in air.

These experiments are complemented by a theoretical modeling of the excitation of Surface Plasmon Polaritons (SPP) in a thin-film surrounded by two semi-infinitely extended media. Three configurations were considered. (i) While, in air, a thin layer of silicon is transiently excited by the femtosecond laser irradiation, it is found that the period of the SPP-laser interference in the excited layer can reach 100 nm at very high intensities. (ii) In water, such a small period can be also reached at very high intensities. However, these two scenarios are not consistent with the experimentally induced carrier densities. Hence, a third scenario is proposed here: (iii) By taking into account the transient excitation of water and the presence of an oxide layer at the laser-excited silicon sample surface, the excitation of SPP in the oxide layer allowed to explain the 100-nm-period at reasonable carrier densities. Such a thin-film SPP model successfully describes the tremendously reduced LIPSS periods in water, and the orientation perpendicular to the laser polarization.

Abstract— We investigate the ablation threshold and nanostructuring of polished natural diamond exposed to 515 nm intense 200 femtosecond laser pulse. The dynamics of the photo-excited electrons inside the bulk is modelled with time-dependent Schrodinger equation. We find that electron dynamics depends sensitively on the characteristics of the substrate band structure, the intensity and polarization of the radiation field. We show that 8 photons are required to surpass the diamond bandgaps for relatively weak field strength. We scrutiny the intensity dependence of the electron density, that is helpful in the interpretation of the experimental data.

On-chip Laser-written Photonic Circuits for Quantum Applications

Armando Perez-Leija, Markus Gräfe, René Heilmann, and Alexander Szameit
Institute of Applied Physics, Abbe Center of Photonics
Friedrich-Schiller-Universität Jena, Max-Wien-Platz 1, Jena 07743, Germany

Abstract— Quantum computation and information science is a new and rapidly developing interdisciplinary research field. In this context, one of the most ambitious goals is to realize scalable quantum information processing and computing based on only linear optical configurations and photon-counting devices [1, 2]. In that vein, a promising approach for miniaturizing and scaling optical quantum circuits is to use on-chip laser written waveguides, which promises strong improvements in performance due to high stability, low noise and therefore almost negligible decoherence. In addition, this particular fabrication method allows creating complex three-dimensional waveguide architectures with multiple degrees of freedom, such as diffraction control and birefringence.

In this talk, we report on our recent progress in integrating laser-written photonic quantum circuits. The presentation will be twofold: in the first part we give a brief overview of the physics and fabrication of integrated multiport waveguide configurations. In the second part we provide a closer look at several particular examples regarding the experimental realization of quantum circuits to achieve particular tasks: On-chip generation of high-order single-photon W-states [3], implementation of Fractional Fourier transforms of classical and quantum wave functions [4], an integrated single-photon counter device [5], and a perfect state transfer protocol [6].

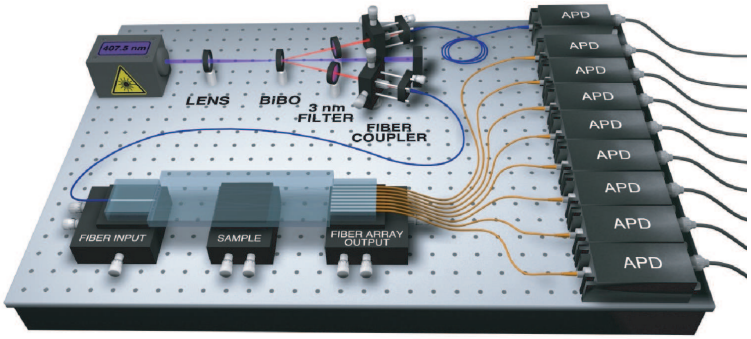

Figure 1: Characterizing quantum waveguide networks on chip. Except photon source and detection devices, all optical components such as beam splitters or wave plates are integrated on chip.

Coupling Single Molecules to a Fabry-Perot Cavity with Ultrasmall Mode Volume

V. Sandoghdar
Max Planck Institute for the Science of Light (MPL) and
Friedrich Alexander University Erlangen-Nürnberg, Erlangen 91058, Germany

Abstract— Cavity Quantum Electrodynamics has offered a powerful approach for manipulating and enhancing light-matter interaction. Two central parameters in this type of study are the quality factors (Q) and cavity mode volume (V). Ideally, one aims to maximize the former while minimizing the latter, but this combination is often very challenging, especially if one insists on facile tenability of the cavity resonance. Indeed, most spectacular results of the last two decades were obtained by increasing Q while V was left at hundreds or thousands of λ^3. Working in this regime means that one deals with very narrow resonances with two undesirable consequences. First, one can only couple to one atomic transition at a time, Second, one has to tune the cavity precisely and work hard to keep its resonance frequency against thermal and mechanical instabilities in the laboratory.

In this work, I will report on the realization of a tunable and scannable microcavity with an ultralow mode volume of the order of $0.5\lambda^3$. The cavity is made of a curved micromirror fabricated using focused ion beam milling and coated with gold placed in front of a planar distributed Bragg reflector (see Fig. 1). Using a very highly curved mirror at the end of an AFM tip, we also achieve a high numerical aperture of 0.4, which offers a large collection angle and compatibility with tightly focused laser beams. A further important feature of our design is maintaining a low Q of about 150, corresponding to a cavity linewidth of 5 nm. The ultrasmall mode volume of such a cavity yields a Purcell enhancement factor of more than 25.

We present our results on the investigation of the effect of a single gold nanoparticle on the cavity resonance and Q. Furthermore, we discuss ongoing work on the coupling of single organic molecules to the microcavity at cryogenic temperatures, where a modest Purcell factor of 25 is expected to have a substantial influence on the emission branching ratio of the excited state. Finally, we will discuss the potential of our experimental arrangements for novel studies of nonlinear quantum optical effects and for optomechanics.

Crystalline WGM Resonators on the Road from R&D to Photonics Products

Vladimir Ilchenko, Andrey Matsko, and Lute Maleki
OEwaves Inc., 165 N Halstead St., Se. 140, Pasadena, CA 91107, USA

Abstract— Crystalline optical resonators with whispering gallery modes (WGM) with their uniquely high value of quality factors 10^8–10^{10} and beyond can serve as core elements in photonic filters, modulators, receivers, narrow-linewidth lasers and low phase noise microwave oscillators. We will review the development status of WGM resonators of different crystalline materials, coupling and tuning methods, high speed modulation techniques utilized in functional photonic devices, as well as discuss performance parameters of crystalline WGM resonator-based microwave and millimeter-wave optoelectronic and Kerr comb oscillators. Architectures and properties of agile photonic receivers and filters will be outlined. Latest results on frequency stability and noise in injection-locked semiconductor lasers with optical feedback from crystalline WGM resonators will be presented in context of their utility for traditional and emerging applications ranging from spectroscopy and remote sensing, to data transmission, metrology and navigation. Prospects and challenges of novel WGM resonator materials and devices for expanded spectral range, from visible to mid-infrared, will be discussed.

Small Refractive Index, High Performance: Magnesium Fluoride Whispering Gallery Mode Sensors

Abstract— Whispering gallery mode (WGM) resonators have been used for sensing for more than a decade [1, 2]. The most common implementation are resonators based on silica microspheres [3] and toroids. Although their performance is good [4] we propose a novel class of materials for WGM resonator sensors namely single crystalline materials [5]. Such resonators can feature higher quality factors $Q > 10^{10}$, expand the range of refractive indicies as well as provide birefringent materials as resonators. Such birefingent WGM resonators can show circular and elliptic polarization behaviors if the angle of the optic axis with respect to the rotational symmetry axis is chosen properly [6]. We will show that especially low index materials as well as birefingent materials are ideally suited for sensors such as refractometric aqueous environment sensors [7]. In particular WGM resonators made out of magnesium uoride (MgF_2) have a refractive index very close to that of water $\Delta n \approx 0.05$ and therefore feature significantly enhanced evanescent fields length compared to silica microresonators [7]. Their birefingence and especially the thermorefractive coefficients of MgF_2 allow furthermore to stabilize the temperature of the mode volume down to a few nano Kelvin [8].

Abstract— A notch filter consisting of a resonator and a waveguide plays an important role in both fundamental and applied research such as optomechanics quantum information processing, low-threshold lasing and high-performance sensing. It is always desirable to maintain efficient resonator waveguide coupling (RWC) of the notch filter for the success of all these studies In general, we consider the case in which the waveguide is placed outside the rim of the resonator. In this case, the field exchange between the resonator and the waveguide takes place through their evanescent fields in a region where their spatial modes overlap. As the waveguide approaches the resonator, the RWC goes from under coupling, through critical coupling, to over coupling due to the increase of the spatial overlap between the light leaking out from the resonator and that from the fiber taper.

Here, we investigate a new RWC configuration in which the waveguide is placed between the center and edge of the resonator in a plane parallel to the surface of the resonator. In this case, the RWC takes place at two different regions where the spatial modes of the resonator and waveguide have spatial overlap. We show that with this new configuration, one can obtain as efficient RWC as nearly critical coupling even when the waveguide is moved far from the rim of the resonator toward its center. This is attributed to the destructive interference between the light fields coupled out from the resonator at two different regions and the light propagating through the waveguide directly. As the horizontal position of the waveguide with respect to the center of the resonator is scanned laterally, RWC experiences periodic oscillation when the waveguide is fixed at a constant height above the resonator. A theoretical model based on coupled-mode theory and two-point coupling successfully explains the experimental observations. Similar horizontal oscillatory coupling behavior is also observed in two vertically coupled microdisk resonators.

Ring Resonator Based Silicon Photonic Devices

Abstract— Silicon as a material for forming photonic devices is attractive for several reasons. Devices can be fabricated in CMOS like facilities in large volumes and with high yield and as a result costs are low. Another attraction is compactness. In most cases silicon photonic devices are built on silicon-on-insulator substrates. Sub-micrometer single-mode strip and rib waveguides based in this high index contrast system are highly confining and low loss bends can be produced with a radius of just a few micro meters. This feature allows ring resonators which occupy extremely small footprints to be produced. In this work an overview of some of our recent work in the area of ring resonators will be given.

Our recent results about cascade-coupled ring and racetrack resonators based on the Vernier effect for filtering and sensing applications and operating in the near-infrared wavelength range are reported. In particular, Vernier spectra with overall free spectral ranges as long as $\sim 36\,\text{nm}$, Vernier gains up to 30, extinction ratio of 30 dB and overall insertion loss as low as 2 dB have been achieved experimentally around 1.55 μm in excellent agreement with the theoretical predictions

Optical modulators are key components in photonic systems for data transmission. In silicon the use of the plasma dispersion effect to achieve optical modulation in a carrier depletion structure has been the preferred approach for many working in the field due to their ease of fabrication, attainable performance and CMOS compatibility. There are two main approaches for converting the phase modulation produced by such a device into intensity modulation. The first involves incorporating the phase modulator into a Mach-Zehnder interferometer (MZI) and the second into a ring resonator. In this work we present experimental results from both approaches demonstrating a ring resonator based optical modulator operating up to 40 Gbit/s.

The Midinfrared wavelength range is become an increasingly vibrant research area in silicon photonics for many application areas. In particular, ring resonator based structures are particularly suitable for sensing and filtering applications to be performed in the mid-infrared; although integrated microcavities based on suspended and membrane waveguides on silicon-on-sapphire technology platform, As_2Se_3 chalcogenide glass, and $Ge_{23}Sb_7S_{70}/Zr_{0.6}Ti_{0.4}O_2$ material systems have been demonstrated to operate up to $\sim 5\,\mu\text{m}$, to date there have been very few demonstrations of silicon ring resonators based on non-exotic waveguide architectures, operating in this wavelength range. In this work we also present our work on single and cascade-coupled ring and racetrack resonators based on standard rib and strip silicon waveguides operating in the 3.7–3.8 μm wavelength range. Our devices can exhibit insertion loss lower than 1 dB, extinction ratios up to 30 dB, quality factor up to $\sim 10,000$ and free spectral ranges even shorter than 5 nm.

Spatial and Temporal Control of Cavities

Abstract— Semiconductor microcavities have proven to be essential for light confinement in space and also for storage in time, which enables manipulating light matter interactions [1]. The control of the cavity refractive index spatially and temporally will allow for complete control over the light stored in a cavity; in real space, wavevector space, frequency space, and in time domain. The control of the refractive index at ultrafast time scales enables to convert the frequency of light stored in a cavity [2]. The spatial control will allow for controlling the coupling of the cavity to the environment and enable to shape the mode profile.

The generation of light with a controllable frequency is a long standing challenge. Literature has it that the physics of frequency conversion in a cavity differs from traditional non-linear optics, regarding the rate of phase change and output spectrum [2, 3]. Here, we unify these disparate views. We have reversibly switched the resonance of GaAs-AlAs microcavities in the near-infrared ($\lambda = 1280\,\mathrm{nm}$) within 300 fs by the electronic Kerr effect [4]. Fig. 1(a) shows spectra measured at several pump-probe delays Δt. We observe a significant red- and blue-shift of light trapped in the cavity, controlled by the pulse-timing. Blue-shift occurs at $\Delta t = -100\,\mathrm{fs}$ when the phase decreases, and red-shift light at $\Delta t = -500\,\mathrm{fs}$ where the phase increases, in seeming agreement with usual non-linear optics [4]. Fig. 1(b) shows that the integrated blue-converted reflectivity increases remarkably with inverse quality factor. We identify $(1/Q)$ as a measure of the density of optical states (DOS) that leak into any cavity at frequencies off-resonance. We conclude that frequency conversion in a cavity is controlled by the density of vacuum states and the non-linear polarization [4]. Our new insights provide a unified framework for seemingly disparate results in traditional nonlinear optics and nanophotonics, and offer a complete control of on-chip frequency conversion.

Arrays of coupled high-Q nanocavities, collectively provide a superior system than a single cavity that can be used to observe light localization [5, 6]. A challenge remains; namely to fabricate an array of cavities at the same resonance frequency to observe localization. Due to technical limitations, fabrication of many high-Q cavities at the same resonance frequency is not simply achievable. Here, we control the resonance frequency of each cavity individually by locally changing the refractive index in an InGaP photonic crystal cavity array. We use wavefront shaping to shape the pump beam and we address individual cavities [7]. As a result, we spatially control the refractive index and manage to manipulate the coupling of the cavities. We show that we can counteract the unintentional shift of the cavity resonance frequency and we can bring multiple cavities to a collective resonance.

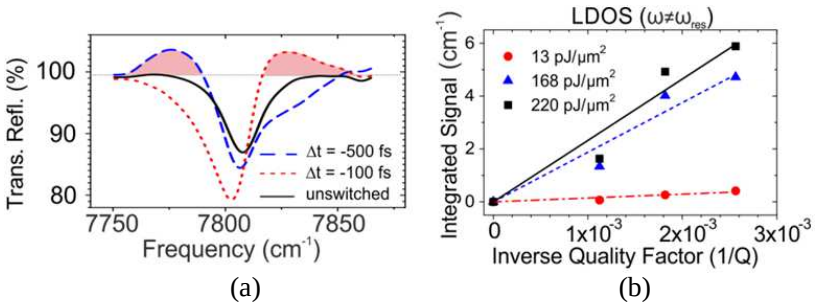

Figure 1: The measured transient reflectivity versus frequency at several time delays. Filled regions show newly generated frequencies. In the absence of color conversion the transient reflectivity is 100%. Cavity has $Q = 390$. (b) Integrated signal versus inverse quality factor $(1/Q)$, a measure of the density of states, for different pump intensity. Top abscissa: LDOS. Lines are guides to the eye.

Abstract— Optical sensors can offer many advantages in terms of increased sensitivity or compatibility with environments where electronic devices are not suitable.

Whispering gallery modes microresonators (WGMRs) exhibit high quality factor ($> 10^7$) optical resonances. These are very sensitive to changes to the structure of the resonator and their wavelength position shifts when molecules bind to its chemically functionalised surface.

This effect can be exploited to build very sensitive sensors and can be utilised to develop point of care equipment or environmental sensors, among the most relevant applications.

In this presentation, after a short recall of the working principles of these structures and a review of the highlights of the advances in this field, the presentation will describe our activity in the development of optical sensors based on WGMRs.

The presentation will focus in particular on our activity in the development of microbubble resonators.

We have been working on the interdependent aspects such as modelling, fabrication, localised chemical functionalization for selective response, structural and modal characterisation, coupling, which are all challenging tasks in order to obtain optimised devices. The presentation will give an account of our efforts to harness all these factors and the related results we obtained.

Coupling, Controlling, and Processing Non-transversal Photons with a Single Atom

A. Rauschenbeutel
Vienna Center for Quantum Science and Technology, Institute of Atomic and Subatomic Physics
Vienna University of Technology, Wien, Austria

Abstract— I will report on recent experimental investigations of the interaction between single rubidium atoms and light that is confined by continuous total internal reflection in a whispering-gallery-mode (WGM) bottle microresonator. We discovered that the non-transversal polarization of WGMs fundamentally alters the physics of light-matter interaction [1]. Taking advantage of this effect, we recently demonstrated switching of signals between two distinct optical fibers controlled by a single atom [2]. Owing to the excellent optical properties of our bottle microresonator, the scheme yields high switching fidelities and low losses. Furthermore, we made use of the strong nonlinear response of the atom-resonator system and experimentally realized an optical Kerr nonlinearity at the level of single photon [3]. Analyzing the transmitted light, we observe a nonlinear phase shift of π between the cases of one and of two photons passing the resonator. This phase shift leads to entanglement between previously independent fiber-guided photons, which we verify by performing a full quantum state tomography of the transmitted two-photon state. And finally, via the WGM microresonator, we coupled a single atom to a nanophotonic silica waveguide and demonstrate nonreciprocal transmission of light at the single-photon level through the system [4]. The resulting optical diode is the first example of a new class of nonreciprocal nanophotonic devices which exploit the chiral interaction between quantum emitters and transversally confined photons.

Micro-optical Wall Shear Stress Sensor for Fluid Mechanics Applications

Ulas K. Ayaz[1], **Tindaro Ioppolo**[2], **and Volkan Otugen**[2]

[1]Mechatronics Department, German University in Cairo, Berlin, Germany
[2]Mechanical Engineering Department, Southern Methodist University, Dallas, TX, USA

Abstract— In recent years, several micro-sensors have been proposed based on the excitation of optical modes of dielectric micro-resonators. These optical resonators could come in spherical, cylindrical or torroidal geometries and vary in size from a few microns to several hundreds of microns. The optical modes of these resonators are called whispering gallery modes (WGM), and have been exploited in a number of applications in spectroscopy, micro-lasers, optical communications as well as sensor technologies. The WGM based optical sensors in the literature include biosensors, trace gas detection, impurity detection in liquids, structural health monitoring of composite materials, detection of electric and magnetic fields, as well as mechanical sensing such as force, pressure, shear stress and acceleration. In this talk, some of these optical sensors in mechanical sensing, with the focus given on the wall shear stress sensor for fluid mechanics applications, will be presented.

Quantum Operations Based on Waveguide Nonlinear Optical Materials

Takashi Yamamoto
Graduate School of Engineering Science, Osaka University, Toyonaka, Osaka 560-8531, Japan

Abstract— Photonic frequency conversions based on nonlinear optical phenomena have attracted much interest in the context of the manipulation of the quantum states recently. One of the immediate applications is the frequency conversion of a single photon without destroying its quantum states. Such a quantum frequency converter is useful for linking diverse matter based quantum systems through the quantum states of light. Especially, when we look at the long distance quantum communication, entangling the distantly located matter quantum memories via photons is considered to be an elemental building block for the quantum repeaters. Here we report on such a single photon frequency converter from visible to telecommunication wavelength with a second order nonlinear optical phenomena based on a waveguide PPLN, which aims at linking Rb atom quantum memories with a long distance optical fiber communication. The single photon frequency converter with a adjusted conversion efficiency is also useful for the manipulation of quantum states encoded in the frequency degree of freedom. Along this direction, we also present an interference of a photon in two different frequency modes and also Hong-Ou-Mandel (HOM) interference of two photons in two different frequency modes. The enhancement of the conversion efficiency with microcavities is also an important issue for the future applications. We also present our recent activity on slow and fast light observation based on high-quality-factor whispering gallery mode (WGM) resonators in the form of microtoroids and bottle microresonators with high quality factors.

Silicon Optical Matrix Processor for Parallel Computing

Lin Yang, Lei Zhang, Hao Jia, and Jianfeng Ding
State Key Laboratory on Integrated Optoelectronics
Institute of Semiconductors, Chinese Academy of Sciences, Beijing 100083, China

Abstract— Matrix-vector multiplication is a fundamental operation in modern digital signal processing fields. Inspired by the intrinsic spatial parallelism of optics, much effort has been made to develop optical apparatuses that can perform such a parallelizable operation. The Stanford multiplier is one of the most notable demonstrations, which is composed of light source array, optical lens, spatial light modulator matrix and photodetector array. Almost all implementations are large in volume and high in power consumption. Moreover, many removable elements adopted make them extremely sensitive to the environmental vibration. To overcome these limitations, we propose an on-chip optical matrix processor (MVM), which is composed of laser-modulator array, multiplexer, splitter, microring modulator matrix and photodetector array. The fan-out and fan-in with optical lenses in the traditional optical MVMs are replaced by the power splitting and wavelength multiplexing with waveguide devices in the proposed optical MVM, which greatly reduces the complexity and size of the system. The discrete components in the traditional optical MVMs are replaced by the integrated ones in the proposed optical MVM, which improves the stability and power efficiency of the system. 1.6×10^9 multiplications and accumulations per second is implemented by a demo system with a 4×4 microring modulator matrix.

Efficient Optical Fiber Coupling to Whispering Gallery Modes of Optically Manipulated Emulsion Microdroplets

S. Anand[1], **M. Eryürek**[1], **Y. Karadag**[2], **A. Serpengüzel** [1], **and A. Kiraz**[1]

[1]Department of Physics, Koç University, Rumelifeneri Yolu, Sarıyer, İstanbul 34450, Turkey
[2]Department of Physics, Marmara University, Göztepe, İstanbul 34722, Turkey

Abstract— We demonstrate efficient coupling to the optical whispering gallery modes of a spherical resonator consisting of a liquid droplet embedded in another liquid medium. Whispering gallery mode particle sensing experiment is commonly performed with solid resonators, whereby the sensing volume is limited to the weak evanescent tail of the mode near the resonator surface. In this work, we demonstrate efficient coupling to the optical whispering gallery modes by introducing a portable, all liquid emulsion microdroplet resonator held in a single beam optical trap. We have observed coupling to the fundamental whispering gallery modes of 10 to 60 µm diameter emulsion droplets at 1550 nm. The experimental challenges towards making, stabilizing and coupling to the droplet resonators are also addressed in this paper.

Optical Resonances in Quantum Plasmonics

M. S. Tame
University of KwaZulu-Natal, South Africa

Abstract— Quantum plasmonics is a rapidly growing field of research that involves the study of the quantum properties of light and its interaction with matter at the nanoscale. Here, surface plasmons — electromagnetic excitations coupled to electron charge density waves on metal-dielectric interfaces or localized on metallic nanostructures — enable the confinement of light to scales far below that of conventional optics. We review recent progress in the experimental and theoretical investigation of resonant optical phenomena in quantum plasmonic systems, including the role of surface plasmons in controlling light-matter interactions at the quantum level and potential applications, such as entanglement generation and the distillation of entanglement.

Abstract— Circular cavities [1] such as microspheres [2], microdisks [3], and microtoroids [4] with high quality factor whispering gallery modes (WGMs) continue to open up new perspectives in sensing [5–8]. In this paper, an optical setup for a DNA optical biosensor based on sapphire microsphere was built. Transmitted and elastic scattering intensity at 1510 nm were analyzed from a sapphire microsphere on an optical fiber half coupler for the first time. The 0.43 nm angular mode spacing of the WGMs correlated well with the optical size of the sapphire microsphere. The spectral linewidths of the WGMs were on the order of 0.01 nm, which corresponded to quality factors on the order of 10^4. As a proof for principle, a polydopamine (PDA) layer has been used as a functionalizing agent on sapphire microspheres in view of the implementation of biosensors. The various PDA layer thicknesses on the sapphire microsphere were characterized as a function of the WGMs wavelength shift. It was shown that the polymeric functionalization does not affect the high quality factor ($Q \approx 10^4$) of the WGMs. This functionalizing process of the microsphere constitutes a promising step towards the achievement of an ultrasensitive biosensor. Afterwards, the sapphire microsphere was modified with DNA and an optical biosensor is demonstrated for the first time using an insulating implant material such as sapphire. A probe DNA, consisting of a 36-mer fragment was covalently immobilized on sapphire microsphere and hybridized with a 29-mer target DNA. WGMs were monitored before the sapphire was being functionalized with DNA and after it was functionalized with single stranded DNA (ssDNA) and double stranded DNA (dsDNA). The shift in WGMs due to the surface modification with DNA was measured and correlated well with the estimated add-on DNA layer. It was shown that ssDNA are more uniformly oriented on the sapphire surface than the dsDNA. In addition, it was shown that the functionalization of the sapphire microsphere's surface with DNA does not affect the high quality factor ($Q \approx 10^4$) of the WGMs. All in all, we have taken the first step towards utilizing a structural, electrically insulating implant material as an optical microcavity based biosensor platform paving the way for future in vivo biosensing devices [9, 10].

Abstract— Non-radiative Forster Resonance Energy Transfer (FRET) between a pair of donor and acceptor chromophores can serve as a precise ruler to measure the distance between the two chromophores in the nanometer range with atomic-scale resolution. The strong dependence of the Energy Transfer (ET) rate in FRET on the donor/acceptor distance has already been used to detect conformational changes in large biomolecules such as proteins and nucleic acids or to quantify interactions between different biomolecules and molecular complexes in live cells. Commonly, the change in the intensity of the donor or acceptor fluorescence is used to determine the change in the ET rate. To increase the sensitivity of fluorescence measurements, the ET can be coupled to a suitable optical cavity, forming a laser with FRET-based active medium. This approach takes advantage of the strongly non-linear dependence of the amplified stimulated emission on minute changes of the overall laser gain.

Using rate equations describing FRET coupled to a Fabry-Perrot optical resonator, we study theoretically the dependence of the output lasing energy from a simple donor/acceptor dye pair placed in the cavity on the distance between the two chromophores. Subsequently, we compare these results with the sensitivity of the output fluorescence intensity when there is no lasing or feedback mechanism present. Our analysis shows that for an example dye pair of Rhodamine 6G as a donor and Acid Blue 7 as an acceptor with 6.1 nm Forster distance, the sensitivity of the fluorescence intensity to the changes in the donor-acceptor separation in the FRET-lasing case increases at least by a factor of 10 relative to the non-lasing case with identical dye concentrations in the 1 to 10 micro-molar range. The presented theoretical analysis supports our recent experimental works on optofluidic FRET lasers and suggests a direct strategy for optimizing the performance of FRET-based molecular sensors.

Operating Speed Extension of SOA External Modulator Using Microring Resonator

Abstract— Semiconductor optical amplifiers (SOAs) have recently been receiving intense research interest for use as external modulators. The main technical challenge faced in this effort is the SOAs modulation bandwidth, which is limited below 1 GHz due to the SOAs finite differential carrier lifetime [1]. In order to overcome this difficulty, a widely adopted option exploits optical filtering to manipulate the spectral components of the signal at the SOA output [1]. For this purpose various technologies have been employed [1, and References [11–14] therein]. In this paper we propose to apply a passive single microring resonator (MRR) as notch filter [2] for extending the modulation speed of directly modulated SOAs. This scheme features several attractive operating and practical characteristics [2], which render it an alternative solution for allowing conventional SOAs to be used as external modulators at enhanced data rates.

Figure 1 depicts the block diagram of the directly modulated SOA followed by the MRR of radius R, notch (resonance) detuning, $\Delta\lambda$, to the longer sideband of the data carrier position, and field transmission coefficient r that meets the necessary requirement of critical coupling [2]. We simulated the operation of this setup by calculating first the temporal response of the SOA [2] when the latter is driven under the same input signal and bias conditions as in [1]. Afterwards we transferred this function into the frequency domain by means of Fast Fourier Transform (FFT) in Matlab software and convolved it with the MRR spectral response. This response is described by a compact mathematical form [2] and has the periodic comb-like profile shown inside the MRR box in Fig. 1. Finally, we converted the convolution product back into the time domain using Inverse FFT. By following this procedure we investigated the impact of the MRR radius and detuning on the quality of the encoded optical signal. Provided that the MRR is properly designed against these parameters, which is practically feasible, then it can efficiently suppress the SOA pattern-dependent distortion. Thus the MRR-based notch filter can help improve the performance of SOAs as externally modulators at data rates several times faster than those enabled by their electrical bandwidth.

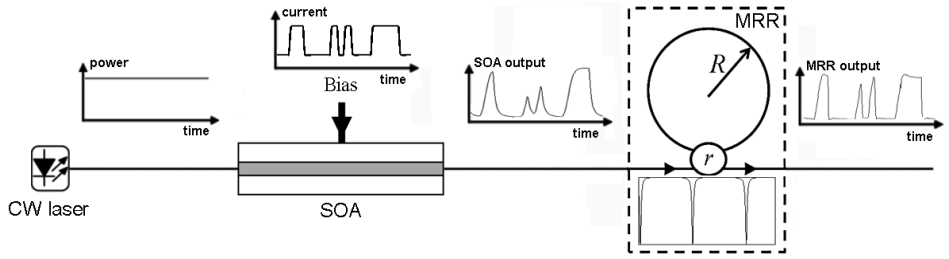

Figure 1: Configuration of directly modulated SOA and MRR-based notch filter.

Abstract— In recent years there has been considerable interest in exploiting temperature dependence of sapphire whispering gallery mode resonator's (WGMR) frequency to develop a mechanical stable temperature sensor that could provide measurement capabilities on par with a Platinum resistance thermometer (PRT). While PRTs can routinely measure temperatures with uncertainties of 10 mK, they are sensitive to mechanical shock which causes the sensor resistance to drift over time requiring frequent off-line, expensive, and time consuming calibrations. Disk-resonator-based devices have been demonstrated to measure temperature with accuracies of 10 mK or better in the temperature range of 273 K to 373 K. We are utilizing automated data acquisition and processing to rapidly evaluate a mechanically-stabilized sapphire whispering gallery mode resonators based on a hollow cylindrical configuration. Our results preliminary results indicate the metal support structure contributes to increased loses of the resonator which results in significant reduction in resonator mode's quality factors.

Abstract— Variability of space weather and its impact on the near-Earth environment is a natural norm. These phenomena can not be avoided, but should be studied and taken into account for the successful functioning of modern communication and GNSS systems. Moreover, the rapid development of technology in the last 20–30 years has meant that the potential accuracy of the use of modern communication and navigation systems are limited to the influence of media in which information signals are distributed. It is particularly sensitive the malfunctions of high-orbit GNSS due to the impact of the physical conditions (space weather) prevailing in the near-Earth space.

The considered "slips" or "failures" are the two possible events in the GPS operation. First of all, it is impossible to determine as the phase or pseudo accompanying signal. These phenomena have a direct impact on the positioning accuracy. Secondly, the failure may also be considered short-term variations of the recorded total electron content (TEC), the values of which can not bear the physical sense and explains the process in the ionosphere and magnetosphere.

In our work we analyzed the dynamics of manifestation of GPS slips and failure in some significant time periods around the date of the studied powerful geomagnetic disturbances 2010–2014. Discussed magnetic storms have the amplitude more 1500 nT. In consideration GPS data on more than 100 stations in the modern global and regional networks (IGS and CHAIN) are used. The used stations are located north of the inclination of the system GPS. Consideration of the chains of power plants mainly in a northerly direction on the territory of Alaska, Canada, northern Europe has allowed for the first time to study the dynamics of the growing influence of the high-latitude ionosphere to the received satellite signal.

The data on the occurrence of slips compared to the behavior of the high-latitude geomagnetic indices AE and AL. We found that failures in determining pseudorange occur much less frequently than in phase measurements. The probability of slips for the phase L2 frequency even in calm conditions receive are several times more than the frequency code capture L1. These relations are preserved and for the pseudorange faults. The presence of geomagnetic storms (or disturbances) leads to an increase of this magnitude in a few dozen times for the considered magnetic events.

Slips rate in determining the TEC significantly — 100 times — more than the phase losses and also during the growing geo-solar magnetic disturbances of different nature. The analysis shows that a possible solution to reduce the impact of failures on the navigation GPS system is to increase the mask on the elevation angle of the satellite 20° .

Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia

Abstract— Based on vertical and oblique-incidence sounding data we carried out an analysis of HF propagation characteristics during magnetoactive period in February 2014. The oblique-incidence data were obtained along subauroral and midlatitude paths: from Magadan to Irkutsk, from Khabarovsk to Irkutsk, from Khabarosk to Norilsk The period under consideration was characterized by series of solar flares accompanied by X-ray flares, intensification of proton fluxes and coronal mass ejections (CME). These processes caused two magnetic storms of different intensity. The former storm developed on February 18–26. It was characterized by minimum Dst $= -112$ nT at 08 UT on February 19 and prolonged recovery phase. The latter one with minimum Dst $= -99$ nT at 23 UT on February 27 happened on February 27–March 3. Increase of X-ray radiation on February 25 (X4.9/2B) led to a growth in the lowest observed frequencies at the oblique and vertical sounding ionograms and weakening of a signal near the maximum observed frequencies (MOF). During the main and recovery phases of the storms the MOF along the path from Magadan to Irkutsk sharply fell by 3–5 MHz. Intervals of low MOF values alternated with those of absence of reflected signals at the ionograms. It specifies that boundaries of the main ionospheric trough could be displaced to the latitude of this path average point. Similar absence of reflected signals at the ionograms was registered along Khabarosk-Norilsk path. Besides, during these two storms at the oblique sounding ionograms the additional signals with large temporary delays were observed over paths from Magadan to Irkutsk and from Khabarovsk to Irkutsk in the evening and nocturnal hours. The amplitude relief of abnormal signals was characterized by strong diffusion and frequencies exceeded MOF of standard propagation modes. Since the ionosphere is not perfectly horizontally stratified during magnetic storms the signal associated with propagation mode may arrive at received point over a wide range of azimuth angles.

Abstract— We present the results of comparative analysis of geomagnetic field and total electron content (TEC) variations. The analysis is based on the long series of data from the Siberian GPS network of the Institute of solar-terrestrial physics (ISTP) of Siberian Brunch of Russian Academy of Science (SB RAS) and Norilsk GPS station operated by the Geophysics Service of RAS (GS RAS.) ISTP SB RAS Siberian network make continuous TEC measurements since 2012 and provide TEC-variation data with time resolution of 1 sec. The calculation of TEC is based on two-frequency phase measurements of GPS receivers. We analyzed TEC variations in two period ranges (0–10 min and 10–40 min), which are correspond to different modes of ionospheric disturbances. Magnetic intensity data were obtained from ISTP SB RAS observatories and INTERMAGNET sites. The common level of TEC disturbance is estimated by the index W_{tec} of the TEC-variation intensity. The index is calculated for all available GPS satellites, with the data of highest elevation angle at every moment. This method allow to investigate continuous changes of TEC variation intensity. The Wtec calculated for all the GPS data 2013. The W_{tec} dynamics features is revealed for different times of day, seasons and levels of geomagnetic activity for middle-latitude and Arctic regions. The response of the W_{tec} to sudden storm commencements (SSC) was also investigated.

ACKNOWLEDGMENT

The authors thank the Geophysics Service of RAS and INTERMAGNET for the data they provide. This work was supported by the Grant of the Russian Scientific Foundation (Project No. 14-37-00027.).

TEC Response to Geomagnetic Storms and Solar Flares as Observed with SBAS L1/L5 Signals

G. A. Kurbatov[1], **V. E. Kunitsyn**[1], **A. M. Padokhin**[1], **and Yu. V. Yasyukevich**[2]

[1]Faculty of Physics, Lomonosov Moscow State University, Russia
[2]Institute of Solar-Terrestrial Physics SB RAS, Russia

Abstract— The development of Satellite Based Augmentation Systems (SBAS) provides the possibility to retrieve ionospheric Total Electron Content (TEC) from the dual frequency L1/L5 observations from a number of geostationary satellites using the same approach as for dual frequency GPS/GLONASS observations.

In this work we study L1/L5 signals of Indian GAGAN and American WAAS geostationary satellites observed with geodetic GNSS receivers at several stations at mid- and low-latitudes and estimate corresponding geostationary TEC variations and errors of such estimations. We discuss the quality of these data showing that SBAS TEC RMS could reach up to 1.5 TECU with typical values of 0.25–0.5 TECU which is up to one order greater than for common GPS/GLONASS observations. We present the evidence that such large values of SBAS TEC RMS are satellite dependent and are not of ionospheric origin, so they could be easily filtered out without losing significant ionospheric information providing continous TEC datasets for selected satellite-receiver pairs instead of short 2–6 hours records as in GPS/GLONASS case.

We present geostationary SBAS TEC response to increasing solar X-Ray and EUV ionizing radiation during several recent X-class flares. Good correlation was found between TEC and EUV flux for the stations at the sunlit hemisphere. We also present SBAS TEC response to geomagnetic field variations during strong and moderate geomagnetic storms showing examples of both positive and negative TEC anomalies of order of tens of TECU during main storm phase.

Our results show the capability of SBAS L1/L5 observations for continuous monitoring of ionospheric TEC. Intensively growing networks of receivers capable to work with L1/L5 SBAS signals (for example MGEX network) and increasing number of dual-frequency satellites in SBAS constellation potentially make it a powerful instrument for TEC climatology.

Acoustic-gravity Waves in Space Generated by Near-ground and Volume Sources

Elena S. Andreeva[1], **Viacheslav E. Kunitsyn**[1,2], **Ivan A. Nesterov**[1], **and Artem M. Vorontsov**[1]

[1]M.V. Lomonosov Moscow State University, Moscow, Russia
[2]Institute of Physics of the Earth, Russian Academy of Sciences, Moscow, Russia

Abstract— Numerical analysis of acoustic-gravity waves (AGW) generation and propagation in the Earth's atmosphere is performed based on computer model of stratified atmosphere with dissipation.Atmospheric and ionospheric wavelike disturbances generated by near-ground or volume sources such as oscillations of the Earth's or oceanic surface, earthquakes, explosions, seiches, tsunami waves and temperature heating are studied. These wavelike phenomena in the atmosphere and ionosphere appear as the alternating areas of enhanced and depleted density (in the atmosphere) or electron concentration (in the ionosphere).

Observation and investigation of various ionospheric perturbations under assumption of their correct physical interpreting and understanding of their hydrodynamic generation mechanisms commonly allows obtaining current or predictive configuration of near-ground or volume sources of disturbances. The least studied problem here is a question about acoustic energy transferring from the ground sources into near-Earth space that primarily is related with incompleteness of AGW propagation theory in the real atmosphere. Moreover, complete analysis of the observed ionospheric perturbations should be performed using conventional characteristics of ionospheric waves such as amplitude, phase, period, velocities of corresponding wave packets and angular characteristics of the wave vector. Notice, that for most near-ground or volume sources in geophysical bibliography there is a significant variance regarding values of basic AGW parameters as well as absence of unified point of view on AGW generation mechanisms. As the examples of mentioned mechanisms different authors provide infrasound wave generation, internal gravity waves generation, eddying motion of the neutral component generated by an acoustic pulses, the generation of shock-acoustic waves, etc..

The numerical simulation of upper atmosphere responses to various near-ground or volume sources can provide estimations of basic AGW characteristics and to clarify AGW generation mechanisms. The major results of the paper consist in determining of common as well as unique tendencies in AGW behavior for a wide class of sources, analysis of these tendencies and estimation of AGW wave packets' parameters. Numerical simulation studies of wavelike AGW disturbances generation by particle precipitation are presented. The ionospheric footprints of atmospheric disturbances are given. These two sentences should be removed.

Testing NmF2 Data from UV SSUSI Measurements with Global Ionospheric Maps and Satellite Radio Tomography at Mid and High Latitudes

G. A. Kurbatov, **E. S. Andreeva**, **S. A. Kalashnikova**, **V. E. Kunitsyn**, **I. A. Nesterov**, **A. M. Padokhin**, **and Yu. S. Tumanova**
Lomonosov Moscow State University, Russia

Abstract— Development of the Defense Meteorological Satellites Program (DMSP) and its new instruments such as Global Ultraviolet Imager (GUVI) and Special Sensor Ultraviolet Spectrographic Imager (SSUSI) provides the opportunity to get ionospheric F2-layer peak density (NmF2) as the product of the measurements of the natural nighttime emissions of O+ ions, generated by its reaction of radiative recombination. This dataset is distributed via http://ssusi.jhuapl.edu/ by Johns Hopkins University Aplied Physics Laboratory.

The aim of the present work is to compare this new NmF2 product with broadly used Global Ionospheric Maps (GIM) and data obtained using such well-developed method as GNSS radiotomography (with both low- and high-orbiting navigational satellites) for various geomagnetic conditions during last two solar cycles.

The results of such comparison along radio tomography system in Russia (covers mid and high latitudes) during the periods of various geomagnetic conditions showed that large structures reaching the size of about 10° are distinctly reconstructed in both RT and UV data and are in good agreement within the accuracy of both methods, while the same structures are typically smoothed in GIM data due to poor spatial and time resolution.

Having poorer SNR values compared to radio measurements, UV data can give important information about the ionosphere, especially over the regions where application of radio tomography methods is limited. The possibility of incorporating UV measurements into radiotomography routines should be further investigated and modeled.

ACKNOWLEDGMENT

Adaptation of IRI-2012 Model for Estimation of IAR Harmonic Structure

A. S. Potapov[1], **T. N. Polyushkina**[1], **A. V. Oinats**[1], **T. Raita**[2], **and B. Tsegmed**[1, 3]

Abstract— The ionospheric Alfvén resonator (IAR) is a structural formation in the ionosphere between two peaks of Alfvén speed in its altitude profile. The IAR can amplify and accumulate ultra low frequency (ULF) wave energy in the upper ionosphere. As a result of the IAR occurrence the multiband spectral resonance structure (SRS) appears in the ULF observations, both ground-based and satellite. Frequency of discrete spectral bands and spacing between them are determined by the geometry of the resonator and the Alfvén speed in its cavity; the change in band frequency during the day with a minimum around noon and a maximum after midnight or in the early morning hours is due to diurnal variation of ionospheric parameters. Close connection of SRS mode and features with state of the ionosphere motivates many authors to study the details of this connection, and make suggestions about how to use observations of the spectral structure of the electromagnetic background in the range of 0.5–10 Hz for sounding ionospheric parameters and clarifying ionospheric models.

In this paper we propose a new approach to analysis of emission of ionospheric Alfvén resonator (IAR). We apply the IRI-2012 version of International Reference Ionosphere model to calculate difference between frequencies of adjacent harmonics (frequency scale) of IAR emission. The calculated values are compared with the frequency scale data obtained from search-coil magnetometer observations made at two different stations, the mid-latitude observatory Mondy (Eastern Sayan, Russia) and the high-latitude Sodankylä Geophysical Observatory (Finland). For measurements made at medium latitudes, it appears that to reach satisfactory results it is necessary to modify IRI-2012 model replacing the vertical profile of ionospheric parameters adopted in the standard model with the profile elongated along the magnetic field lines. For polar latitudes, where the field lines deviate from the vertical insignificantly, such a procedure is not so important. On the other hand, irregular behavior of the polar ionosphere results in the diffusive character of the SRS. That is why the spectral bands of the SRS at SGO spectrograms are blurred which cumbers precise measurements of frequency values. To improve the estimates of the frequency scale we corrected the model using local f0F2 measurements. Finally, our results showed strong correlation between the estimated and measured values of the frequency scale.

Comparison of Polar, Sub-polar and Mid-latitude Ionospheric Variability Using Ionosonde and SuperDARN Data

K. G. Ratovsky[1], **A. V. Oinats**[1], **and N. Nishitani**[2]

[1]Institute of Solar-Terrestrial Physics SB RAS, Russia
[2]Solar-Terrestrial Environment Laboratory, Nagoya University, Japan

Abstract— We study ionospheric variability using HF radio facilities within three latitudinal regions: polar (Norilsk vertical sounder; 69.4N, 88.1E), sub-polar (Ekaterinburg SuperDARN radar; 56.4N, 58.5E) and mid-latitude (Hokkaido East SuperDARN radar; 43.53N, 143.61E). As characteristics we select the peak electron density (NmF2) and peak height (hmF2) measured with the ionosonde and the ground backscatter range corresponding to the skip distance (Rsd) from HF radar measurements. The disturbances of characteristics are the deviations of characteristics from their 27-day running median values. We assume that 27-day running medians are associated with climatological specifics of the diurnal, seasonal, and long-term solar activity variations. The variability is considered as the root mean square of disturbances. For different tasks we used different types of averaging. Annual averaging was used for studying year-to-year changes in the variability (solar cycle variations). To study the difference between the day- and nighttime variability we made separate averaging for the day- and nighttime using ground terminator as a day-night boundary. To obtain the diurnal-seasonal pattern of the variability we performed averaging over years for each local time and day of year. In the paper we discuss similarities and differences between the selected characteristics and between the polar, sub-polar and mid-latitude ionospheric variability.

[2]Irkutsk State University, 20 Gagarin Blvd, Irkutsk 664003, Russia

Abstract— In this paper, the analysis of geomagnetic effects on measurements, made by Global Navigation Satellite Systems (GNSS), relies on both the contribution of the geomagnetic field to the refractive index of ionospheric plasma and the presence of random irregularities aligned along the magnetic field lines. In the geometrical optics approximation at high GNSS frequencies, the refractive index, phase and code distances can be expanded in a rapidly decreasing series in inverse powers of frequency. This allows us to eliminate ionospheric effects from multifrequency measurements. In dual-frequency measurements, the ionosphere-free combination is used to remove most of the ionospheric error — first-order error proportional to electron density. Improvement in accuracy of dual-frequency GNSS measurements is associated with elimination of the second-order error caused by geomagnetic effects on the refractive index of magnetoactive ionospheric plasma. The paper reports results of exploration of the possibility for simultaneous removal of first- and second-order errors by modifying the ionosphere-free combination of dual-frequency measurements. The geomagnetic field affects not only the refractive index but also the structure of ionospheric irregularities. Afraimovich et al. [1] based on the dependence of the GNSS phase slips on the angle between the satellite-receiver line of sight (LOS) and the magnetic field line, have revealed the anisotropy effect of ionospheric irregularities. To analyze the role of this effect on GNSS measurements, we used numerical simulation for studying anisotropy effects of ionospheric irregularities on the probability of occurrence of slips in phase measurements. When examining GNSS signal phase fluctuations, we determined the relation between the probability of slips in GNSS system operation and the degree of elongation of field-aligned irregularities. The simulation results allow us to study and account for the factors which mask effects of this anisotropy. In the future, we are going to exploit this method of estimating the degree of elongation of irregularities to monitor parameters of ionospheric irregularities in the Arctic region.

Abstract— At present, remote sensing methods relying observations of signals from global navigation satellite systems (GNSS) are finding ever-widening application in environmental research. These methods allow remote diagnostics of wide sectors of overground space, which makes them attractive for use especially in the Arctic region. However, the spatially and temporally variable ionosphere significantly affects the accuracy and reliability of GNSS remote sensing, hence the need to study inhomogeneous ionosphere effects on GNSS measurements, and to explore possibilities of their elimination. In the geometrical optics approximation, the ionospheric part of error in measuring phase and code delays of the satellite signal may be represented as a rapidly decreasing series in inverse power of frequency. Such simple frequency dependence allows us to use multi-frequency measurements for eliminating the error in multi-frequency GNSS. However, the elimination of errors is handicapped by diffraction effects during signal propagation through turbulent ionospheric plasma. In this study, the elimination of diffraction effects from the measurement error via Fresnel inversion and then the elimination of this error via multi-frequency combination are analyzed. We demonstrate the possibility of reducing residual ionospheric errors in ionosphere-free combination by Fresnel inversion. The inversion parameter — the distance to the virtual screen — may be selected from the minimum of amplitude fluctuations. This suggests the possibility of improving the accuracy of GNSS remote sensing in meteorology. In investigations into ionospheric disturbances through geometry-free combinations, the Fresnel inversion eliminates only the third-order correction. To eliminate the random TEC component which, like the measured average TEC, is the first-order correction, we should use temporal filtering. However, measurements of this random TEC component allow us to examine the fine structure of ionospheric plasma via GNSS. The Fresnel spatial processing requires constructing a phase GNSS array of sufficiently large sizes. Despite the difficulty in constructing this array, it seems necessary to develop the array, taking into account feasibility of using it in many fields of research on the troposphere, ionosphere, earthquakes, and volcanic activity.

Lermontov st. 126a, P. O. Box 291, Irkutsk 664033, Russia

Abstract— For the analysis of transparent inhomogeneous, it is appropriate to use phase tomography, which is based on measuring the phase of the wave transmitted from the transmitter to receiver. Finding the physical characteristics of inhomogeneous media by these methods carried out in several stages. At the first stage the receiving system consisting of antennas registers the phase of wave scattered by the inhomogeneity. Then, depending on the type of tomographic measurements the optimal method of computer tomography is selected. The final step is finding the required physical parameter of the inhomogeneous medium. In particular the diagnosis of the inhomogeneous plasma by standard methods ray and diffraction tomography is not always possible to find the parameters of the medium. For more accurate diagnostic results of the inhomogeneous medium we can use additional processing phase measurements. Earlier in the papers was obtained spatial processing phase measurements based on the method of double weighted Fourier transform (DWFT). This process allows to diagnose small-scale plasma under conditions of strong and weak phase fluctuations. However, the use of DWFT for direct and inverse problems of wave propagation in inhomogeneous media is often hampered by the necessity to integrate in two planes. In particular, in tropospheric and ionospheric investigations we can integrate measurement data in coordinates of only one plane, say a receiving plane.

Here we will consider the DWFT method modifications permitting the use of it both without possibility of integrating over two planes and under wave reflection from an inhomogeneous medium (plasma).

Investigation of Nanoantennas Using Surface Integral Equations and the Multilevel Fast Multipole Algorithm

B. Karaosmanoğlu, U. M. Gür, and Ö. Ergül
Department of Electrical and Electronics Engineering, Middle East Technical University, Ankara, Turkey

Abstract— Nanoantennas, i.e., antennas designed for optical frequencies, have attracted the interest of many researchers [1–4]. Although the idea of using nanoscale antennas operating at visible lights, e.g., for harvesting solar energy, was purposed decades ago, realization of nanoantennas had to wait for the developments in nanotechnology. Recently, various nanoantennas have been designed, manufactured, and tested for diverse applications, including energy harvesting [1], optical sensing [2], and imaging. Along this direction, computational simulations of nanoantennas have become essential for designing and investigating these structures in alternative scenarios before their actual realizations [4].

Computational analysis of nanoantennas using the conventional solvers is not trivial. While nanoantennas are commonly made of highly conducting materials, such as silver and gold, scaled solvers with perfectly conducting assumptions fail to provide realistic and accurate modeling of nanoantennas [4]. This is mostly due to different behaviors metals at optical frequencies, namely plasmonic effects [5], which become dominating factors especially for nanoscale objects. Incorporating plasmonic effects in the existing solvers is also a challenging task, especially for full-wave solvers. This challenge can partially be solved by resorting to Drude or Lorentz-Drude models that allow for macroscopic analysis via electromagnetic parameters. Specially, changing the electrical permittivity to a complex value with a negative real part based on these models leads to a direct analysis of a plasmonic structure using existing solvers developed for penetrable objects.

In this study, we investigate nanoantennas using surface integral equations and a powerful method, namely, the multilevel fast multipole algorithm (MLFMA) [6]. Among alternative formulations, we prefer the electric and magnetic current combined-field integral equation (JMCFIE) for accurate and fast iterative solutions using MLFMA. JMCFIE is modified carefully by considering complex permittivity values with negative real parts. MLFMA is also updated for stability in handling complex wavenumbers with large imaginary parts, leading to rapidly decaying interactions. In this paper, after demonstrating the effectiveness of the developed solver on canonical problems, we present numerical simulations of bowtie nanoantennas at optical frequencies. Different material properties and frequencies are considered for single bowtie nanoantennas. Electromagnetic interactions between pairs of nanoantennas and their effects in the power enhancement abilities are also investigated. Numerical results show that MLFMA is a strong alternative to space-discretization solvers for accurate and efficient full-wave analysis of nanoantennas.

Abstract— The paper discusses the polarization properties of the compositions of the light-sensitive media. The compositions include a polymer matrix, fluorescent tags: the dyes-phosphors which have been used, including specially synthesized, and the fluorescent polymer. The activators of photo anisotropy based on the organic dyes, chiral dopants, dendrimer. As the matrix polymer were used: polycarbonate, polystyrene, polymethyl methacrylate. Were created the optical schemes, allowing us to investigate the polarized luminescence, and conduct the ellipsometric measurements of the photo-anisotropic parameters obtained compositions. For polarized radiation were used the standard lasers with lengths of waves: 405 nm, 441.6 nm, 532 nm. For the quantitative measuring of the polarized luminescence the parameter-coefficient of anisotropic radiation was used. The created compositions had had few maximums of the polarized luminescence, what determined by the structure of making elements. Data are presented as tables and spectral curves of coefficient of anisotropic radiation. Were developed compositions with initial optical activity, thanks to the introduction of specific chiral additives. We investigated the change in the optical activity of the resulting compositions by the irradiation with circularly polarized radiation. Conducted ellipsometric measurements allowed us to estimate both the magnitude and the direction of rotation of the polarization plane of the media. We investigated the change in the optical activity of the resulting compositions by the irradiation with circularly polarized radiation. Were obtained curves of the exposition induced anisotropy of the investigated circular media for the purpose of comparing the gradient sensitivity, depending on the chemical structure of the used dopants. Were revealed the dependence arised anisotropy and gyrotropy in the samples under investigation on the chemical activity of the used dopants. The done work allows to make conclusions about the mutual influence of elements of the composition on the magnitude and specificity of the induced Weigert effect, which demonstrates the enormous scope for the developers of polarization-sensitive media.

Investigation of the Free-space Propagation Operator Eigenfunctions in the Near-field Diffraction

Mikhail S. Kirilenko[1], **Valery V. Pribylov**[1], **and Svetlana N. Khonina**[1, 2]

[1]Samara State Aerospace University Named After Academician S.P. Korolyov, Samara, Russia
[2]Image Processing Systems Institute of the RAS, Samara, Russia

Abstract— In recent years, there have been many attempts to overcome diffraction limit. It could provide the visualization of features that are smaller than half a wavelength. In this work we demonstrate possibilities of creating monochromatic light distribution with details comparable with the wavelength. The investigations are based on the scalar diffraction theory. We consider one-dimensional case of a beam expansion by plane waves in analogy with [1]. We take into account finite aperture size and spectrum width (for example, evanescent waves are not examined if the spectrum is limited to the range of minus one to one).

The plane of optical signal formation is located at a distance of several wavelengths from the input plane. The observed domain width is equal to the aperture size D, so we get two equivalent areas on the input and output of the optical system.

We use integral transformation based on the method of plane wave expansion for laser beam modeling. After sampling considered transformation we get a square matrix with eigenvalues and eigenfunctions that we should find. These functions represent a system of orthogonal modes propagating from the input plane to the output without changes except the scale factor.

Previously, we study eigenfunctions for the limited system of two lenses where Fourier transform (or Hankel transform in case of radial symmetry) plays the role of propagation operator [2, 3]. The eigenfunctions are spheroidal functions if the optical system is Cartesian [2]. The difference of this work consists in free-space propagation in the near-field diffraction rather than through the lenses, therefore, modeling can be done at a small distance from the input plane.

The beam propagation distance is a parameter of the operator and it significantly changes the set of eigenvalues and eigenfunctions. The eigenvalues modules define corresponding "survival" eigenfunction at a given distance. Thus, calculations allow to find out the number of degrees of freedom in dependence of the distance. In addition, it is determined the maximum number $N_{\max}$ of "survived" eigenfunction at the distance. Hence, the minimum size of details, reproduced on the propagation distance, is approximately equals $d \approx D/N_{\max}$. Thereby, we get the answer to the question, what resolution is achievable at a given distance.

Shielding Effectiveness in Coaxial Cable Connectors in Ultra High Frequency — UHF — 1 GHz to 3 GHz

Kenedy Marconi Geraldo dos Santos[1,2], **Marcela Silva Novo**[2], **Glauco Fontgalland**[3], **Marcelo Bender Perotoni**[4], **and Caio Luminatti Andrade**[5]

Abstract— The Shielding Effectiveness parameter of the transmission lines and coaxial cables/connectors is an important item to ensure the correct operation of electro-electronic devices. Eventual problems in this shielding could generate unintentional electromagnetic disturbs. Fundamentally, an Electromagnetic Compatibility (EMC) problem can be divided into three parts: noise source, coupling and receptor (victim) [1, 2]. In this paper, the coupling will be investigated in order to mitigate the radiated or induced electromagnetic interferences. Cable and connectors shielding is one of the most used techniques to minimize this kind of disturbs [1, 2]. The Shielding Effectiveness (SE) can be defined by [3, 4]

$$\mathrm{SE_{dB}} = 20\log\frac{V\ \text{(without shielding)}}{V\ \text{(with shielding)}} \quad \mathrm{SE_{dB}} = 20\log\frac{E\ \text{(electric al field without shielding)}}{E\ \text{(electric al field with shielding)}} \tag{1}$$

In order to determine the SE factor of a coaxial cable connector, this paper proposes a methodology based on a physical model, using the R&S ® EMC32 Measurement Software. Figs. 1(a) and 1(b) illustrate the measurement software and the measurement setup, respectively.

The measurement setup consist of an electric field probe, the coaxial cable and connectors. Both the electric field and the voltage standing wave ratio (VSWR) will be measured. The main objective of this paper is to investigate shielding effectiveness of coaxial cable connectors, in order to ensure the best performance in Ultra High Frequency (UHF) and also to reduce electromagnetic radiation. By using the EMC32 integration software that controls both injected signals and measured parameters, a constant power is injected into the cable and the electric field is measured. To reduce the irradiated and inducted electromagnetic interferences in the transmission line, a coaxial cable with solid outer conductor will be used. It should be noted that there are still many challenges to determine the transfer impedance, as well as the shielding effectiveness of coaxial cables in the microwave range [5].

Abstract— There are various parameters of quantum system which play important role in quantum computing. However the most interesting and perspective parameters are entanglement and polarization. In particular, entanglement has many applications in quantum information theory. Namely, the best-known applications of entanglement are superdense coding and quantum teleportation [1]. Also the entanglement is used in some protocols of quantum cryptography [2]. In quantum interferometry, entanglement is necessary for surpassing the standard quantum limit and achieving the Heisenberg limit [3].

In this work we consider the biphoton states formed in the process of degenerate spontaneous parametric down-conversion. The purely polarization biphoton states (the so-called qutrits) are described by a superposition [4, 5]:

$$|\psi\rangle = c_1|\psi_{HH}\rangle + c_2|\psi_{HV}\rangle + c_3|\psi_{VV}\rangle$$

of photons in modes with horizontal (H) and vertical (V) polarizations. The degree of entanglement can be derived from the Wootters' parameter (the so-called Wootters' concurrence):

$$C = |2c_1c_3 - c_2^2|.$$

The degree of biphoton polarization [4, 6]

$$P = |\mathrm{Tr}\,(\rho_r\vec{\sigma})| = |\mathrm{Tr}\,[\vec{\sigma}\mathrm{Tr}_2\,(|\psi\rangle\langle\psi|)]|\,,$$

where ρ_r is the reduced density matrix, $\vec{\sigma}$ are the standard Pauli matrices, can be compared with the Wootters' concurrence and the result is [4]:

$$C^2 + P^2 = 1.$$

This expression (first derived in [4]) shows the anti-correlation between the entanglement and polarization.

In this work we also discuss in details the von Neumann entropy of the qutrit, namely

$$S_r = -\mathrm{Tr}\,(\rho_r \log_2 \rho_r)\,.$$

Moreover, we consider the time evolution of parameters P (polarization) and C (Wootters' concurrence) using the solution of equation for density matrix (von Neumann equation) taking into account the various initial states of the biphoton system.

T-matrix Formulation of the Linear Sampling Method

Gregory Samelsohn and Kobi Aflalo
Center for Advanced Imaging Systems, Department of Electrical and Electronics Engineering
Shamoon College of Engineering, Ashdod 77245, Israel

Abstract— The linear sampling method (LSM) aimed at the reconstruction of target shape and based on the so-called far field equation [1] is reformulated in terms of the transition (T) matrix. The latter reflects only the intrinsic properties of the scatterer and does not depend on locations and radiation patterns of the antennas constituting the transmitting and receiving arrays [2]. The information on the antenna arrays is contained in the corresponding sampling matrices $\mathbf{A}_t$ and $\mathbf{A}_r$ transforming $\mathbf{T}$ matrix into the response matrix, $\mathbf{H} = \mathbf{A}_r\mathbf{T}\mathbf{A}_t^{\dagger}$, measured in experiments. For simplicity, a scalar 2D version is considered, however the proposed approach can be generalized to both scalar or vector 3D problems.

LSM is reduced to solving the linear problem $\mathbf{Ta}(\mathbf{r}) = \mathbf{b}(\mathbf{r})$ for all points $\mathbf{r} = (r, \phi)$ of the sampled domain, providing the transition matrix $\mathbf{T}$ is estimated at the previous step. The unknown vector $\mathbf{a}(\mathbf{r})$ is the incident field causing, after interaction with the target, a scattered field $\mathbf{b}(\mathbf{r})$, a cylindrical wave emanating from sampling point $\mathbf{r}$, i.e., the elements of $\mathbf{b}(\mathbf{r})$ are given by $b_m(\mathbf{r}) = J_m(kr)\exp(-im\phi)$. The behavior of $\|\mathbf{a}(\mathbf{r})\|$ serves as an indication of the scattering object support. This formulation of LSM is more flexible than the original far field version [1].

Usually, we would like to recover a large T-matrix using as few as possible measure-ments (a small response matrix $\mathbf{H}$). This is a classical under-determined problem. Also, the data includes noise. To improve the situation, the inversion is supplemented with a number of physical constraints the transition matrix should satisfy. In particular, conservation of energy leads to the passivity of the related scattering matrix, $\mathbf{S} = \mathbf{I} + 2\mathbf{T}$, the eigenvalues of which have to lie inside the unit circle in the complex plane. Another constraint is the reciprocity of the T matrix; this means that only (roughly) one half of its elements should be found, the others may be restored by using the symmetry relation: $T_{mn} = (-1)^{m+n}T_{-n,-m}$.

The quality of the object recovery may be controlled by the normalized Frobenius norm $\varepsilon_F = \|\mathbf{T} - \hat{\mathbf{T}}\|/\|\mathbf{T}\|$, and can be seen directly in the LSM-based images, see Fig. 1. Upper row corresponds to unconstrained inversion ($\varepsilon_F = 0.41$ and $\varepsilon_F = 0.71$, respectively, for SNR values equal to 5 and 0 dB), lower row presents constrained results ($\varepsilon_F = 0.23$ and $\varepsilon_F = 0.38$, respectively).

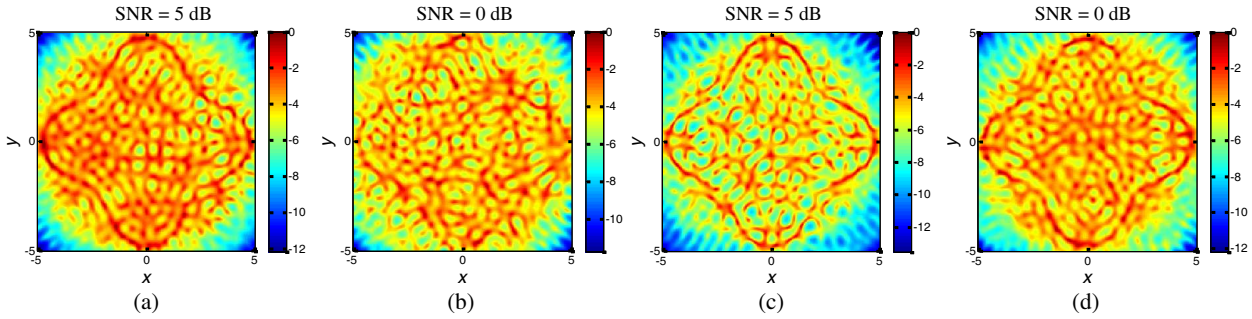

Figure 1: Results of the LSM reconstruction.

Radon Tomography of Forward-scattering Objects

Gregory Samelsohn and Eliya Ben-Avraham
Center for Advanced Imaging Systems, Department of Electrical and Electronics Engineering
Shamoon College of Engineering, Ashdod 77245, Israel

Abstract— In classical X-ray tomography it is assumed that the radiation propagates along straight lines [1]. The log-intensity measured in the observation plane is then a Radon transform of the attenuation coefficient α. Since the Radon transform is invertible, it is possible to reconstruct uniquely the distribution of α, providing the measurements are performed for all possible projections. In optical or microwave tomography the propagation is no longer along straight lines, because the refraction and diffraction effects can play an essential role. In this situation the use of the same Radon-based algorithms leads to low resolution and strong artefacts in the image, or even makes the reconstruction impossible. In this paper we analyze a new reconstruction algorithm based on approximate propagators describing the high-frequency radiation scattered by (lossy) dielectric objects [2, 3].

We assume that the wave propagation is governed by a standard parabolic wave equation [4] relating the wavefield measured in point $(\mathbf{r}, z)$ to a point source located in $(\mathbf{r}_0, z_0)$. Since the parabolic equation coincides with the Schrödinger equation of quantum mechanics, we apply the path integral formalism to obtain a required solution. The main motivation of using the path integral technique here is to reduce the (infinite-dimensional) path integral to an approximate finite-dimensional quadrature provided the solution is able to reproduce the relevant diffraction effects [3, 5]. Introducing mixed input/output coordinates, $\mathbf{r}_1 = \mathbf{r} + \mathbf{r}_0/2$ and $\mathbf{r}_2 = \mathbf{r} - \mathbf{r}_0/2$, we show that an approximate solution for the normalized wave field $h(\mathbf{r}_1, \mathbf{r}_2)$ can be presented in the form $\Phi_1 \Phi_2^{-1}\{h_0(\mathbf{s}_1, \mathbf{s}_2)\}$. This operator consists of two independent ordinary Fresnel transforms (the first one is direct and the second is inverse), coupled only by the object "hologram" h_0. Function $h_0(\mathbf{s}_1, \mathbf{s}_2)$ is the exponential of the permittivity integrated along a *straight line* connecting the points $\mathbf{s}_1$ and $\mathbf{s}_2$, which are defined in the same mixed space. Hence, in order to perform the inversion, the transmit/receive arrays should cover a sufficiently large area of the hyperplane $(\mathbf{r}_1, \mathbf{r}_2)$.

Having at hand the reconstructed hologram h_0, we can calculate its logarithm (a phase unwrapping can be required at this stage), and then apply the usual Radon transform. Note that in a possible tomographic experiment the scanning is not restricted to the fan (cone) beam geometry. In particular, using only a cross-section of the reconstructed hologram, which in the mixed coordinates satisfies the condition $\mathbf{s}_2 = \mathbf{s}_1/3$ (this corresponds to $\mathbf{s} = \mathbf{s}_0$ in the original space), the parallel scanning geometry may be realized. The results of simulations show a rather good resolution of reconstructed images well beyond the weak scattering regime. In contrast to many known lensless imaging techniques suitable for reconstructing only thin samples [6], our method allows for imaging extended objects.

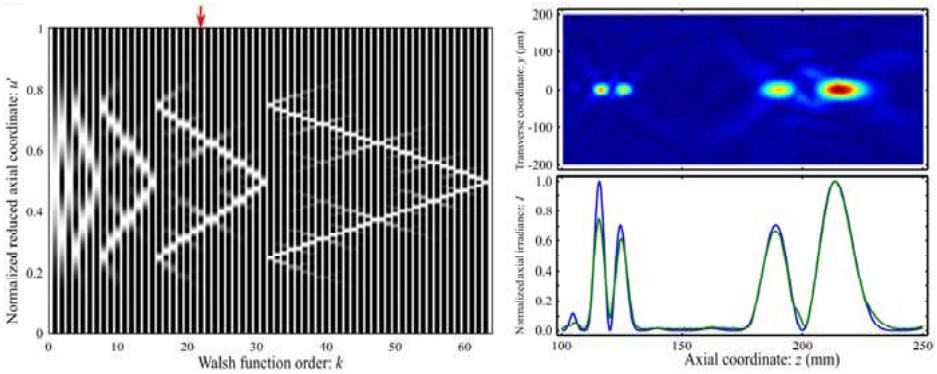
Abstract— Walsh functions are a complete set of normal orthogonal functions that, except at a finite number of points of discontinuity, take on values 1 or -1 over a given finite interval. The number of zero crossings within the specified domain determines the order of the Walsh functions. As is well known, a Fresnel zone plate consists of alternately transparent and opaque zones whose radii are proportional to the square root of the natural numbers. Thus, it can be generated starting from a 1D compact-supported periodic function $q(x)$, followed by a change of coordinates $x = r^2$ (r is the radial coordinate) and then by a rotation of the transformed function around one of its extremes. In a similar way a Walsh zone plate can be constructed by replacing the periodic function $q(x)$ by a given Walsh function. Walsh zone plates (WZPs) of various orders are designed from corresponding Walsh functions by realizing values of 1 or -1 with 0 or π phase, respectively. To evaluate the focusing properties of the WZPs we have computed the irradiance along the optical axis (z coordinate) provided by these lenses illuminated by a plane wave of wavelength λ, using the Fresnel approximation. Fig. 1(a) shows axial irradiances provided by the WZPs of several orders along the normalized reduced axial coordinate: $u' = ka^2/2\lambda z$, being a the radius of the WZP, and k is a constant for each order. It can be observed that in general a WZP has several foci depending on the order of the Walsh function. Self-similarity can also be observed in the axial intensity distributions. We have experimentally tested the focusing properties of the WZPs by implementing them on a liquid-crystal display. Fig. 1(b)) shows the transverse irradiance of the order $k = 22$ (red arrow in Fig. 1(a)). A profile of the experimental axial irradiance is represented in the same figure together with the analytical axial irradiance for comparison.



(a) (b)

Figure 1: (a) Axial irradiances provided by the WZPs of several orders. (b) Experimental transverse irradiance of the WZP with order $k = 22$ (blue line) and the corresponding analytical axial irradiance (green line).

Experimental Study on Low-profile of Multi-layer Noise Suppression Sheet Using Periodic Metal Film

K. Otsuka[1], **T. Ohno**[2], **and K. Tanii**[2]

[1]The University of Electro-Communications, Japan
[2]National Institute of Technology, Kisarazu College, Japan

Abstract— This paper examines a method to reduce the thickness of a Noise suppression sheet (NSS) by using a periodic metal film. NSS with the periodic metal film is placed on the microstrip line, and the transmission characteristics are measured.

Figure 1 shows the setup to measure the attenuation of conducting current noise along a transmission line, including a microstrip line (MSL) based on the IEC (International Electrotechnical Commission) standard. A network analyzer is connected to the MSL by coaxial lines, the transmission characteristics $|S_{21}|$ of the MSL shown in Figure 2 is measured. The MSL is fabricated by dielectric substrate (manufactured by ARLON, DiClad522, $\varepsilon_r = 2.55$, $\tan\delta = 0.0022$). The NSS ($\dot{\varepsilon}_r = 169.15 - j15.31$, $\dot{\mu}_r = 8.40 - j5.22$ @ 1 GHz) is placed on 4.4 mm wide strip conductor. Then NSS with and without the periodic metal film (Aluminum, $\sigma = 37.4 \times 10^6$ [S/m]) are measured. Figure 3 shows the multi-layer NSS with periodic metal film. The sheet consists of the metal film sandwitched by NSS to prevent from radiated noise. Figure 4 shows the result of measured transmission characteristics of the MSL with the multi-layer NSS and with the NSS not to use the metal film. In Figure 4, when the thickness of NSS decreases from 0.834 to 0.204 mm, f_c is shifted from 0.98 to 1.92 GHz. It is also noticeable that f_c of the NSS with periodic metal film is 0.99 GHz, which is approximately equal to fc in the case of the NSS thickness of 0.834 mm. Moreover, the low-pass characteristic of the multi-layer NSS is similar to the NSS which has 0.834 mm thick. As a result, the thickness of NSS can be reduced up to 40.9% by attaching the periodic metal film. As further investigation, re ection and absorpition of radiated noise by the multi-layer NSS should be examined.

Abstract— It is known that, due to the high optical activity, some chiral metamaterial structures implemented in printed circuit board (PCB), such as those based on mutual rotation between faces [1, 2] and on conjugated faces [3, 4], exhibit negative values of the refractive index ($n_{\pm}$) for the right handed (+) or left handed (−) circularly polarized waves. Unfortunately, in these structures the negative refractive index is related to high losses because of the high value of the refractive index imaginary parts. Only in a narrow frequency range the structure presents negative refractive index and low losses simultaneously. However, in this case the figure of merit of the negative refractive index (defined as $FoM_{\pm} = n'_{\pm}/n''_{\pm}$), is small. Consequently, these facts prevent the use of the aforementioned CMM structures for developing applications that take advantage of the negative refraction.

In order to decrease the losses and the FoM, Zhaofeng in [5] proposes a composite chiral metamaterial (CCMM) constituted by the combination of a conjugated rosettes CMM structure with a fishnet structure that presents continuous metallic wires at the edges and in the center of the unit cell (see Fig. 1 of [5]). With the addition of the continuous metallic wires the maximum FoM values enlarges from 8.4 for the original conjugated rosettes structure to 50 for the CCMM.

In this work a new CCMM composed by a conjugated gammadion CMM structure [4] and a cross-shaped fishnet structure without metallic wires at the edges is analyzed numerically with the aid of Keysight EMPro 3D electromagnetic simulator. For that purpose the aforementioned structures are individually characterized using the EMPro Finite Differences Time Domain engine. The obtained results show that the CCMM enlarges in more than 20° the moduli of the polarization plane rotation angle than the original CMM does. Regarding to the refractive index, the CCMM displays a wider frequency band with negative index, lower losses and higher FoM values (See Fig. 2).

Abstract— A method of successive integral equations is developed to describe electromagnetic wave transmission through a subwavelength nano-hole in a thin plasmonic sheet in terms of the dyadic Green's function for the associated Helmholtz problem. No assumptions about boundary conditions are needed as they are implicitly embodied in the integral equations. This approach has facilitated relatively simple numerical computation, and it is not in any way restricted to a metallic screen. Taking the subwavelength radius of the nano-hole to be the smallest length of the system, we have obtained an exact solution of the integral equations for the dyadic Green's function analytically and in closed form. This dyadic Green's function is then employed in the numerical analysis of electromagnetic wave transmission through the nano-hole for normal incidence of the incoming wave train. The electromagnetic transmission involves two distinct contributions, one emanating from the nano-hole and the other is directly transmitted through the thin plasmonic layer itself (which would not occur in the case of a perfect metal screen). The transmitted radiation exhibits diffraction interference fringes in the vicinity of the nano-hole, and they tend to atten as a function of increasing lateral separation from the hole, reaching the uniform value of transmission through the sheet alone at large separations. The calculated results also exhibit a positional broadening of the central electromagnetic transmission maximum as the height above the hole increases from the near to the far zones. This is to be expected as a simple geometric spreading of the radiation emanating from the nano-hole itself, but, as indicated above, the transmitted radiation is further supported by electromagnetic transmission *directly* through the plasmonic sheet. Furthermore, our results incorporate the role of the 2D plasmon of the thin layer, which is smeared by its lateral wavenumber dependence.

Photodynamic Properties of a C_{60} Organosol

Abstract— The fullerene C_{60} is a wonderful molecule becoming more common in photonics due to high optical nonlinearities and singlet oxygen quantum yields ($\varphi = 0.96$) [1, 2]. The both properties are determined by high probable singlet-triplet intersystem crossing in fullerene molecule populating a metastable triplet state ($T1$) with appropriate characteristics. In practice, large polarizabilities lead to the aggregation of the C_{60} molecules owing to strong dispersion forces, the process causing formation of various supramolecular structures depending on physicochemical properties of media.

The strongest aggregation of fullerenes is observed in polar solvents, in which long-living or stable colloidal sols can be formed on the grounds of solely repulsive electrostatic interactions between the aggregates [3]. It is well known that aggregated fullerenes have rather poor $T1$ quantum yield and pretty short life-times, these factors decrease photodynamic ability of materials [4]. This is the most important issue regarding singlet oxygen photosensibilization in such potential applications as photodynamic therapy and oxygen-iodine lasing [2]. In the present communication we show that under certain circumstances C_{60} aggregation is not so dramatically detrimental with respect to its photodynamic properties in some media.

C_{60} solution in CCl_4 was mixed with acetone in different proportion provided fullerene concentration constant. Absorption spectra changes, representative the begging of cluster formation in the liquid, appeared in the mixtures with values of its dielectric constant ε over 14. At ε about 19 we found a stable suspension on the time scale of two days. The dynamic light scattering study shows a narrow size distribution about 220 nm with polydispersity index 0.005.

Singlet oxygen ($^1\Delta_g$ state) IR luminescence ($\lambda = 1268$ nm) was measured both in the C_{60}/CCl_4 and the C_{60}/CCl_4&Acetone-D_6 systems at the excitation by LED light of different wavelengths ($\lambda_{ex} = 370$ nm, 405 nm, 465 nm, 525 nm, 625 nm) under the same experimental conditions. The singlet oxygen quantum yield φ of C_{60} in the sol form was found to be only 3 times less than the one of C_{60} in solution.

A theoretical model of quasi-two-level scheme for fullerene and three-level scheme for oxygen employed to describe the generation process involving fullerene light absorption, singlet-triplet intercrossing, photosensibilization and quenching of $^1\Sigma_g$ oxygen state by $T1$, $^1\Sigma_g$–$^1\Delta_g$ oxygen transition and $^1\Delta_g$ quenching by the solvent molecules. The solution of the set of kinetic equations using kinetic constants of the levels as parameters established a dependence of generated singlet oxygen concentration vs. $T1$ lifetime. This dependence explains why although the $T1$ lifetime value is dramatically decreased by two orders of magnitude following the aggregation, the singlet oxygen photosensibilization efficiency still remains high.

The results obtained show up rather perspective regarding working out fullerene-aggregates-based singlet oxygen generators, which are expectedly germane to practical applications.

[2]ITMO University, Saint-Petersburg, Kronverksky pr., 49, Russia

Abstract— It is well-known that semiconductor nanocrystals (NCs) have high non-linear optical properties. But the interaction between these NCs and with surrounding matter can have strong influence on their non-linear light absorption and scattering [1].

In this work we present the results of the preparation of the suspension and coatings containing PbS QDs stabilized by high-molecular (M_s =1300000) polyvinylpyrrolidone (PVP). PbS suspensions were prepared from mixed water — propanol-2 solution of Na_2S and $Pb(NO_3)_2$ at the presence of PVP. Composite PbS/PVP coatings were deposited on glass surface by dip method at room temperature.

The spectra of prepared suspensions demonstrated the absence of absorption bands in visible spectral range. Experiments show that PbS suspensions and coatings demonstrate strong luminescence in NIR spectral range (1100–1200 nm) at the excitation of visible light with different wavelengths. Luminescent properties of our suspensions non-linearly depend on the power of exciting irradiation and, also, they are changing during storage at room temperature.

The measurements of non-linear transmittance of PbS suspensions were made on special setup using Nd:YAG laser ($\lambda = 0.532\,\mu$m). Experiments show that prepared suspensions can effectively limit powerful laser irradiation at $\lambda = 1.06\,\mu$m with the limiting threshold $2 \cdot 10^{-4}$ J.

Non-linear refractive index γ and two-photon absorption coefficient β were measured at $\lambda =$ 1540 nm by Z-scan method with open and closed apertures. These measurements gave values $\beta = 4.2 \cdot 10^{-9}$ cm/W and $\gamma = -3.4 \cdot 10^{-13}$ cm^2/W for the suspension containing 8.6 10^{-4} mol/l PbS.

The registered effects are seen to be explained through dependencies between luminescent and non-linear optical properties of PbS aggregates, and their structure in the polymer environment. The use of the polymer composites studied makes appearance as promising in fixing issues of photo-voltaics and non-linear optical limiters. The observed regularities would enhance efficacy of such solutions.

Semipolar InN Growth on $LaAlO_3$(112) Substrate by Metal Organic Molecular Beam Epitaxy

Fang-I Lai[1] and Shou-Yi Kuo[2]

[1]Department of Photonic Engineering, Yuan Ze University, Taoyuan, Taiwan
[2]Department of Electronic Engineering, Chang Gung University, Taiwan

Abstract— Most of the III-nitride semiconductor hetero-structures are grown along the *c*-axis on Si (111), GaAS (111), SiC and sapphire (0001) with wurtzite structure which the basal plane (0001) is a slide plane. The basal plane dislocation slip brought about the majority of dislocation in the III-nitride semiconductor layers. The spontaneous and piezoelectric electrical polarizations produce the electric fields along the ⟨0001⟩ direction to separate the spatially electrons and holes and to reduce the recombination probability result in the poor performance in optoelectronic device devices.

Indium nitride (InN) is one of the members in III-nitrides semiconductors, and has attracted intensive interest because of the narrow band gap $\sim 0.7\,\mathrm{eV}$ and high electron mobility approximately $4400\,\mathrm{cm}^2/\mathrm{V\text{-}S}$ among III-nitrides semiconductors. However the Fermi level pinning above the conduction band in InN accompanied with donor-like surface states leading to an ultrahigh-density of surface electron accumulation layer on the InN surface. Most InN reported recently are degenerate *n*-type materials with an electron concentration of approximately $1 \times 10^{18}\,\mathrm{cm}^3$ or higher, and these problems result in the difficulties in the fabrication of InN-based devices practically. Hence, the semi- and non-polar III-nitride semiconductors including InN have been attracted considerable attention in recent years because of the reduction of the polarization-induced electric fields and the improvement of the efficiency of optoelectronic devices. Moreover, the problems of the Fermi-level pinning and the surface electron accumulation were predicted that would be mitigated by distract from the growth in polar orientation.

In this paper, we present the structural and optical properties of metal organic molecular beam epitaxy grown semi-polar InN with (10–13) surface orientations on $LaAlO_3$ (112). The (10–13) crystal spacing of InN films is very close to the bulk InN revealed the almost stress-free in the InN (10–13) axis direction confirming by XRD. The result of XRD in-plane □-scan indicates there a two domains InN epitaxy on $LaAlO_3$ substrate. The PL spectrum display the near-band-edge and free-to-bound recombination with localization effect due to the urbach band tails located at both conduction and valence band edge. The surface electron accumulation is mitigated by the growth of InN (10–13). In contract to *c*-plane InN, the polarization-depended PL reveals strong optical anisotropic polarization in semi-polar InN due to the valence band structure could be modified by anisotropic in-plane strain in semi-polar InN.

Optical Method for Investigation of the Parameters of the Thin Film

Abstract— The Snell law and Fresnel formulas for plane monochromatic waves were successfully used during generations, but they are not correct for light beams. Any light beam can be represented as a superposition of plane waves propagating at different angles and each plane wave has its own amplitude and phase. The dependence of the reflection and refraction on the angle of incidence and refraction index leads to the violation of the Snell law for light beams. For the first time the Snell law violation was predicted and observed by Goos and Hanchen in 1947. The longitudinal shift of the linear polarized beam center of gravity was observed under the total internal reflection. The shift was about a wavelength. The transverse shift of a circular polarized light beam was predicted by Fedorov in 1955 and was experimentally observed by Imbert in 1978. The shift direction depended on the circularity sign and the shift value was about a wavelength. The longitudinal shift can be increased by the beam reflection from layered medium.

We present our results of computer simulation and experimental observation of the Gauss beam reflection from a thin film (an one-dimension photonic crystal). The beam splitting and the beam center of gravity shift were observed after the beam reflection. The shifts were different for s and p-polarization and depended on the angle of incidence, the film thickness and the refractive indices of the film and the substrate. The value of the shifts was a few micrometers. The beam intensity distribution after reflection is shown in Fig. 1.

We have demonstrated coincidence between of the experimental results and the results of computer simulation. The results can be used for the thin film parameters determination.

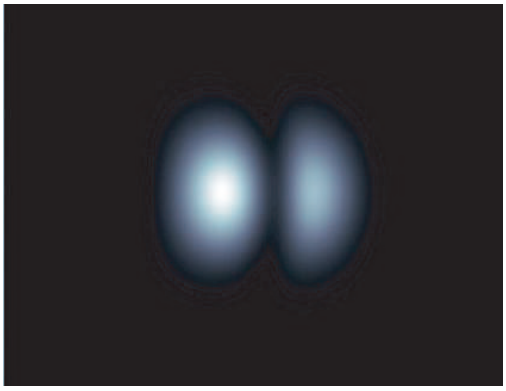

Figure 1: The intensity distribution of the Gauss beam after reflection from the film-substrate system.

Luminescence Evolution of Co-evaporated $Cu(In,Ga)Se_2$ Films

Fang-I. Lai[1] and Shou-Yi Kuo[2]

[1]Department of Photonic Engineering, Yuan Ze University, Taoyuan, Taiwan
[2]Department of Electronic Engineering, Chang Gung University, Taiwan

Abstract— $Cu(In,Ga)Se_2$ (CIGS) thin films and related materials are promising absorbers for use in solar cells. They have attracted considerable research interest because of their wide gap, $E_g > 1.3\,\mathrm{eV}$ ($x = \mathrm{Ga}/(\mathrm{In}+\mathrm{Ga}) > 0.5$), large absorption coefficient of greater than $10^5\,\mathrm{cm}^{-1}$ close to the band gap, and the cheapness of the large-scale deposition of polycrystalline CIGS. Low-cost and high-efficiency CIGS-based solar cells have recently been fabricated with a high recording conversion efficiency over 21%. The improvement of the film quality and reducing defects in CIGS absorber layer were significant issues for high-performance of CIGS solar cell. However, the characteristics of defects in CIGS films are not clearly understood because of the fluctuation in its complex device structures, and multinary composition.

In this study, the $Cu(In,Ga)Se_2$ absorption layers were prepared on an Mo-coated soda-lime glass (SLG) by three-stage co-evaporation. The mean alloy composition had [Cu]/[In]+[Ga] and [Ga]/([In]+[Ga]) (GGI) ratios of approximately 0.67 and 0.28 respectively. The as-deposited CIGS thin film was utilized to fabricate a CIGS solar cell with a ZnO:Al (AZO)/ZnO/CdS/CIGS-/Mo/SLG structure with an efficiency of 10–12%. Optical properties of $Cu(In,Ga)Se_2$(CIGS) films were investigated by taking temperature-dependent (TD), power-dependent (PD) and time-resolved photoluminescence (TRPL) measurements. The TDPL results revealed that various carrier dynamics and recombination processes in CIGS thin films, and obvious near-infrared emission peaks were observed. Two dominant emission peaks were associated with the donor-acceptor pair (DAP) transitions in a CIGS absorber layer with an inhomogeneous structure and composition. The PDPL measurement demonstrated anomalous evolution of emission spectra as the excitation power is increased. We conclude that this phenomenon is attributed to the competition between two DAP emissions, which are correlated to indium vacancies (V_{In}), copper vacancies (V_{Cu}) and isolated oxygen substituted selenium (O_{Se}) atoms in CIGS thin films. The nature of defects in CIGS films significantly influenced the luminescence performance and current density-voltage characteristics of photovoltaic devices as well.

Patterned Nano Magneticstructures

D. Bajalan
St. Pölten, Austria

Abstract— Patterned magnetic nanowires are extremely well suited for data storage and logic devices. They offer non-volatile storage, fast switching times, efficient operation and a bistable magnetic configuration that are convenient for representing digital information. Key to this is the high level of control that is possible over the position and behaviour of domain walls (DWs) in magnetic nanowires. Magnetic random access memory based on the propagation of DWs in nanowires has been released commercially, while more dynamic shift register memory and logic circuits have been demonstrated. Here, we discuss the present standing of this technology as well as reviewing some of the basic DWeffects that have been observed and the underlying physics of DWmotion. We also discuss the future direction of magnetic nanowire technology to look at possible developments, hurdles to overcome and what nanowire devices may appear in the future, both in classical information technology and beyond into quantum computation and biology [1].

Design of Double Cladding Photonic Crystal Fibers with Low-loss and Broad Dispersion

Na Wang, **Shanglin Hou**, **Yanjun Liu**, **Jingli Lei**, **Suoping Li**, **and Wenyu Zhang**
School of Science, Lanzhou University of Technology, Lanzhou, Gansu 730050, China

Abstract— Photonic crystal fiber (PCF) is a new type of optical fiber with periodic arrangement of air hole on certain substate materials. Due to the periodic cladding structures PCF can be changed flexibly, double cladding structure photonic crystal fiber (double-cladding photonic crystal fiber, DC-PCF) is designed and its transmission characteristics are much more easily tailored. In recent years researchers were interested in reducing the loss of PCF because the high loss restricts the further development of some applications. The method to control the loss by tailoring the structure of PCF is studied and optimizing design of PCF can obtain low loss and broad dispersion. This paper demonstrates a new type DC-PCF with hexagonal air hole configuration. This kind of PCF is composed of double-cladding made by different air holes, the double-cladding structure not only makes the coupling reduced difficultly but also has a unique dispersion characteristics. In order to investigate the influences of this structure on its dispersion and loss, the effects of the inner cladding diameters, outer cladding diameters and air-hole pitches on dispersion and loss are all numerically simulated.

When the cladding structure of DC-PCF is similar as the conventional PCF, the similar dispersion characteristics can be obtained for that the dispersion characteristics of DC-PCF is mainly determined by the inner core and the surrounding air hole structure. And the loss can be reduced by optimizing the out-layer structure that affects the limited loss. In the paper, the dispersion characteristics of PCF is tailored by changing the diameters of inner and outer cladding air holes, and the effective index of which is lower than that of the fiver core so that the total internal reflection theorem is satisfied. The results indicate that values of its dispersion varies from $-23\,\mathrm{ps/(nm \cdot km)}$ to $-10\,\mathrm{ps/(nm \cdot km)}$ in the band of 1.30–1.8 μm, which has broadband dispersion compensation characteristics. By changing these structure parameters carefully, the loss can reach $7.39 \cdot 10^{-6}\,\mathrm{dB/km}$ at the wavelength of 1.55 μm, which is the smallest value that has ever been reported. The results of this DC-PCF provide a reference for designing some devices based on PCF with dispersion compensation, and also provides a theoretical basis for practical applications for the low loss characteristics which can increase the transmission efficiency of PCF.

Investigation on Reflection of Brillouin Dynamic Grating in Single Mode Optical Fibers

Junfeng Li, **Shanglin Hou**, **Wenyu Zhang**, **Yanjun Liu**, **Jingli Lei**, **and Suoping Li**
School of Science, Lanzhou University of Technology, Lanzhou, Gansu 730050, China

Abstract— Stimulated Brillouin scattering (SBS) is a nonlinear process that can occur in optical fibers, which can be described classically as a nonlinear interaction between the pump and Stokes fields through an acoustic wave. The pump field generates an acoustic wave through the process of electrostriction. The acoustic wave in turn modulates the refractive index of the medium. This pump-induced index grating scatters the pump light through Bragg diffraction. Scattered light is downshifted in frequency because of the Doppler shift associated with a grating moving at the acoustic velocity v_a.

Optical fiber gratings is manufactured by the photosensitive characteristic of fiber, the refractive index of fiber core is modulated periodicity, where will occurred coherence reflection when the frequency have coincidence with phase-matching condition during incident light. With this special property and the advantage of optical fiber such as low losses, anti electromagnetism etc.. It have developed into a mature technology with a wide range of applications in various areas, including physical sensing for temperature, strain, acoustic waves and pressure.

In this letter, the theory of static fiber Bragg grating was used to investigate the phenomenon that the perturbation of the refractive index modulated during the process of SBS which named as Brillouin dynamic gratings in optical fibres. Then the reflection of Brillouin dynamic gratings are studied and simulated by the coupled-mode theory in single-mode optical fibers. It is shown that the reflectivity becomes larger and the FWHM becomes narrower with the length of Brillouin dynamic grating increasing. However, with the increasing of refractive index modulation, the reflectivity becomes larger and the FWHM becomes broad. Additionally, the maximum reflectance red-shifts with the increase of core index. Finally, the maximum reflectivity is 0.9329 when the length of Brillouin dynamic grating is 100 meters and the refractive index modulation is 1×10^{-8}.

Enhanced Femtosecond Optical Pulses Compression in Highly Nonlinear Photonic Crystal Fibers at 850 nm

Qiling Wu, **Shanglin Hou**, **Yanjun Liu**, **Jingli Lei**, **Suoping Li**, **and Wenyu Zhang**
School of Science, Lanzhou University of Technology, Lanzhou, Gansu 730050, China

Abstract— Ultrashort optical pulse have potential applications in ultrafast optical communication, optical signal processing, optical machining, sensing technology and other fields. Fiber-based pulse compression technology is one of effective ways for obtaining ultrashort optical pulse. However, the conventional fiber has been restricted by its geometric parameters and it's not easy to get a good pulse compression effect. Photonic crystal fibers effectively overcome the deficiency of conventional fiber, and greatly improve the efficiency of pulse compression. Thus, the photonic crystal fiber-based pulse compression technology has become a hotspot in the research of pulse compression technologies.

Highly nonlinear photonic crystal fiber has important applications in various areas such as ultrashort laser pulse frequency conversion, spectrum broadening, pulse compression, wave breaking and so on. The effect of high nonlinearity can be achieved by minishing the area of core, increasing the air filling fraction or using the background material with large nonlinear refractive index. The development of optical communication system has experienced the process from the short wavelength (850 nm) to the long wavelength (1310 nm and 1550 nm), considering the communicating cost of the short wavelength of 850 nm is lower than the long wavelength, we numerically investigate the compression of femtosecond optical pulses in HN-PCF at 850 nm.

In this letter, we numerically investigate the soliton-effect compression of femtosecond optical pulses in highly nonlinear silica-core photonic crystal fiber at near-infrared region of the spectrum (specially at 850 nm) using full-vector finite element method and split-step Fourier method. We propose a novel photonic crystal fiber structure featuring a anomalous group velocity dispersion ($\beta_2 = -50.698\,\mathrm{ps}^2/\mathrm{km}$), small higher-order dispersions and enhanced nonlinearity ($\gamma = 268.4191\,\mathrm{w}^{-1}/\mathrm{km}$) for efficient soliton-effect compression of femtosecond optical pulses. We numerically investigate the effect of the high-order soliton compression of chirped Gaussian pulses in HN-PCF. It shows that high-quality ultrashort optical pulses with little pedestal energy can be obtained. The parameters, such as the fiber length, chirp parameter or the soliton order, have significant influence on the pulse compression properties, such as compression ratio and peak power.

A Universal Optical Network Unit for Hybrid TDM-PON and WDM-PON Transport Systems

Ching-Hung Chang, **Liang-Shuo Tu**, **and Meng-Chun Tseng**
Department of Electrical Engineering, National Chiayi University, Taiwan

Abstract— Fiber to the Home (FTTH) transport systems have attracted plentiful attentions to provide triple-play multimedia services for residential and business clients due to their low loss and high capacity characteristics. Time-division multiplexing (TDM)-passive optical networks (PONs) are therefore developed to share the extended bandwidth for clients. Nevertheless, if the bandwidth requirement is increased with the extended multimedia service environment, the network capacity of an optical network unit (ONU) in such TDM-PON structure is difficult to be upgraded. Converting the TDM-PON structure to wavelength-division multiplexing (WDM)-PON structure will be a suitable solution to upgrade the ONUs' capacity. A WDM-PON with logical point-to-point connection for each ONU will be able to extend the available downstream bandwidth from 100 Mbps in TDM-PONs to 1 Gbps or larger bandwidth for a client. There are two main methods to achieve this objective. One is to insert an optical wavelength selector, such as tunable optical bandpass filter (TOBPF), in front of an TDM-ONU to select a dedicated optical wavelength and reject other inserted optical wavelengths, and another one is to replace the optical passive splitter deployed in the remote node of a TDM-PON by an optical wavelength de-multiplexer, such as arrayed waveguide grating (AWG), to direct various downstream optical carriers into dedicated directions. Utilizing a TOBPF to select the inserted optical carriers in an ONU is convenient and the entire TDM-PON can be gradually migrated to WDM-PON according to consumers' requirements. However, the expensive TOBPF makes this solution inacceptable. On the other hand, the TDM-ONU is still able to be utilized in WDM-PON architecture if the optical splitter of a TDM-PON is replaced by an AWG. This can save a lot of cost but the entire network will need to be upgrade from TDM-PON to WDM-PON simultaneously. In addition, the type and amount of the employed optical wavelengths in such WDM-PON are fixed by the employed AWG. The internet service provider will not able to gradually achieve the migration according to consumers' requirements and the scale of the WDM-PON is fixed. It is clear from the discussion that utilizing a TOBPF to achieve the TDM-PON to WDM-PON migration is much more flexible than employing an AWG, if there is a method to provide economic wavelength selector for a TDM-ONU. To achieve this target, a novel wavelength selector is proposed and developed to compose a universal optical network unit (ONU) for both TDM- and WDM-PON architecture. Unlike the published TDM-PON to WDM-PON migration architectures which utilizing expensive TOBPF or complicated optical routing schemes to select proper optical wavelengths, the proposed universal ONU can utilize an economic vertical-cavity surface-emitting laser (VCSEL) as a TOBPF to select a specific lightwave from multiple injected optical carriers. Besides, the VCSEL-composed wavelength selector with electrically adjustable characteristic will be able to assist the universal ONU with an ability to switch its receiver functionality for either economic TDM-PONs application or high-capacity WDM-PONs structure. Experimental results proof that by modifying the driving current of the VCSEL-based wavelength selector, both TDM-PON signal and WDM-PON signal can be received individually. This proposal provides an economic and flexible method for clients to migrate between TMD-PON and WDM-PON architecture.

Sub-micron Particle Detection Using a Spatial Light Modulator Based on Fluorescent Imaging

Serap Altay Arpali[1] and Çağlar Arpali[2]

[1]Department of Electronic and Communication Engineering, Çankaya University, Ankara, Turkey
[2]Department of Mecatronic Engineering, Çankaya University, Ankara, Turkey

Abstract— Because of the high modulation efficiency and programmability, Spatial Light Modulator (SLM) is widely used in many fields of optical imaging. In this study, we implement the multiple and scanning type Gaussian beams using SLM with amplitude modulation to detect fluorescent sub-micron particles in the specimen. With this new on-chip fluorescent imaging modality, fluorescent samples onto an opto-electronic sensor-array (e.g., a CCD chip) are scanned by multiple Gaussian spots. Using multiple Gaussian excitations we can detect the sub-micron fluorescent beads which are not apparent with classical illumination schemas such as plane wave illumination. In this experiment, blue laser is collimated and directed to the SLM. The whole active area of the SLM was used to produce Gaussian spots with amplitude modulation. To create the each Gaussian spot, one pixel is used from the SLM screen (1024×768 pixels, $19\,\mu$m pixel size). And then amplitude modulated light is reflected to the cascaded lens system to provide demagnification at opto-electronic sensor-array. Higher diffraction orders were eliminated by a filter at back focal plane of the lens system. Using the $21\times$ demagnification rate, $0.9\,\mu$m spot size that is half beam with of each Gaussian spot was obtained onto an opto-electronic sensor-array. In this on-chip fluorescent imaging platform, specimen which is smeared on top of the faceplate (that is a planar optical component) to increase the efficiency of fluorescent emission is positioned onto an opto-electronic sensor array. Since we use vertical illumination, the rejection rate of the filter that is onto an opto-electronic sensor array is very important. So we used the only coated faceplate as a filter to increase the efficiency of fluorescent emission. Based on this on-chip fluorescent imaging technology, $1\,\mu$m particles were detected nearly within $1\,\text{mm}^2$ area. This system might be useful for detection of viruses in scatter media such as whole blood.

Analogy between the Ising Model and the Polarization Switching of Vertical-cavity Surface-emitting Lasers

Tsu-Chiang Yen, **Yueh-Chen Li**, **and Yu-Heng Wu**
Department of Physics, National Sun Yat-sen University
No. 70, Lienhai Rd., Kaohsiung 80424, Taiwan

Abstract— Conventional vertical-cavity surface-emitting lasers (VCSELs) have a cylindrical laser cavity, which provides an intrinsic two-degree of freedom to the polarization direction of the emitted light. This isotropic symmetry of polarization is usually broken by the anisotropy of the physical structure of VCSELs; for example, the anisotropy of the lattice structure, residual stress, or thermal distribution. In some VCSELs, the broken polarization symmetry conducts a polarization switching (PS) phenomenon. During this process, the VCSEL remains in a phase of emitting linearly polarized light around the laser's threshold, and then switches to another phase of emitting orthogonally polarized light when the laser's current surpasses a switching current. The VCSEL's PS (VPS) can help to build some components for the high speed optical computing. Accordingly, the characteristic of VPS is an important research pursuit.

Recently, VPS was reported to be a second-order phase transition (SOPT). That discovery was based on the criticalities observed in the experiments, which are the unique characteristics of SOPTs. This research attempts to explore the connection between VPS and the conventional Ising model. The said model employs the spin-up and spin-down spins to study the transition of magnetic materials from the ferromagnetic state to the paramagnetic state and identifies that transition as an SOPT. Therefore, both of the phase transitions of VPS and Ising model are SOPTs between two orthogonal states. Typical Ising model employs a two dimensional spin lattice to simulate the magnetic material. In this work, a Gaussian-distributed interaction was introduced into the center of the spin lattice to simulate the laser's beam profile and the spatial coherence. The investigation focused on the examination of the relaxation time required to transit from the ferromagnetic state to the paramagnetic state. The simulation results present an exponent of the relaxation time of about 2.23. This result approximates the experimental result of 2.3 well, revealing a success of this model. Some other results will also be reported.

Electromagnetic Modeling of Antenna Array Based on Circular Carbon Nanotubes Bundle

M. Aidi and T. Aguili
SysCom Laboratory, National Engineering School of Tunis, BP 37 Le Belvedere 1002, Tunis, Tunisia

Abstract— A novel antenna array structure, formed by carbon nanotube bundle is proposed. The geometric structure and radiation characteristics have been investigated using a proposed integral equations system. This equations system is numerically solved using the moments method. The dependence of the radiation performance, upon geometrical parameters, e.g., nanotube length and number and the coupling distance is accurately discussed. Some illustrative numerical results have been presented to discuss the radiation performance of carbon nanotube antenna array for different coupling distances.

Radiative Heat Transfer in the Extreme Near-field

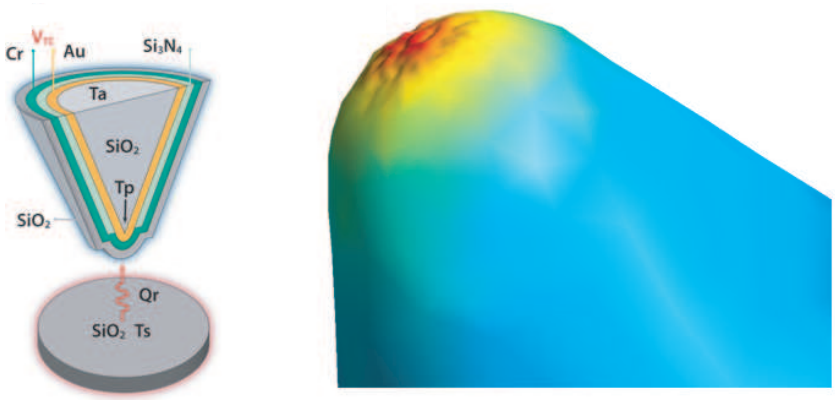
Abstract— One of the central open problems in nanoscience is the study of the heat transport in nanoscale devices, which has remained largely unexplored due to experimental challenges. In this context, a key issue is the understanding of the heat transfer via thermal radiation between systems separated by nanometer-size gaps. In this extreme regime, the electromagnetic near-field is expected to give rise to a dramatic enhancement of the radiative heat transfer, something that has only be quantitatively verified for gaps on the order of 20–30 nm [1]. In this work, we present a combined experimental and theoretical study of the radiative heat transfer in the extreme near-field regime (gaps of 1–10 nm). From the experimental side, we performed systematic studies using AFM-based scanning probes with integrated nanoscale thermocouples [2], which were coated with dielectrics (SiO_2 or SiN_x). Our experiments of heat transport between the scanning probes and a flat substrate coated with dielectrics, performed in an ultra-high vacuum environment, confirm that heat transport is dramatically enhanced in the near-field. To understand our experimental results, we investigated these near-field enhancements within the framework of the theory of fluctuational electrodynamics [3]. To be precise, we performed extensive numerical simulations making use of a combination of a fluctuating-surface-current formulation of radiative heat transfer with the boundary element method [4, 5]. Such a combination allows us describing realistic geometries for our tip-sample setups. Our theoretical results are in good agreement with the measured heat flows between both dielectric and metallic surfaces, which establishes the validity of fluctuational electrodynamics in modeling near-field heat transport all the way to nanometer-size separations.



(a) (b)

Figure 1: (a) Schematic diagram of the experimental setup. The AFM probes incorporate a thermocouple, made by a spherical Au/Cr junction with a diameter of 200 nm. (b) Numerical simulation of the spatially resolved heat transfer between a tip and a plate made of silica and separated by a distance of 1 nm. The radius of the tip is 225 nm. The color scale is logarithmic, showing the radiative heat transfer enhancement in the extreme near-field.

Abstract— Electrically Small Antennas (ESAs) are desired and essential for many applications and especially at lower frequencies like HF and VHF band. Nowadays, compact antennas have become standard equipment for radio receivers on vehicles and mobile terminals which lead to new requirements for small, efficient and low cost designs. The good performance of a radio receiver is heavily depended on the antenna performance. A variety of FM antenna types have been reported for automotive and portable applications including, the active [1] and short meander line monopoles [2], fractal Hilbert curve antenna [3], chip antennas [4], window-printed active antennas [5] and the shark type antennas [6].

In this work, a compact printed FM antenna is reported and operates over the frequency range of 87.5–108 MHz. The antenna was designed and printed on a 100 mm × 50 mm double sided FR-4 substrate ($\varepsilon_r = 4.3$, $\tan\delta = 0.025$, thickness = 1.5 mm) with copper metallization thickness of 0.035 mm. The antenna is fed by a microstrip line which is connected to a SMA connector. The miniaturization is based on its spiral structure occupying a 50 mm ($0.023\lambda_0$) × 50 mm ($0.023\lambda_0$) area on the PCB board. In order to improve the antenna bandwidth, a network matching circuit is added so that the impedance bandwidth of antenna can be wider, covering the frequency range of 20 MHz bandwidth at VSWR 6 : 1. The antenna was also measured and simulated on 900 mm × 900 mm ground plane which is representative of a vehicle roof.

A Wideband Matching Technique for Polarization Versatile Applications

A. G. Koutinos, G. A. Ioannopoulos, M. T. Chryssomallis, and G. A. Kyriacou
Microwaves Lab, Department of Electrical and Computer Engineering
Democritus University of Thrace, Xanthi 67100, Greece

Abstract— A novel patch feeding technique is proposed, in order to achieve wideband matching for linear (horizontal or vertical) and circular polarization around the WiFi band of 2.4 GHz, which is allocated for computer-to-computer communications and Internet access. In addition, patch antennas fulfill many requirements regarding portable communication systems, combined with ease of fabrication at low cost and therefore are a fair solution.

As stated in [1], polarization diversity can be achieved by imposing a 90° phase difference between two adjacent linear resonances TM_{10} and TM_{01}, exploiting shorting posts. Each resonance (one regarding vertical and one horizontal polarization) can be slightly moved higher than the other by small differences in a square patch dimensions, so that the input impedance of, e.g., the vertical mode is inductive, while the input impedance of the horizontal mode is capacitive. Thus, the patch can effectively radiate in vertical mode or horizontal mode, while when operating in an intermediate frequency (thus giving rise to both resonances), circular polarization is achieved.

Furthermore, wideband linear resonances can be achieved using a technique proposed in our previous work [2]. The shorting posts which play a crucial role in [1] are replaced with feeding points, each symmetrical pair of them giving rise to either vertical or horizontal polarization. The point is that, regarding a single mode, we can enhance its bandwidth by introducing a feeding path inequality between its symmetrical feeding points. The novelty in the proposed configuration is that wideband operation for linear resonances is managed, while there is still the possibility for circular polarization mode by appropriately adjusting the frequency of operation between the two resonances.

As shown in Fig. 1, the feeding points centered on the x-axis are fed via holes in the substrate, while the path inequality regarding their distance to the common source (source 1) enables wideband matching for the horizontal mode around a frequency f_{R1}. The same approach is adopted for the feeding points located on the y-axis (source 2, for vertical polarization), this time around a frequency $f_{R2} \neq f_{R1}$. Introducing now 90° phase difference between sources 1 and 2, circular polarization is achieved at an intermediate frequency, between f_{R1} and f_{R2}. The designed patch antenna dimensions are 33.5 mm long and 34 mm wide, which printed on a $50 \times 50 \times 1.524$ mm Rogers dielectric substrate with $\varepsilon_r = 3.4$ and $\tan\delta = 0.002$.

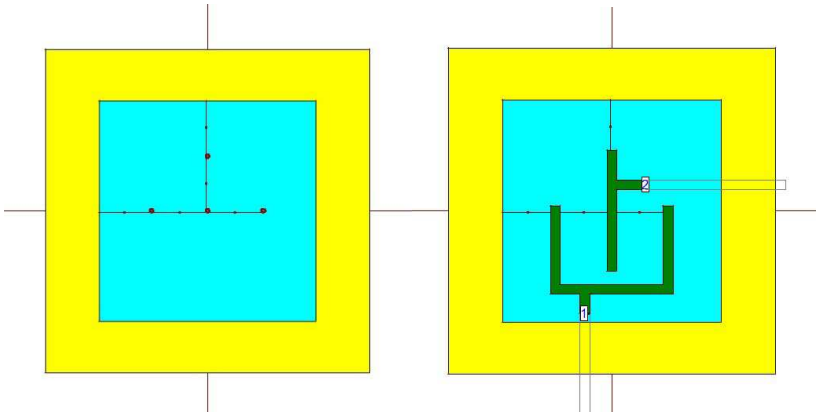

Figure 1: (a) Downwards and (b) backwards aspects of the proposed configuration.

Design and Implementation of a Planar Slot Antenna for SSR

Maziar Hedayati, Gholamreza Askari, Parisa Moslemi, and Hamid Mirmohammad Sadeghi
Information and Communication Technology Institute (ICTI)
Isfahan University of Technology (IUT), Isfahan 84156, Iran

Abstract— Secondary surveillance radar (SSR) mechanism is based on sending a pair of signals at the frequency of 1030 MHz for interrogation and receiving a pair of signals as an answer at 1090 GHz [1]. SSR radars are built in the form of planar or cylindrical array antenna [2]. Reflector and multi layer antennas are the most common SSR antennas in the literatures that have some disadvantages like complexity and being bulky [3, 4]. One layer microstrip array antenna which is proposed in this work is useful in mass production because of its advantages like easily printed, light weight and low cost which makes it suitable for radar applications. However it has some disadvantages like narrow bandwidth and high side lob level which is solved in this paper. To enhance the bandwidth, many attempts have been done in microstrip technolpgy. [5] using stacked elements for increasing the bandwidth of microstrip antenna and [6] proposed an stacked patch array of 1×8 elements with 14 dBi gain and the SLL of -14 dB, which is not enough to satisfy the Side Lobe Suppression (SLS) for the SSR [1]. In addition using stacked element increase the complexity of the system.

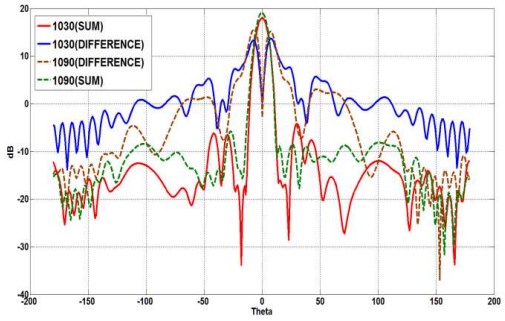

Figure 1.

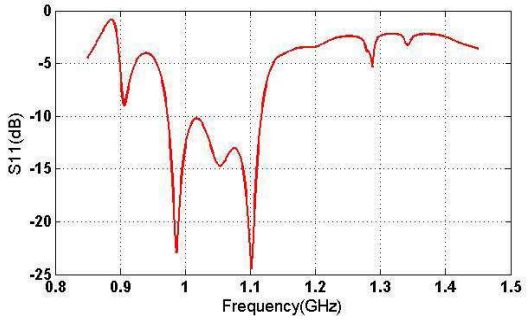

Figure 2. Simulated S_{11} of the 2×8 SSR antenna.

Table 1. Total characteristics of the proposed antenna.

Features	Unit	Value
#Channels	-	2 (Sum/Difference)
Frequency Range	MHz	1030 ± 5, 1090 ± 5
Polarization	-	Vertical
Sum Gain	dB	18.5
Sum Azimuth SLL	dB	-23
Sum Azimuth BLL	dB	-28
Difference Nu	dB	19
Difference Coverage	dB	> 4
Sum Azimuth B.W	Degree	9.5
Sum Elevation B.W	Degree	52
Size	cm^3	$200 \times 10 \times 60$
Gain at Elevation Angle ($-20°$, $-40°$)+5 dB > maximum Gain		
Gain at Elevation Angle (± 60) + 12 dB < maximum Gain		
Gain at Elevation Angle (± 90) + 18 dB < maximum Gain		
Gain at Elevation Angle (± 145) + 28 dB < maximum Gain		
Back lobe + 30 dB < maximum Gain		

In this paper a useful, low cost, low complexity, and one layer microstrip slot antenna for secondary surveillance Radar (SSR) application is presented. The feed network of antenna is a rat-race divider to create sum and difference ports and sixteen unequaled power dividers to satisfy the Chebyshev distribution with −30 dB SLL. The feed network has a special structure that creates constant group delay in all output ports and wide frequency bandwidth. The antenna gain for the sum pattern is 18.5 dB and 19 dB at 1030 MHz and 1090 MHz respectively (Fig. 1), with a 3 dB beam width of 52° in elevation and 9.5° in azimuth. The difference has a −19 dB null at the peak of the sum pattern and an acceptable pattern against the sum pattern for SSR applications. Furthermore, the antenna pattern has no need the back fill antenna to satisfy the back lobe conditions, which is critical for SSR applications. The total characteristics of the proposed antenna are shown in Table 1. A 2 : 1 VSWR bandwidth of 9.4% is achieved with the presented geometry in simulation to cover the 1030 ± 10 MHz transmit and the 1090 ± 10 MHz receive frequency band (Fig. 2).

Design And Analysis of Uniplanar Compact Electromagnetic Bandgap Structures

Shivam Gautam[1], **Komalbir Kaur**[1], **N. S. Raghava**[1], **and Asok De**[2]

[1]Delhi Technological University, India
[2]NIT Patna, India

Abstract— A uniplanar compact electromagnetic bandgap (UCEBG) antenna and its performance analysis is presented in this paper. The EBG structure in the antenna presented improves the antenna's efficiency and increases its compactness, enabling it to perform better at a lower frequency.

The antenna is composed of a ground plane, an EBG plane, a dielectric substrate and a radiating patch. Figure 1 depicts the top view of the antenna. The length of each side of the ground plane is L which is equal to 191.2 mm. The antenna consists of a 17×17 matrix of unit UCEBG structure. The substrate between the UCEBG layer and the radiating patch is of 0.7 mm thickness and a dielectric constant of 1.96. The air gap between the ground plane and the UCEBG layer is 9 mm. The radiating patch element is of dimension 70 mm $\times$ 54 mm.

CST Microwave Studio is used for the design and analysis of the UCEBG antenna. The results obtained from the simulation show that the central frequency of operation of the antenna is 1.271 GHz. The antenna has a reflection coefficient bandwidth (< -10 dB) of 17 MHz and covers the frequency range from 1.263 GHz to 1.28 GHz. The graphical representation of reflection coefficients are shown in Figure 2. The radiation pattern of the antenna is shown in Figure 3.

The antenna has a gain of 8.08 dB at $\theta = 0°$, $\phi = 0°$.

Abstract— Hybrid coupler is an essential component in modern wireless communication systems. It has been widely used in a variety of applications, such as the feeding network of an antenna array, power dividing/combining networks and balanced-mixers. Recently, electric tunable quadrature hybrid coupler has gained much attention, because of its reconfigurable performance. In this paper, we propose a novel wideband quadrature hybrid with tunable power dividing ratio. It is consist of a modified structure of hybrid and two varactor diodes (Cp), as shown in Fig. 1. By verifying the biasing voltage, the power dividing ratios between the two output ports (i.e., port 3 and port 4) of the hybrid can be easily controlled. Analytical design equations are derived using the even-odd mode method. To verify the design concepts, a miniaturized tunable power dividing ratio hybrid working at 1.85 GHz is designed. The parameters of the proposed antenna are as follows: $L_0 = 14.2$ mm, $L_1 = 16$ mm, $L_2 = 9$ mm, $W_0 = 1.5$ mm, $W_1 = 2.8$ mm, $W_2 =$1mm, $W_3 = 0.25$ mm, $W_4 = 1.2$ mm. When verifying the capacitance of the varactor diodes from 0.9 to 3.3 pF, the power dividing ratios between the two output ports of the hybrid can be controlled from 0 to 6 dB within a wide bandwidth for (1.75–1.95 GHz). Moreover, the size of the quadrature hybrid is much small ($60.4 \times 26.8\,\text{mm}^2$). The measured results agree well with the simulated ones.

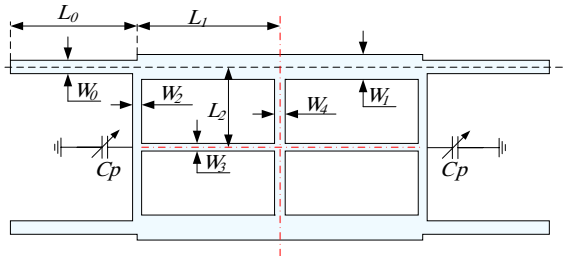

Figure 1: The structure of the proposed tunable power dividing ratio wideband quadrature hybrid coupler.

A Wide Stopband Filter with Source-load Coupling Technique

[2]Department of Electronic Engineering, Far East University, Taiwan

Abstract— In this paper, a wide stopband bandpass filter with source-load coupling technique is proposed. Multiple transmission zeros are generated at the stopband to suppress the harmonic responses of the bandpass filter. With the gap-coupling structure, transmission zeros can be controlled by adjusting the input/ouput tapped position. Moreover, additional transmission zeros can be obtained by using the source-load coupling technique. By controlling the value of the gap capacitance, the locations transmission zeros can be controlled. The stepped-impedance resonator (SIR) is utilized to minimize the overall circuit size. The impedance and length ratios of the SIR are determined to move its first harmonic to a higher frequency. The center frequency of the filter is 2.45 GHz, and the stopband rejection is higher than 30 dB from 2.9 GHz to 13.36 GHz. The circuit is fabricated on a Rogers RO4003C substrate with $\epsilon_r = 3.6$, $h = 32$ mil, and $\tan\delta = 0.0027$. The total circuit size is $0.15\lambda_g \times 0.23\lambda_g$.

Analysis and Implementation of a Dual Mode Cavity Band Pass Filter

Zohre Pourgholamhossein, **Fattah Talaei**,
Gholamreza Askari, **and Hamid Mirmohammad Sadeghi**
Microwave and Antenna Group, Information and Communication Technology Institute (ICTI)

Abstract— Microwave filters play an important role in almost every RF-microwave communications system. In communication system, narrowband filters are essential components to reject the interference signals. Therefore it is necessary to utilize high Q resonant circuits to achieve a narrow bandwidth in the pass band at high frequency. Microwave band pass filters have been typically implemented using waveguide technology or cavity due to low loss, high quality factors, narrow bandwidth and high power handling capabilities [1]. On the other hand, waveguide filters are massive and heavy. A solution has been done to reduce the size and weight of filters involves using dual mode cavities that support two degenerate resonances. Therefore, to reduce the number of physical cavities, dual mode or triple mode resonators are often employed. The advantages of these filters are the fewer number of cavities and improved performance. The first working multi-mode cavity microwave filter has been introduced by Li [2]. Elliptic dual mode filters for space applications were introduced by Atia and Williams [3]. Designs in other methods were reported by many authors [4, 5]. In addition, the transmission line must be coupled together. In the coaxial case, the probe excitation is carried out in the cavity resonator by introducing the probe inside the cavity.

This paper presents a structure of the dual mode rectangular cavity filter using coaxial probes for excitation. By using cross coupling technique with perturbation theory, transmission zeros in the stop band are realized, so the shape factor can be improved. Also, by this technique, bandwidth of pass band can be optimized. On the one hand, cross coupled filters are difficult to tune, due to coupling effects in the filter. This dual mode cavity design is used for the implementation of second order filters with two TE_{101} and TE_{011} modes. The two independent modes can be coupled so that, energy is transferred from the first modes into the second. Actually, the probe is inserted from the broad dimension of the cavity and it should be kept at the place inside the cavity where electric field is maximum, which is discussed completely. Considering the topology of two orders band pass, is designed to meet the center frequency of 9050 MHz, 3-dB bandwidth of 60 MHz, insertion loss less than 0.5 dB, and 20 dB return loss in the pass band. In this design cavity is perturbed by a small deformation of its boundary as shown in Figure 1(a). This perturbation causes disturbing in the electrical field and so direct coupling between them is occurred. Also this cause cross coupling that is discussed completely. It is obvious that the bandwidth of the filter can be altered to desired values by changing the dimension of perturbation Furthermore, to indicate the effect of perturbation on the bandwidth, circuit analysis is done. The proposed cavity filter is structurally compact size and requires only one tuning screw. This tuning mechanism is presented to adjust the resonant frequency without causing any coupling of the degenerate cavity modes. Finally, EM simulation is done for the filter. Full wave analysis of the filter confirms the designed filter and performance of the full wave simulation of the complete structure. In order to validate the performance of the filter design, the filter was fabricated and measured. Figure 1

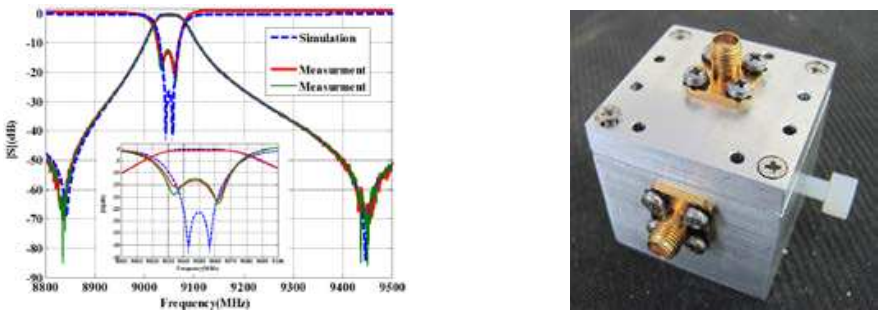

Figure 1: EM Simulated and measured results of the proposed band pass rectangular dual mode cavity filter and its photo.

shows the comparison between the measured response as the solid curves and simulated response (dashed lines) and its photo. The 3 dB bandwidth of the simulated filter is 63 MHz centered at 9050 MHz, insertion loss is about 0.28 dB, and return loss is better than 26.4 dB in over the pass band. The measured results are the return loss of better than 12.5 dB in the pass band and the insertion loss of better than 0.5 dB.

Propagation of Electromagnetic Waves in Cylindrical Three-layers Waveguide with Metamaterial Layer

V. A. Meshcheryakov and V. A. Zhuravlev
Tomsk State University, Tomsk 634050, Russian Federation

Abstract— Results of computer modeling of the coefficients of waveguide mode propagation in a tree-layered circular screened waveguide are presented. The waveguide center is filled with the medium having a negative refractive index. The results presented here suggest that frequency transparency windows, complex waves, waves with anomalous dispersion, and waves with significant retardation of the phase velocity exist in such waveguides.

In the course of computer modeling, different variants of relationship between the thickness of the internal dielectric core made from the left-handed material and the layer of the right-handed material have been studied. The qualitative pattern of the behavior of the parameter propagation differed significantly from that in the waveguide with two right-handed media. Thus, we can indicate the following special features of electromagnetic wave propagation in the examined waveguide:

1. In the tree-layered screened waveguide whose the second layer has negative refractive index and external layer represents an air layer, both the wave process and the cutoff regime of waveguide mode propagation can be observed for definite internal layer radii.

2. The layer of the left-handed medium leads to the occurrence of modes with large retardation coefficient.

3. Regions of complex waves (without losses in the filling media) are observed.

4. There are waves with anomalous behavior of the propagation parameter.

5. The presence of the central LHM layer leads to the occurrence of the frequency transparency windows. The waveguide represents a bandpass filter.

Thus, this suggests the possibility of designing bandpass filters, retardation lines, and devices operating based on retarding systems from segments of such waveguides.

A Broad-band End Launch Double Ridge Waveguide to Coaxial Transition Using LPDA

Abstract— Waveguide to Coaxial transition, as an important passive component has wide application in antennas, radars and microwave systems. Nowadays, broad band transitions are necessary for feeding wideband antenna in developing of the microwave systems. Most of designs like aperture-coupled slot [1] or aperture coupled patch element [2] have been expanded in the literature to introduce a useful transition from waveguide to microstrip. Although aperture-coupled structures are compact, but their fractional bandwidth is compact. Besides, the waveguide to microstrip transition based on the coupled probe at the E-plane [3] has been presented which is small but its bandwidth is limited ($\sim$ 22% for less than 15-dB return loss). To modify the bandwidth, [4] has proposed transition using the stepped waveguides and [5] has presented the short-circuited tapered finline to widen the band width. However, the circuit size is also large. To decrease the size of the circuit, some researchers use the aperture slot coupling [6], and patch element [7] as a transition. The circuit size of these transitions can be reduced but in cost of narrow bandwidth. To enhance the bandwidth, waveguide to microstrip transitions using the open-circuited probe [8] and tapered coplanar strip (CPS) probe [9] were presented. But there is an additional slotline to microstrip transition in their designs. Furthermore, although [10] has presented a compact and broadband waveguide to microstrip transition using the anti-symmetric tapered probes, but there is an imbalance problem while transitioning from the ML to the rectangular waveguide. All of those transitions have been designed for simple rectangular waveguides, but for wideband application the ridge waveguides are more useful than rectangular waveguides which is not commonly presented any transition for them in the literatures.

In this paper, a wideband end launch ridge waveguide to coaxial transition is proposed, which operates in 8 $\sim$ 14 GHz. The microwave characteristics of double-ridge waveguide to coaxial transition are analyzed and simulated by full-wave analysis. Quarter wavelength Chebyshev impedance matching method used to design the middle part of the transition. Dimensions of the first part of transition have been calculated by time domain solver of Ansoft Designer based on finite element method (FEM). The compact LPDA is designed on microstrip to receive signal from the waveguide. This antenna is placed in the E-plane of the ridge waveguide to stimulate the TE_{10} dominant mode which is shown in Fig. 1. Higher modes propagation can disturb the performance of the wide band transition. Also in this paper a C shape part is used to increase the cut off frequency of higher modes. Furthermore; power analysis is done to investigate arcing across the transition for 100 Watt input power. The simulation results show that the S_{11} of the transition is below -10 dB in 8–14 GHZ that is shown in Fig. 2.

Abstract— Recent progress in computation performance and computational electrodynamics allows various analyses on many problems related to electro-magnetic (EM) waves using general purpose EM simulators. In this paper, we describe and demonstrate 3D ISAR image generation of a realistic target using FEKO, which is one of the representative general purpose EM simulators on the commercial market. This method can benefit us many advantages like building the database of many targets for target recognition with cost-and-time effective way and designing a radar and evaluating its performance under more realistic situations.

A Comparison of SAR Imaging Performance between Matching Filter and Compressed Sensing

Gang Wang, Ze Yu, and Peng Xiao
School of Electronics and Information Engineering, Beihang University, Beijing 100191, China

Abstract— Compressed sensing (CS) is a newly developed technology for sparse or compressible signal which can be applied to synthetic aperture radar (SAR) imaging to achieve high-resolution images. As the SAR image is the spatial distribution map of target reflectivity function, it can be sparse or compressible in some transform domain such as wavelet domain or Fourier domain. This character is just exactly meet the requirement of CS theory, and provides the theoretical support for application of CS in SAR imaging. Generally, SAR utilizes matching filter (MF) technique to improve resolution, but due to the superiority of CS, the need for MF technique has been doubted. In recent years, some scholars have discussed CS in SAR imaging and published some related articles. Based on the above, this paper analyzed the principle of both methods, and compared CS with MF during processing SAR images in several aspects such as resolution and SNR, which aims to expatiate the differences between them. Furthermore, several new indicators are proposed in this paper during the comparison between these two methods, such as microscopic and macroscopic resolution and group spread function (GSF), to evaluate imaging performance due to new features caused by CS processing. The comparison results are given and verified by theory derivation and data simulation. Several experiments are carried out and simulation results are presented to illustrate imaging performance based on MF and CS theory. Firstly, we present reconstruction result obtained when range is greater than and less than microscopic resolution and macroscopic resolution in CS imaging. Next, we introduced GSF comparison between MF and CS. After that we explained statistical results on SNR when changing input SNR and the value of M/N in CS imaging, and finally demonstrated SNR comparison between MF and CS. According to the simulation results, the resolution can be improved considerably by using CS when the sampling rate is greater than corresponding bandwidth, but ambiguity phenomenon will appear as the distance increases which does not occur when using MF. Besides macroscopic and microscopic resolution, GSF is also an important indicator to measure resolution, and it is proved that two methods' GSF are almost the same when sampling rate is close to bandwidth. In addition, output SNR for CS imaging varies with the number of rows and columns in sparse dictionary when input SNR is given, and its anti-noise ability is weaker than that when using MF which is designed to produce the maximum achievable SNR. Each method has its own strength and weakness, and CS can't replace MF even if it has so many advantages because CS still has some characteristics not so good as that of MF, such as SNR. So we must select appropriate imaging method based on the specific situation. Moreover, besides this two methods mentioned in this paper, there are still many other effective SAR imaging processing methods for consideration, and we have also listed the advantages and disadvantages between them.

Micro-motion Target Detection Based on Wall Envelope Alignment in Through-the-wall Ultra-wideband Radar

Lei Qiu, **Tian Jin**, **Biying Lu**, **and Zhimin Zhou**
College of Electronic Science and Engineering, National University of Defense Technology
Changsha, Hunan 410073, China

Abstract— The detection of human targets behind obstacle has become a keen research topic in recent years and is highly desired in military and civil applications particularly in urban battle, anti-terrorism, disaster rescue, and medical application. Change Detection techniques are used to detect moving targets and mitigate the heavy clutter caused by strong reflections from stationary targets in through-the-wall ultra-wideband radar. However, the radar antenna platform jitter caused by working engine wobble or environmental factors such as wind blowing, results in stationary targets position change in different data frames. Although the change is tiny, the residual energy of stationary targets after change detection is much greater than that of moving targets, particularly of micro-motion human targets due to the low reflectivity of human and high signal attenuation of wall. This paper proposes an antenna platform jitter compensation method based on wall envelope alignment, aiming to detect micro-motion targets behind wall. Firstly, the antenna platform jitter model is established. The stationary position is assumed unchanged during a frame time, and the motion compensation is only performed between different frames. Then wall envelope alignment method is applied to compensate antenna jitter in range direction. There exists a strong plane reflection of the wall, the jitter can be compensated by the front surface of the wall who has the maximum amplitude in every frame data. Finally, the jitter effect in cross direction is evaluated. Simulation and experimental results demonstrate that the proposed approach can compensate antenna platform jitter, eliminate the stationary clutter and detect micro-motion targets correctly and effectively.

Analysis of a Polycarbonate RFID Tag for Blood Chain Tracking

G. Boi, **R. Secci**, **S. Casu**, **A. Fanti**, **and G. Mazzarella**
Department of Electrical and Electronic Engineering
University of Cagliari, Italy

Abstract— In this paper we describe an antenna especially designed used for a RFiD passive tag working at UHF (987 MHz), for healthcare applications, in particular for the transfusion medicine and the blood supply chain. The tag has to be able to work placed on the top of a blood sack, while the bag is full of blood, and the antenna has been designed with this goal in mind. Therefore we require an antenna able to work close to a (relatively large amount of) lossy medium with high permittivity. Moreover, the bag shape is curved but cannot be predicted exactly, so that the antenna worst retain its behavior for a large set of different environments. In order to comply with all those requirements, a printed slot antenna built with a flexible substrate has been selected, so that the whole tag can be flexible too. The first step was the optimization of the working parameters of the antenna while placed in a perfect planar surface (i.e., assuming the blood bag to be a parallelepiped). Since the actual bag shape is not known, this choice allows to take into account the lossy material, but using a simple geometry. The antenna has been optimized to get the maximum reading distance. Then we consider the effects of a real blood bags (i.e., a curved one), filled with blood, on the antenna behavior. We consider a bag with a transverse section bounded by two arc of circles (with a radius quite a larger than the bag size). Since we found a reasonable agreement with the planar antenna we can assume that the antenna behavior is quite insensitive to the bag shape. Finally, we evaluated the SAR into the blood and compare it with the compatibility parameters. A robustness analysis, respect to the bag curvature radius, has been performed, too, to assess the antenna use in real environments.

EM Level Evaluation in Hospital Indoor Environment

G. Boi[1], **S. Casu**[1], **A. Fanti**[1], **G. Gatto**[1], **G. Mazzarella**[1], **S. Pisu**[1], **P. F. Orrù**[2], **I. Spano**[1], **E. Tanzi**[1], **and F. Zedda**[2]

[1]Department of Electrical and Electronic Engineering
University of Cagliari, Piazza d'Armi, Cagliari 09123, Italy
[2]Department of Mechanical, Chemical and Materials Engineering
University of Cagliari, Piazza d'Armi, Cagliari 09123, Italy

Abstract— During the last decades, the level of the EM field in urban areas has increased at a fast rate, due to the increase of radio services using RF electromagnetic waves, mainly in the VHF and UHF bonds. Among those services, we can quote cellular phone systems, broadcasting, public utility services and, more recently, wireless internet networks.

This shady increase of EM field level in urban areas is the reason for an equal increase of the public concern about the (possibly hazardous) effect of EM field on the human body. And, as a consequence, both the number of researchers in this field and the (more or less cogent) regulations have been boosted.

A completely different problem is the prediction of indoor EM field. As a matter of fact the co-existence of a significant number of RF sources in an almost of environment makes the monitoring of EM field level inside a building a difficult task. The starting point for the monitoring of the electromagnetic field inside a building can be represented by the study of the propagation of electromagnetic waves' in indoor environments. The indoor propagation characteristic is a fundamental point in the design of wireless LAN, cordless phones networks and every other type of indoor system based on radiofrequency communication. It is easy to understand that indoor environments are very complex and it is clear that the level of electromagnetic fields usually depends on many, different, factors. As a matter of fact, it is well known that is sometime sufficient to move a device just a couple of centimeters to significantly, odify the service level of that device. The scope of this work is to evaluate how long the standard antenna knowledge (gain and radiation pattern) help to product the EM level in an hospital indoor environment.

Comparison of Optimization Methods for Background Rejection in High Resolution UWB ISAR Imaging

Se-Yeon Jeon, **Sumin Kim**, **Tae-Yun Lee**, **Jiwoong Yu**, **and Min-Ho Ka**
School of Integrated Technology, Yonsei Institute of Convergence Technology
Yonsei University, Republic of Korea

Abstract— Inverse synthetic aperture radar (ISAR) is an imaging technique that provides images of the targets by observing the targets in rotational movements using stationary radar sensor system. By using impulse ultra wideband (UWB) radar, high resolution ISAR images can be acquired. Since radar signals are non-destructive to human body, the high resolution UWB ISAR imaging is a promising technology for biomedical, security, through wall observation, and military applications. To achieve better quality ISAR images of a wanted target only, a process for removing background signals is necessary. To remove the background signal, the UWB radar system measures the background only signal and the background with target signal. In most cases, the background only signal is simply subtracted from the background with target signal to acquire the target only signal. Unfortunately, this method is not effective because of the phase error between the background only signal and the background with target signal due to the pulse drift UWB radar equipment. One way to solve this problem is to calibrate the pulse drift by measuring the transmitting signals directly from the transmitter. However, this method requires additional receiving channel. This research provides an effective pulse drift correction method for background rejection in UWB ISAR imaging. The proposed background rejection method does not require any additional receiving channels or additional measurement for calibration. The pulse drift correction is optimized by finding the amount of pulse shift that has minimum mean absolute error (MAE), mean squared error (MSE) or total energy between the background only signal and the background with target signal. This study shows the results of optimized background rejection in UWB ISAR images and compares the performances of the optimization methods.

Response of Oscillator Model of Cardiac Conduction System on Modulated Electromagnetic Radiation

E. Ryzhii and M. Ryzhii
Complex Systems Modeling Laboratory, University of Aizu, Japan

Abstract— Various model approaches utilizing systems of ordinary differential equations have been applied to study cardiac rhythm dynamics. Different modifications of Van der Pol oscillator equations are the most popular in such studies as they allow adoption of intrinsic pacemaker frequency to the driving signal with minimal change in its amplitude.

Recently, we proposed a mathematical model of cardiac conduction system based on set of heterogeneous oscillators including main pacemakers and heart muscles [1, 2]. Sinoatrial node, atrioventricular node and His-Purkinje system are represented by modified Van der Pol type oscillators connected with time-delay coupling. For description of atrial and ventricular muscles, the depolarization and repolarization processes are considered as separate waves described by modified FitzHugh-Nagumo equations.

The model allows generating physiologically correct electrical signals of action potentials of all three major natural pacemakers (sinoatrial node, atrioventricular node, and His-Purkinje system) as well as atrial and ventricular muscle response. Resulting dynamic response of the oscillator system is obtained in the form of the synthetic electrocardiogram (ECG) which is one of the most important clinically comparable characteristic of human heart electrical activity. The model allows reproducing a number of various normal and pathological situations including arrhythmias.

We consider the behavior of the heterogeneous oscillator model of cardiac conduction system under periodic electrical stimulation caused by applied modulated electromagnetic radiation. We investigate initiation and termination of different arrhythmias, in particular, conduction blocks, atrial and ventricular fibrillations.

[4]Faculty of Biomedical Engineering, Czech Technical University in Kladno, Czech Republic

Abstract— Continuous energy supply to a biological system creates a state far from thermodynamic equilibrium. Excitation of coherent electromagnetic field is considered to be a crucial condition for life. [1] formulated a hypothesis of excitation of electric polar vibration and energy condensation in a single vibration mode forming a coherent state with essential biological function. Fröhlich's hypothesis is supported at acoustical frequencies by a) measurement of mechanical vibration in yeast cells *Saccharomyces cerevisiae*-dead cells do not exhibit any vibrations [2], b) comparison of measured mechanical vibrations and electric oscillations [3], c) analysis of nanoscale vibrations of different cellular systems as an expression of metabolic activity and signature of life [4]. The majority of biological macromolecules and structures are electric polar systems and vibrations generate electromagnetic field which was measured by dielectrophoretic attraction of small dielectric particles with a high permittivity by cells [5, 6] and the greatest electromagnetic activity in the M phase was confirmed by [7] in the frequency range 8–9 MHz. Microtubules represent the oscillating structure in eukaryotic cells [8]. [9] measured resonant frequencies of isolated microtubules in the frequency range 10–30 MHz, 100–200 MHz, in the far infrared region (at about 500 and 700 cm^{-1}), and the UV absorption spectrum at about 270 nm. The frequency spectrum from 1 to 100 GHz should be analysed to.

The frequency spectra below 1 GHz and in the far infrared region measured by [9] and Vedruccio and [10] should be verified. The power supply to the electric polar vibrations in a cell is assumed to be of the order of magnitude 0.1 pW (10^{-13} W). If the number of microtubules in a cell is about 400 then the power supply to a single microtubule is of about 0.1 fW (10^{-16} W). For quality factor of about 80 the power of electric polar vibrations in one microtubule is about 10 times greater (i.e., of 1 fW). The electromagnetic component of oscillations may be smaller than 1 fW. The measurement system should consist of a sensor (metal contacts of linear dimension 50 nm or smaller) integrated with preamplifier with extremely low noise followed by further amplifiers. Impedance matching of the preamplifier is a special problem. The sensor measures the potential difference of the near field excited by electric polar vibrations in microtubules between two points at the membrane. The input impedance of the preamplifier should correspond to the impedance of the plasma membrane in the region of the sensor. Nevertheless, reaction of the living cell to power losses caused by preamplifier consumption is an unknown factor. The whole measurement system should be in a doubly screened box. The coherent signal evaluation should be performed by a real time spectrum analyser controlled by a computer. Measurement in the far infrared region may be performed by Surface Enhanced Raman Spectroscopy (SERS) using a substrate with convenient metallic space pattern and infrared excitation. Synchronized, non synchronized, and control group of yeast cells (*Saccharomyces cerevisiae*) might be investigated at the beginning to assess properties of the measurement system.

28 GHz Delay Spread Measurement Using a Broadband Channel Sounder in Small Urban City

Young Keun Yoon, **Jong Ho Kim**, **Myoung Don Kim**,
Young Jun Chong, **and Myoung Sun Song**
ETRI (Electronics and Telecommunications Research Institute), Republic of Korea

Abstract— This paper describes the relations between the R.M.S delay spread and TX-RX separation distance for Daejeon City measurements at 28 GHz frequency with 500 MHz channel bandwidth. R.M.S delay spread is caused by multipath due to a large number of reflective characteristics none line of sight environments in small urban city.

Introduction: Recently, the fifth generation (5G) mobile communication to satisfy the needs of high data rates in the small cell environment has attracted the attention. Millimeter frequency bands for 5G services are the lands of new frontier being able to support broadband bandwidth from 0.5 up to 2.0 GHz. We know that feasibility research at millimeter bands is carried out currently. Yet, there is still the lack of the collected field data and statistical models based on measurement. Therefore, we performed measurement in small urban city of Korea to find specific R.M.S delay spread characteristics.

Hardware & Measurement Campaign: Millimeter wave Band Exploration and Channel Sounder (mBECS) developed by ETRI was used in the outdoor R.M.S delay spread measurement campaign. Using a 500 Mcps broadband channel sounder with 2.0 ns multipath resolution, we conducted R.M.S delay spread measurements at 28 GHz in Daejeon City, Korea. A 4095 chips pseudo-random noise (PN) sequence sliding correlator was utilized, which was modulated to a 5.2 GHz intermediate frequency (IF) and upconverted 28 GHz. The maximum transmitter (TX) power was 29 dBm, fed to a 30° beamwidth 15.4 dBi horn antenna that was mechanically rotated or tilted. The receiver (RX) used the 10° beamwidth 24.4 dBi horn antenna and the same type of enable mechanically rotating or tilting structure as the transmitter.

The measurement campaign was taken during daytime. During measurement, TX location was fixed, and RX put none line of sight (NLOS) locations. We choose one TX at a height of 4 m and 15 RX measurement locations. The distance between the TX and RX ranged from 120 to 400 m. At RX at a height of 1.5 m, a 360° azimuth sweep at each RX position was automatically performed in steps of 10° because of using 24.4 dBi horn antenna with the 10° half power beamwidth. Extensive measurements were conducted for the thirty six different RX azimuth angles ranged from 0 to 350°, and for the three different RX elevation angles of −10°, 0°, and +10° creating one hundred eight possible antenna pointing steps. For each of one hundred eight steps, measurement data were recorded. Finally, R.M.S delay measurements were done at the RX locations in Daejeon, Republic of Korea.

Results: We note that the maximum value of R.M.S delay spread appears to be up to 400 m TX-RX separation distance at 28 GHz frequency, and then decreases for relative large TX-RX separation distance. In NLOS case, the TX and RX antennas were indirectly pointed at each other, and large multipath existed. But, when the separation distance between a TX and Rx is too large (exceeding 400 m), the path loss is so great that the power of the transmitted signal declines to zero before reaching the RX, resulting in fewer or no received multipath. For the relations between the R.M.S delay spread and TX-RX separation distance as well as the cumulative distribution function (CDF) of the R.M.S delay spread at 28 GHz. The maximum value of measured multipath components in our research using wide band channel sounder with 2.0 ns multipath time resolution has R.M.S delay spreads below 125 ns, the average has below 58 ns to NLOS environments in small commercial urban environment, Daejeon, Republic of Korea.

Conclusion: We found that the measured values from the light urban environment of Daejeon City in Korea have substantial differences in comparison with the dense urban environment in R.M.S delay spread in [1]. To find adequate R.M.S delay spread components, we believe that the results through extensive measurement in various urban environments should be more discussed.

Minimum Sum Algorithm Decoder for LDPC Nonregular Parity Check Matrix in BPSK System

Yi Hua Chen, **Jue Hsuan Hsiao**, **Zong Yi Saio**, **and Hua Ting Syu**
Oriental Institute of Technology
Institute of Information and Communication Engineering, New Taipei, Taiwan

Abstract— Referring to the approximate lower triangular low-density parity-check code check matrix of the IEEE P802.11n™/D1.04 (Part 11: Wireless Local Area Network Medium Access Control and Physical Layer specifications), this study established a decoder based on LabVIEW program language on a single program architecture that can adjust the transmission end to generate diverse codeword patterns, including three subblock sizes (27, 54, and 81 bit) and four code rates (1/2, 2/3, 3/4, and 5/6). Combined with the minimum sum algorithm (MSA), the decoder completed decoding tasks by changing the check node and variable node structures on the basis of the selected subblock size and code rate In addition to providing an introduction on the decoding mechanism of the MSA and completing decoding program optimization and analysis of bit error rate (BER) performance curves, this study applied the LabVIEW program to simulate the BER of the ratio of energy per bit to the spectral noise density (Eb/No) at each point from 0 to 10 dB, when subblock sizes (27, 54, and 81 bit) were combined with code rates (1/2, 2/3, and 5/6) operating in an additive white Gaussian noise channel environment. The error rate performance curve diagrams of two studies were referenced (regular weight (3,6) and 802.11n irregular subblock size 27 bit combined with code rate 5/6) and compared with the simulation outcome yielded in this study. The result showed that the subblock size did not affect the error rate, but the code rates substantially affected the error rates. When the code rate was set to 1/2, the error correction performance of the irregular check matrix was considerably higher than that of the regular check matrix.

Asymptotic Analysis of Scattering from Transmitarray for Near Field Focused

Shih-Chung Tuan[1] **and Hsi-Tseng Chou**[2]

[1]Department of Communication Engineering, Oriental Institute of Technology, Pan-Chiao, Taiwan
[2]Department of Communication Engineering, Yuan Ze University, Chung-Li, Taiwan

Abstract— This paper presents the asymptotic formulation of ray fields in the decomposition of electromagnetic (EM) scattering mechanisms from a one-dimensional, semi-infinite and periodic array when it is illuminated by a line source. This technique can be applied to analyze the passive FSS (frequency selective surface) type periodic structure with identical elements, the transmitarray type antennas that are phased to radiate EM fields focused in the near zone of the array aperture. The solutions are built up based on the Floquet mode expansion of the scattering fields, and are obtained by asymptotically evaluating the resulted integrals to express the fields in terms of transmitted and edge diffracted fields as previously addressed in the framework of uniform geometrical theory of diffraction (UTD).

Didactic Simulations in Electromagnetics

Abstract— Electromagnetic theory forms the basis of all electrical engineering from electrostatics to optics. However, the teaching of the basic area of electromagnetics has been considered, for a long time, to be a challenge and a matter of concern due to low student motivation and underperformance in electromagnetic courses. This was attributed to the mathematical complexity and abstract nature of the topic. Moreover, EM field phenomena are normally expressed in 3D vector notation, which are physically invisible and students, at the beginning, have difficulty in relating mathematical models to good mental images. Simulations and computer graphics are strongly suggested to overcome many of the conceptual difficulties. In this direction, we present in this paper some virtual didactic simulations developed as a supplementary tool for teaching electromagnetic field. In the following, we describe some sample simulations which have been developed for some simple electronics components such as capacitors and inductors. The magnetic and electric field lines and distribution can be displayed in real time which makes the application ideal for use in interactive undergraduate and high diploma teaching. In this kind of simulation the student will be able to manipulate variables such as electric and magnetic field strength, field lines and have an idea on the relationship between the value of these electronic components, their geometry and the medium properties. Furthermore, in order for our simulation to comply with the new trends of distance learning and e-learning, the simulation where made using Action-Script to take full advantage of Adobe Flash technology as deemed by its power in the areas of multimedia and the Internet.

Perfect Light Absorption in Ultra-thin Silicon Films on Aluminum and Optical Color Filters

Seyed Sadreddin Mirshafieyan and Junpeng Guo
Department of Electrical and Computer Engineering, University of Alabama in Huntsville
301 Sparkman Dr, Huntsville, Alabama 35899, USA

Abstract— We have demonstrated wavelength selective perfect light absorption in ultra-thin single layer silicon films deposited on aluminum metal surface in the visible and near infra-red spectral range. The perfect light absorption is due to the critical coupling of the incident light to the second-order Fabry-Perot resonance mode of the nano-optical cavity formed by the silicon film on aluminum surface. Perfect light absorption wavelength varies with the thickness of the silicon film. Spectral selective perfect absorption results in different optical colors corresponding to different silicon film thicknesses. The colors of fabricated devices do not change with the increase of viewing angle up to 70 degree with respect to the surface normal. The demonstrated silicon absorption filter technology is intrinsically low cost and compatible with silicon processing platform, and can be used for many applications such as optical displays and wavelength selective photo detectors.

Investigation on Rudimentary Geometries of Dielectric Resonator Antenna

Jitendra Kumar and Navneet Gupta
Department of Electrical and Electronics Engineering
Birla Institute of Technology and Science (BITS), Pilani, Rajasthan 333031, India

Abstract— Due to the variety of basic geometries available to antenna designers such as rectangular, cylindrical, hemispherical etc., a proper practice to select the best geometry for Dielectric Resonator Antenna (DRA) is required. In this paper, various rudimentary geometries of DRA excited by a coaxial probe fed is designed and investigated for selecting the preeminent geometry of antenna. The rudimentary geometries of DRA are rectangular, cylindrical and hemispherical, which are used for investigation of DRA performance as shown in Fig. 1. The dielectric material used for rudimentary geometries is TMM10i, a ceramic thermoset polymer composite material of Rogers high-frequency laminates. The dielectric constant (ε_r) of the material is 9.8, the dissipation factor ($\tan\delta$) is 0.002, and the density is 2.8 gm/cm^3. The DRA is designed to operate around 3.2 GHz. However, the resonant frequency may alter due to different rudimentary geometries. CST Microwave Studio transient solver is used to design and simulate the different rudimentary geometries of DRA. Table 1 summarizes the numerical results for different geometries of DRA. It can be seen that the impedance bandwidth (for return loss below −10 dB) of the DRA is 56%, 46% and 50% for rectangular, hemispherical and cylindrical respectively. These rudimentary geometries of DRA give a better understanding of design parameters of an antenna and their effect on return losses, impedance bandwidth, VSWR, gain, efficiency and resonant frequency.

Table 1: Comparisons between different rudimentary geometries of DRA.

Rudimentary Geometries	***Rectangular***	***Cylindrical***	***Hemispherical***
Dimensions (mm)	$a = b = 30$, $d = 15$	$r = 18$, $h = 15$	$hr = 18.61$
Resonant Frequency	3.2 GHz	3.2 GHz	3.3 GHz
Bandwidth Range	2.9–4.7 GHz	2.9–4.75 GHz	3–4.5 GHz
Bandwidth ($S_{11} < -10$ dB)	56%	50%	46%
Total Peak Gain	1.56 dBi	1.50 dBi	1.54 dBi

Features Processing Lidar Signals in the GHz Frequency Range

A. S. Grishkanich, **S. V. Kascheev**, **V. V. Elizarov**, **and A. P. Zhevlakov**
National Research University of Informational Technologies, Mechanics and Optics
Saint-Petersburg, Russia

Abstract— Laser sensing — a highly effective method of remote operational environmental monitoring on land and over the surface of water bodies. As required substances can be used various substances Indicator hydrocarbon leaks from pipelines and processing plants, toxic agents necessary for chemical plants, smoke from fires, etc.

However, for high-speed sensing, speed of processing information received and ease of operation lidar units necessary to use appropriate hardware and software systems used to solve the problems of collecting, processing, storage, ordering large volumes of data.

The structure of a lidar system includes components that must communicate with each other by exchanging data and control signals. Each component performs a specific function and has a specific set of commands and control signals, as well as send or receive data.

In lidar system uses the method of spontaneous Raman scattering. This physical process is very short-lived, in some cases, no more than a few nanoseconds, so you need to work in the gigahertz frequency range for detecting signals with nanosecond.

Each component of the lidar system must respond a set of requirements due to work in the gigahertz frequency range. Therefore it is necessary to choose both hardware and software solutions that will deliver high-speed data exchange between parts of the system and high-speed processing of the data and system parameters.

The hardware is realized using modules and components with a high speed, as well as interfaces that allow you to exchange data with a high frequency that would exclude the loss of data due to time delays.

Software modules used for controlling, processing and organization of database systems should have adequate algorithms to perform real-time processing of information.

Are known to Raman scattering cross-section is very small (10^{-25}–10^{-27}), so in some cases back radiation captured by the objective can be several tens of photons. For registration of such weak signals and reliable conversion is preferred to use a photomultiplier operating in the photon counting mode. The PMT uses a high-speed electronic circuit that allows measurement with a pulse-pair resolution up to 10 ns. Interface USB 2.0 High-speed provides data exchange rate up to 480 Mbit/s. Information processing using software developed in Labview. To debug and validate the algorithm calculations instead of the photomultiplier used PXI system. This approach allows you to simulate operation of the system in real conditions, using a laboratory bench.

A laser beam scanning system has been developed. It comprises a mirror which oscillates with a frequency of 20 Hz, and the angle of rotation of 20 degrees. For precise positioning of mirrors used stepper motor with controller and specialized control software. For developing of this software was used C#. Control signals are transmitted using RS-232 interface.

In lidar system provides navigation and mapping. Mapping system is organized using a compatible GPS devices and software. The device is connected to the USB port of a PC. All data transmitted over the NMEA 0183 protocol. The obtained coordinates attached to the card, as well as recorded in a database simultaneously with the measurement results.

All information collected from the system components processed by the application developed using C#. The objectives of this application is to monitor uptime and connection of components, management report of possible errors and entering information about them in the database.

As a result of the scheme established inter-component communication hardware lidar complex and selected options that allow you to achieve the required measurement accuracy and high speed data exchange between components. Just developed the software needed to process volumes of information obtained from multiple system components.

Oil and Gas Prospecting by High Resolution Raman Lidar

A. S. Grishkanich[1], **S. V. Kascheev**[1], **V. V. Elizarov**[1], **I. S. Sidorov**[2], **A. A. Il'inskiy**[3], **and A. P. Zhevlakov**[1]

[2]University of Eastern Finland, Kuopio, Finland
[3]All Russia Petroleum Research Exploration Institute, Saint-Petersburg, Russia

Abstract— Remote laser spectroscopy availability for airborne search of the oil-and-gas deposits has been examined. The migration of oil and gas (H_2S, CO, CO_2, H_2, He) leads to a change of the physical properties of the rocks above the deposit and the formation of halos of methane, propane, and other hydrocarbons in the surface sediments and the atmospheric boundary layer. Experiments were carried out under the CARS and SRS circuit. Minimal concentrations of 200 ppb of heavy hydrocarbon gas have been remotely measured in laboratory tests. We have developed airborn lidar system to detect pipeline leakage and explore oil and gas deposits. Tests were carried out on the gas pipeline Urengoy-Novopskov. Field tests (50 to 500 m helicopter flight altitudes) demonstrate that the lidar allows detection of methane with a sensitivity up to 6 ppm for methane and 3 ppm for hydrogen sulfide.

GeoChemical surveys of hydrocarbon deposits based on detection of the oil and gas migration as well as the other molecules such as C_yH_x, H_2S, CO, CO_2. The migration leads to a change of the physical properties of the rocks above the hydrocarbon (methane, propane) deposit and anomalous concentrations of hydrocarbon gases in an atmospheric boundary layer.

Laser sensing is a highly effective method for the deposit exploration. We present a Raman lidar with ultraspectral resolution for airborne oil&gas exploration and pipeline leakage detection. Tests were carried out on the gas pipeline Urengoy-Novopskov. The experiments were carried out to detect leaks on the working section of pipeline with an internal pressure of 60–70 bar. Test flights show the level of sensitivity about 6 ppm (methane) and 3 ppm (hydrogen sulfide) with the measurements at 50 to 500 m flight altitudes.

The probing is done by a compact pulsed diode pumped Nd:YLF laser (50 mJ, 6 ns, 100 Hz) with KTP ISHG (50% conversion efficiency) and BBO frequency shifting (261.7 nm, 6–10 mJ).

Ultraspectral resolution of the double polychromator (3600 mm^{-1}, $d\lambda/dl = 0.224$ nm/mm) reliably differentiates methane (283.31 and 284.42 nm), nitrogen (278.69 nm), and hydrogen sulfide (280.89 nm) what ensures reliable 80% HHG detection for the integration of seismic prospecting and laser remote sensing.

Unlike Raman spectroscopy, CARS employs multiple photons to address the molecular vibrations, and produces a signal in which the emitted waves are coherent with one another. As a result, CARS signal is much stronger than spontaneous Raman emission.

A chamber filled by a mixture of HHG gases and air served as a simulator of hydrocarbon halo. It was irradiated by femtosecond and nanosecond laser pulses. A pump beam (at the frequency referenced ωp) from Ti:Sapphire laser (800 nm, 30 fs, 0.2 mJ, 50 Hz) and a probe beam (at the frequency referenced ωpr) from Nd:YAG laser (1064 nm, 8 ns, 60 mJ, 50 Hz) were focused at the chamber. These beams interact with the sample mixture of gases and generate a coherent optical signal at the anti-Stokes frequency ($\omega pr + \omega p - \omega S$) (Fig. 1). The anti-Stokes signals ($\lambda = 656$ nm for CH4 and $\lambda = 658$ nm for C3H8) are resonantly enhanced when the frequency difference between the pump and Stokes beams (ωp-ωS) coincides with the frequency of Raman resonance due to the intrinsic vibrational contrast mechanism.

In order to anayse back scattering anti-Stocks spectral component, we use HR4000+ compact optical fiber spectrometer (Ocean Optics) with further numerical processing. Pressure of methane and propane chosen as an indicator of hydrocarbon deposits was ~ 0.01 Torr in 0.2 m-length chamber that corresponds to 10 m-thickness of the real halo with concentration at level of $5 \cdot E12$ cm^{-3}, i.e., 200 ppb, for each of these gases (Fig. 2). Since Ti:Sapphire laser has a wide spectrum, the coherent anti-Stock scattering of radiation occurs from corresponding Fourier-components of the pump ($\lambda = 800$ nm) and Stocks signals ($\lambda = 1064$ nm), removed on Stocks shift size of researched gases. Therefore, it was possible to observe an occurrence of the various new components around 650 nm for different heavy hydrocarbon gases (HHG), in the anti-Stock scattering spectrum.

Method CARS allows detection at the level of 3–10 molecules and determines hydrocarbons in the natural atmosphere under the presence of impurities.

Two-sided Inverted F Antenna with LTE, GSM, WLAN, WiMax Frequency Bands for Mobile Phones

Churng-Jou Tsai and Bing-Yan Sie
Department of Computer and Communication
Kun Shan University, Tainan, Taiwan

Abstract— This work presents an internal mobile phone antenna occupying a small board space of 520 mm^2 on the system circuit board and providing three wide operating bands of at least 746–796, 860–1000, 1760–1880, 2390–2499, 3480–3708 and 5120–5957, for the long term evolution (LTE)/wideband local area network (WLAN)/Worldwide Interoperability for Microwave Access (WiMax) operations. These 8 bands includes one LTE bands of LTE700, one bands of GSM900/1800, three bands of WLAN 2.4/5.2/5.8, and two WIMAX 3.5/5.5 GHz bands. The antenna is a modified PIFA with coupled-strip and shows a height of 13 mm and a width of 40 mm only, when mounted at the top edge of the display panel in mobile phone. The ground plane size is 87×40 mm^2.

The antenna architecture is shown in Figure 1. This is a two-sided inverted F antenna structure with a side ground point at left side. The more detail structure is shown in Figure 2. The simulated return losses is shown in Figure 3. These simulated return losses covers the 700 MHz LTE, 900/1800 MHz GSM, 2.4/5.2/5.8 GHz WLAN, 3.5/5.5 GHz WiMax band. The detail operations bands can be divided two parts: the low-frequency bandwidth operation in (746–796 MHz) (860–1000 MHz) (1760–1880 MHz), while operating at high frequency bandwidth (2390–2499 MHz) (3480–3708 MHz) (5120–5957 MHz), in line with the basic LTE, GSM, WLAN and WiMax operating bandwidth.

Analysis of the Imaging Realization of Frequency Modulated Continuous Wave Circular SAR

Gaowei Jia, **Wenge Chang**, **and Ruibin Tu**
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— Frequency modulated continuous wave (FMCW) synthetic aperture radar (SAR) is a compact, lightweight, and low-cost imaging system with high resolution. There has been increasing interest in FMCW SAR in the last years, which has led to the construction of several experimental systems. On the other hand, circular synthetic aperture radar (CSAR) has lately become of the hotspot in the field of SAR due to its characteristics like all-aspect observation, super-high two-dimensional (2-D) resolution, and potential three-dimensional imaging possibility. In order to combine the advantages of both FMCW radar and CSAR, it is suggested to change the acquisition geometry of FMCW SAR from a straight line to a circular trajectory. Thus we could get a novel imaging model FMCW CSAR.

As for the imaging processing of linear trajectory FMCW SAR, it is well known that the intra-pulse movement would introduce new range migration and affect the range cell migration correction (RCMC). Similarly, and it is found that the intra-pulse movement also leads to new range migration in the case of FMCW CSAR and further distorts the imaging results. Correspondingly, we have proposed a modified back projection algorithm (BPA) in a former paper, in which the new range migration has been taken into account. However, the modified BPA and its potential improvements encounter huge computation. To improve the imaging efficiency, the modified Fourier-based imaging procedures of FMCW CSAR is investigated in this paper.

In this paper, we focus on the two dimensional (2-D) imaging of X-band FMCW CSAR in the frequency domain and it is assumed that the targets are located in the flat ground-plane. The main contributions contain:

1. The exact signal spectrum of FMCW CSAR is presented firstly.

2. The influence of the intra-pulse movement on the Fourier-based imaging processing of FMCW CSAR is analyzed in detail and the corresponding correction method is proposed.

To verify the feasibility of the proposed correction method, numerical simulation test is carried out. Specifically, The FMCW CSAR system operates at 10 GHz, and the bandwidth of the transmitted linear frequency modulation (LFM) pulse is 600 MHz. During the simulation test, the modified BPA which is available for FMCW CSAR is used for comparison. The results of simulation test denote that the proposed correction method is feasible to remove the influence of the intra-pulse movement exactly in the frequency domain and figure out well-focused FMCW CSAR image eventually.

A New Sidelobe Reduction Method for Circular SAR

Gaowei Jia, **Wenge Chang**, **and Ruibin Tu**
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— Due to its advantages of all-aspect observation, super high-resolution, the potential three-dimensinal (3-D) imaging, circular synthetic aperture radar (CSAR) has become of particular interest to the SAR community. For isotropic targets, the spectrum of which is ring-shaped so that the corresponding point spread function (PSF) is related to Bassel function, not the sinc function. Correspondingly, the sidelobe level according to isotropic targets is higher than that of linear-trajectroy SAR, which drastically limits the quality of CSAR images. More importantly, the traditional window-function technique is not valid any more and yields even worse results for CSAR. Therefore it is essential to investigate new methods to reduce the sidelobe level for CSAR.

This paper focuses on the sidelobe reduction of two-dimensional (2D) CSAR image, according to isotropic targets. The fundamental motivation of the proposed sidelobe reduction method is to extract the sidelobe-image firstly and then to deduct it. During the sidelobe reduction strategy, the method of extracting the sidelobe image is essential. Specially, a method of dividing the CSAR spectrum is proposed, based on which the sub-images are obtained firstly and then the sidelobe image is produced afterwards. Subtracting the sidelobe image from the former CSAR image yields the sidelobe-reduced CSAR image.

Simulation Result: In order to have a better insight into the performance of the proposed method, a numerical simulation is carried out. The CSAR system operates at 10 GHz, and the bandwidth of the transmitted linear frequency modulation (LFM) pulse is 600 MHz. The radii of the circular trajectory and the observed area are 1000 m and 40 m, respectively. The height of airplane is assumed to be 500 m. Fig. 1(a) shows the pseudo-3D PSF of a marginal point target.

With the proposed sidelobe-image extraction-strategy, we obtains the sidelobe image, as shown in Fig. 1(b). The corresponding pseudo-3D view of the sidelobe image is shown in Fig. 1(c).

Substrating the sidelobe image (in Fig. 1(c)) from the former image (in Fig. 1(a)) yields the sidelobe-reduced CSAR image, as shown in Fig. 1(d). Figs. 1(e) and (f) denote the comparison of profiles of PSF in x and y direction, respectively. Directions x and y are arbitrary orthorhombic axes. In Figs. 1(e) and (f), the dotted and solid profiles denote the result without and with

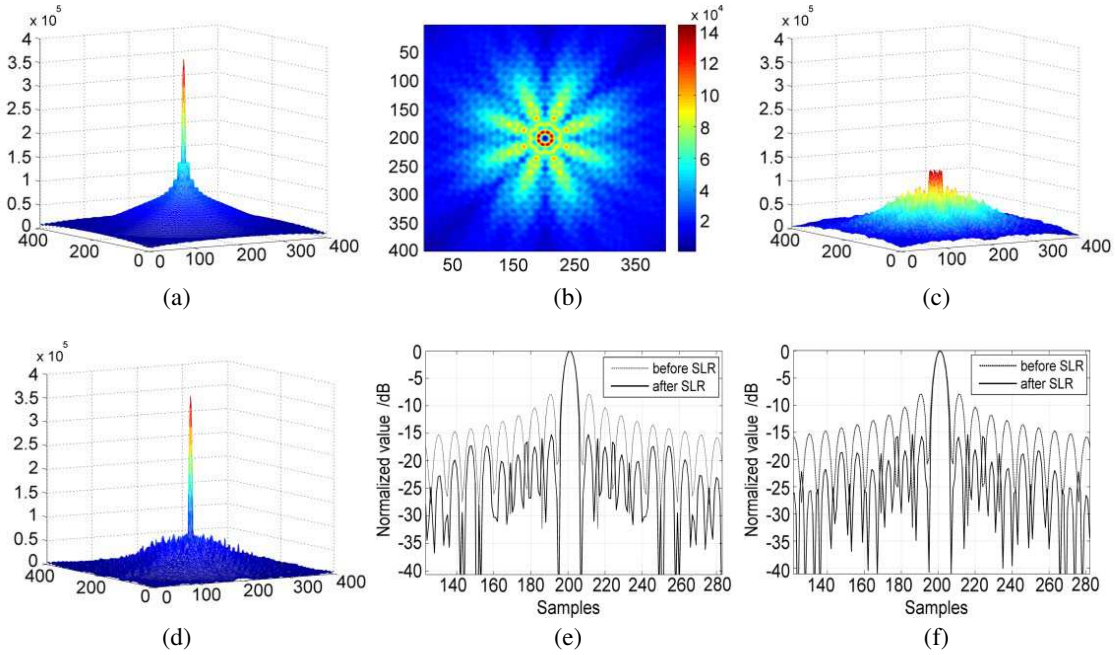

Figure 1: Result of sidelobe reduction.

sidelobe reduction (SLR), respectively. It is learnt that after the sidelobe reduction, the mainlobe of the PSF is preserved, but the peak-to-sidelobe ratio (PSLR) reduces from $-7.95\,\mathrm{dB}$ to $-16\,\mathrm{dB}$, and the 2D integrated sidelobe ratio (ISLR) reduces from $10.62\,\mathrm{dB}$ to $4.27\,\mathrm{dB}$.

Terabit WSDM Optical Access Network Using Multicore Fibers and Advanced Modulation Formats

Z. Feng[1], B. Li[1], R. Wang[1], R. Lin[1,2], M. Tang[1], Z. Xu[1], S. Fu[1], W. Tong[3], S. Liu[1], and P. P. Shum[4]

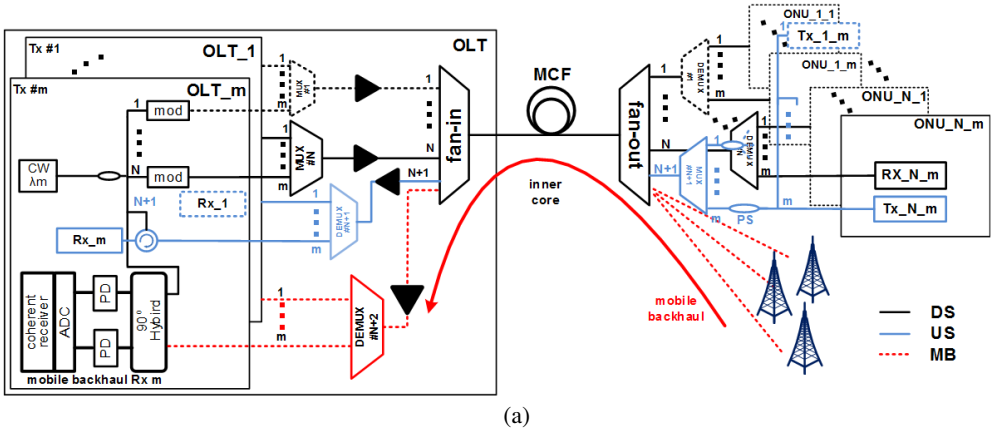
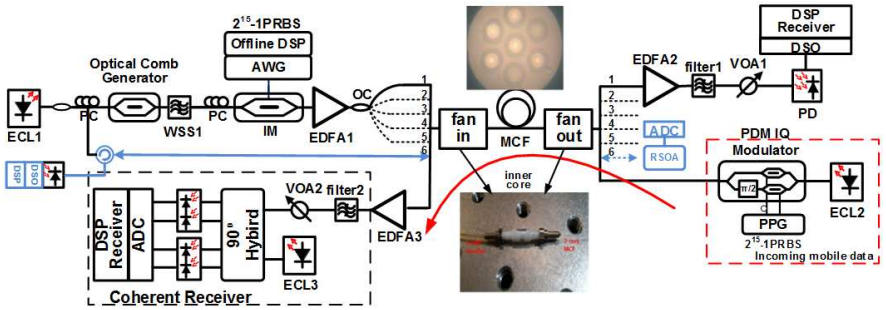
Abstract— Next generation optical access network are envisioned to evolve into a converged, high-speed and heterogeneous-service platform supporting large capacity transmission to enormous number of users covering a wider area. To satisfy these requirements, we proposed a hybrid wavelength-space division multiplexing (WSDM) optical access network architecture utilizing multicore fibers with advanced modulation formats, as shown in Fig. 1(a). As a proof of concept, we experimentally demonstrated a WSDM optical access network with duplex transmission using our developed and fabricated multicore (7-core) fibers and fan-in/fan-out device with 58.7 km distance. To increase the access data rate in the cost-sensitive access network, the IM/DD optical 16QAM-OFDM signal and RSOA based adaptive DMT signal have been adopted for downstream (DS) and upstream (US) transmission, respectively. As a universal platform for wired/wireless data access, our proposed architecture provides additional dimension for high speed mobile signal transmission and we hence demonstrated an upstream delivery of PDM-QPSK modulated signal using the inner core of MCF emulating a mobile backhaul (MB) service. Fig. 1(b) illustrates the experimental setup. For DS transmission, 20 wavelengths with 25 GHz channel spacing from an optical comb generator are employed and each wavelength is loaded with 10 Gb/s baseband



(a)



(b)

Figure 1: Proposed architecture of converged WSDM optical access network: (a) schematic, (b) experimental setup.

16QAM-OFDM signal generated off-line by Matlab, where the IFFT/FFT size is 128 and 63 effective subcarriers are used to convey data information. Boosted by EDFA, 20-wavelength DS signal are power splitted and simutaneously launched into five of the six outer cores of the MCF through the fan-in device, thus the aggregation downstream capacity reaches 1 Tb/s. About -11 dBm sensitivity has been achieved for 3.8×10^{-3} bit error ratio (BER) with 7% Forward Error Correction (FEC) limit for all wavelengths in every core. For US transmission, wavelengths seeded from DS using the 6th outer core are modulated with DMT signal adapted with the channel conditions and then reflected back to the OLT. ONUs served by the same DS wavelength can share a US wavelength within different time slots through TDMA. As an emulation of high speed MB transmission, IQ modulated PDM-QPSK signal with 50 Gb/s per wavelength is transmitted in the inner core of MCF and coherently detected in the OLT side. -19 dBm sensitivity has been achieved under the FEC limit and more than 18 dB power budget is guaranteed. Both DS and US optical signal exhibit acceptable performance with sufficient power budget.

Progress in Developing Fabrics Coated with Nano-particles as Radar Absorbing Materials

A. Teber[1], **H. Kavas**[2], **A. Baykal**[3], **B.Aktas**[4], **I. Unver**[4], **and R. Bansal**[1]

[4]Gebze Technical University, Turkey

Abstract— There exists a long-standing interest in the development of thin, lightweight, and flexible radar absorbing materials (RAM) for various civilian and military applications. One promising research direction [1, 2] has been the use of conducting polymeric textiles incorporating a coating of magnetic metal nano-particles either at the yarn-stage or after weaving the fabric. This paper reports on an experimental investigation that uses a knitted *Polyacrylonitrile* (PAN) fabric (thickness = 2 mm with a yarn diameter of 20 μm) as the host matrix for the composite RAM. The fabric is coated with nano-particles of Ni and Co via an electroless metal deposition method using Sodium borohydride ($NaBH_4$) as a reducing agent. The relative concentrations of Ni and Co as well as the coating time are varied with a view to tailoring the EM absorption characteristics of the resulting material for the intended application. The morphology of the clusters of the Ni-Co alloy incorporated into the fabric volume is established through a microstructure investigation. It is found that the metallic structures grow in a wide range of sizes, from nano- to micrometer, which are believed to contribute to *broadband* microwave absorption.The microwave absorption measurements are carried out in the X, K_u, and K Bands using a vector network analyzer in conjunction with a waveguide system incorporating samples of the coated fabric. Electromagnetic constitutive parameters for the coated sample are calculated from the measured *s*-parameters using the Nicolson-Ross-Weir technique In addition, the return loss (RL) of the samples for RAM applications is estimated from the measured complex permittivity and permeability values.As a potential application, the use of these materials in the design of microwave Fresnel Zone Plate (FZP) lenses is discussed.

Numerical Simulation on the Self-assembled Structures of Colloidal Particles through Magnetic Dipole-dipole Interactions

Chunwei Liu[1], **Zhi Sun**[2], **Shuigen Huang**[1], **Bart Blanpain**[1], **and Muxing Guo**[1]

[1]Department of Materials Engineering, KU Leuven, Leuven 3000, Belgium
[2]Department of Materials Science and Engineering, TU Delft, CD Delft 2628, The Netherlands

Abstract— Functional materials with desired crystal morphologies have demonstrated a vast range of applications because of their advanced properties, such as the ability to achieve thermal, optical and acoustic rectification. Novel fabrication techniques based on magnetic self-assembly, as an attractive method for positioning particles, are currently drawing extensive research interests. Due to the difficulties in manipulating micro- and nanoparticles, however, it remains a considerable challenge to perform accurate experiments in practice. In this study a two-dimension numerical model is developed to provide a fundamental understanding as well as visualization of the magnetic assembly process. In the simulation, dipole-dipole interaction among the particles and hydrodynamic drag between particles and matrix fluid are taken into consideration, and the former is believed to be the dominant force of forming various crystalline morphologies. Three factors, i.e., magnetic field intensity (H), global particle concentration (ϕ), and relative particle concentration (φ) are investigated for the colloidal particle systems on scales ranging from micrometer to millimeter. Additionally, both binary and ternary colloidal systems are evaluated and in particular, the systems composed of different sized particles are investigated systematically. Finally, the evolution of typical assembled structures is observed in-situ, offering a straightforward manner to understand the magnetic self-assembly. The simulation results agree well with the experimental results, which could validate the accuracy of the model. The effect of magnetic field intensity (H), global particle concentration (ϕ), and relative particle concentration (φ) on the assembled structures is revealed. Consequently, desired assembled structures can be expected through varying H, ϕ and φ. A two-dimension numerical model is used to investigate the magnetic self-assembly, enabling a low-cost method for artificial crystalline materials preparation.

Ultra Weak Photon Emission from Yeast Cells Can Be Modulated by Antioxidants

Abstract— The majority of living organisms exhibit a very low but measurable level of electromagnetic radiation in the visible range of the spectrum. This phenomenon is common to metabolically active cells and is referred as the ultra weak photon emission (UPE). Its intensity is usually less than 1000 photons $cm^{-2}s^{-1}$. Origin of UPE is biologically endogenous and is attributed to reactions of reactive oxygen species (ROS) with biomolecules which give rise to electron excited states. In other words, the energy comes solely from chemical reactions, therefore the UPE is also known as weak chemiluminescence. Reasons why organisms exhibit UPE have not been satisfactorily elucidated yet. It is assumed that it may play role in regulatory processes of cells; however it could be simply a byproduct of oxidative metabolism.

The goal of our research is to delineate the origin of UPE from a model organism; yeast cells *Saccharomyces cerevisiae*. UPE from the yeast cells arises spontaneously during the growth of the culture. UPE signal from organism is highly dependent on external factors such as temperature, pH, biotic agents, molecular oxygen consumption or composition of the environment.

Damaging effects of ROS formed during the metabolism can be partly suppressed either by natural antioxidant defense system or by scavengers artificially supplied into the environment or directly into the organism. In this work, the experiments are focused on the description of effects caused by antioxidants. Several kinds of antioxidants were used and we studied the temporal development and changes in intensities of ultra weak photon emission from the culture. Study of antioxidants scavenging effects on UPE signal is crucial in order to understand UPE generating processes.

RF Dynamics of Mode-locked Intracavity Frequency Doubled Laser

A. V. Kovalev and V. M. Polyakov
ITMO University, Birzhevaya Liniya, 14, St Petersburg 199034, Russia

Abstract— Mode-locked lasers are of a great interest in fundamental and applied sciences. Their capability to generate ultrashort pulse trains and equidistant optical spectra has already revolutionized such fields as spectroscopy, data networks, optical clocking and biomedicine.

We report on radiofrequency (RF) dynamics of Nd:YVO_4 laser with intracavity frequency doubling in a KTP crystal. Experimentally, the laser cavity was 109 mm long and consisted of $1 * 3 * 3\,\mathrm{mm}^3$ 1% at. doped a-cut Nd:YVO_4 active element and $5 * 3 * 3\,\mathrm{mm}^3$ KTP crystal. An output coupler was mounted on fast and slow PZTs for cavity length modulation and the output coupler position attenuation.

A narrow longitudinal modes beat signal (less than 300 Hz FWHM) which is an evidence of mode-locking regime was observed for both fundamental and second harmonic radiation. For a certain power and temperature range (the KTP temperature $28 \pm 0.2^{\circ}$C, 420 mW pump power) and a proper placing of the output coupler against the KTP crystal, a regime of the second harmonic amplitude weak modulation was obtained. The fundamental radiation remained not modulated. The modulation manifests itself in the RF spectrum as two sidebands of the central beat note frequency and a low-frequency (order of 50–100 MHz) difference signal. We implemented the cavity length modulation via the PZT with the frequency of several kilohertz which led to occurrence of weak sidebands for the central beat note of the second and fundamental harmonics and a Lorentzian shaped spectrum of equidistant frequencies for the low-frequency signal and the sidebands of the second harmonics beat note. The distance between the spectral components was equal to the modulation frequency.

We propose that the appearance of the second harmonic modulation regime results from bounded phase variations of the laser field. The transition between states with and without the modulation occurred continuously. The stability of the phase bounded mode-locked operation was limited by the cavity elements alignment and stable operation in the regime lasted longer than 300 s. The weak modulation frequency dependence on the central beat note frequency is well fitted by a parabola confirming that the output is that of a stable mode-locked laser with bounded phase.

This newly obtained regime of the phase bounded mode-locked operation can be utilized for synthesis of low-noise microwave frequencies, and can be used for iodine-stabilized schemes of laser frequency standards without additional modulators.

Self-similar Dynamics in Free Space Optics

Nan Gao and Changqing Xie
Key Laboratory of Nano-Fabrication and Novel Devices Integrated Technology
Institute of Microelectronics of Chinese Academy of Sciences, Beijing 100029, China

Abstract— Self-similar dynamics is common in nonlinearity optics. It is well-known that the light spot would collapse self-similarly while keeping the Townes profile, if self-focusing dominates over diffraction [1]. Self-similar optical pulses can also happen with the coexistence of dispersion, gain and nonlinearity, which can be useful in fiber amplifiers and lasers [2]. However, it is difficult to directly extrapolate these solutions to the linear cases by making the nonlinear coefficient to approach toward zero. For example, using variable scaling, the $(2+1)$D nonlinear Schrödinger equation $2ik\partial_z U + (\partial_x^2 + \partial_y^2)U + q|U|^2U = 0$ has solutions in the from of $U_q(x,y,z) = U_{q=1}(\alpha x, \alpha y, \alpha^2 z)/\beta$, where $\alpha = \beta q^{1/2}$. If q approaches zero, which is the case of free space, the solution must tend to a constant value, which is a trivial plane wave.

Here we study self-similar dynamics in linear systems systematically, by finding the exact solution of paraxial wave equation in scaled coordinates. The allowed solutions include:

1) Paraxial Bessel beams [3]: $J_m(\sqrt{d}r)\exp[i(-dz/2k + m\theta + kz)]$,

2) Linear scaling beams: $J_m(\sqrt{d}r/s_0 z)\exp[i(kr^2/2z + d/2ks_0^2 z + m\theta + kz)]/z$,

3) Gaussian-type beams: $M_{dz_R/4ks_0^2,\pm m/2}[kr^2 z_R/(z_R^2+z^2)]\exp\{i[\frac{kr^2 z}{2(z_R^2+z^2)} - \frac{dz_R \arctan(z/z_R)}{2ks_0^2} + m\theta + kz]\}/r$,

4) Elliptic-hyperbolic scaling beams: $\psi_{EHS}(r,\theta,z) = J_{\pm m/2}[kr^2/2z_R(1-z^2/z_R^2)]\cdot\exp\{i[kr^2/2z(1-z_R^2/z^2) + m\theta + kz]\}/\sqrt{1-z^2/z_R^2}$,

and 5) Parabolic scaling beams [4]: $J_{\pm m/2}(kr^2/4z)\exp[i(kr^2/4z + m\theta + kz)]/\sqrt{z}$.

We will show their self-similar propagation dynamics in free space, and Gaussian apodization will also be considered for practical realization. The linearity of free space eliminates the annoying stability problems, and we can construct these beams easily utilizing linear superposition. As shown in Fig. 1, we use diffractive optical elements (Figs. 1(a) and (b)) to experimentally realize the non-trivial self-similar beams (Figs. 1(c)∼(e)).

Size Reduction of Magnetic Resonance Coils for Wide Wireless Power Transfer Applications

In-Kui Cho, **Jung-Ick Moon**, **Seong-Min Kim**, **Jae-Hun Yun**, **and Woo-Jin Byun**
Radio Technology Research Department
Electronics and Telecommunications Research Institute(ETRI), Korea

Abstract— Many researchers have developed the wireless charging system using the magnetic coupling or magnetic resonance [1]. In this paper, we extend previous studies of coupled magnetic resonance into reducing size of the coils for wide wireless power transfer applications.

As shown in Fig. 1, the diameter of TRx magnetic resonance coils is not same. The diameter of Rx coil is even smaller than that of Tx coil by using the impedance matching technology (C-C matching). The resonance frequency is 1.78 MHz. Diameters of TRx' spiral coil are 30 cm and 7 cm. Fig 1(c) shows the measurement result of fabricated TRx coils. The transfer efficiency η is shown with transfer distance and radius distance(misalignment). The proposed coil structure is expected to be applied for energy transfer technology of various home electrical devices as well as portable devices.

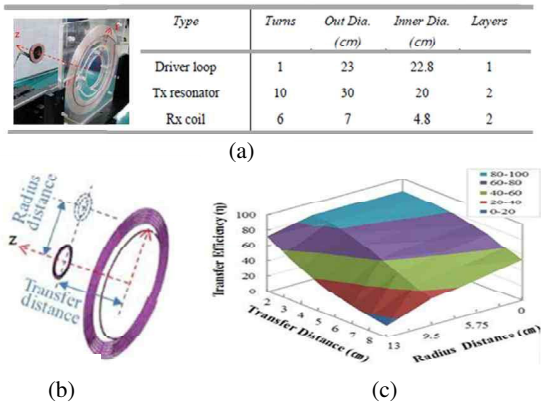

Figure 1: TRx coil's transfer efficiency η with normal transfer distance and radius distance (misalignment).

Near-field Analysis in Wireless Power Transfer Using Magnetic Dipole

Jung-Ick Moon, **In-Kui Cho**, **Seong-Min Kim**, **Jae-Hun Yun**, **and Woo-Jin Byun**
Radio Technology Research Department
Electronics and Telecommunications Research Institute (ETRI), Korea

Abstract— This paper presents the intuitive and simplified analysis of near-magnetic field using magnetic dipole and image theory in wireless power transfer. In modeling of magnetic resonator, it is practice to ignore the volume of the resonator in comparison with the wavelength and consider it into the magnetic dipole on the ground plane. And the analysis presented here leads to reasonable modeling and analyzed results compare well with full-wave simulation. The utility of this approach is useful for the case when the human safety with respect to electromagnetic fields (EMFs) and interference problems should be considered in the design of wireless power transfer system.

Design of 60 W Charging Circuit for Wireless Charging System Using Magnetic Resonance Method

Seong-Min Kim, Jung-Ick Moon, In-Kui Cho, Jae-Hun Yun, and Woo-Jin Byun
Radio Technology Research Department
Electronics and Telecommunications Research Institute (ETRI), Korea

Abstract— In this paper, 60 W power charging circuit for the wireless charging system using the magnetic resonance method is presented. The proposed charging circuit is composed of a constant current signal converter and a controller. The constant current signal converter is designed to convert the dc signal which its voltage range is variable from the rectifier in the wireless charging system. The output current value can be changed from 0.1 A to 1.7 A with 0.1 A step according to the control of the controller. This changing is used for the protection of the human body from the EM field around the system. The controller is designed to control the charging circuit in accordance with the communication results with the transmitter and the final load. Two communication schemes, a 424 MHz FSK and a RS-232C, are adopted in the controller to communicate with the transmitter and the final load. The wireless charging system is implemented to charge a 24 V battery. The system consists of a 100 W power transmitter, two magnetic resonators having 30 cm diameter, a 100 W rectifier, a 24 V battery, a personal computer, and the proposed 60 W charging circuit. The personal computer is used for the user interface of the system. The transmission frequency is 1.8 MHz band. By the test results, the transmission efficiency is about 50% at 30 cm distance between two resonators.

Photonic Integrated Circuits for Electro-optic Microwave Frequency Multiplication and Frequency Translation: Spurious Harmonics Suppression by Design

Ramón Maldonado-Basilio and Trevor J. Hall
Photonic Technology Laboratory, University of Ottawa
800 King Edward Avenue, K1N 6N5, ON, Canada

Abstract— In the past two decades or so there has been a plethora of publications in the field of microwave photonics that have described essentially the same generalized Mach-Zehnder interferometer (GMZI) circuit architecture: a $1 \times N$ splitter directly interconnected to a $N \times 1$ combiner via an array of N electro-optic $LiNbO_3$-based phase modulators; each GMZI adapted to particular design goals. The applications have generally been to single-side-band modulation or electro-optic microwave signal frequency multiplication [1–3]. The difference between the circuits proposed have largely concerned variations of the static optical and electrical phase shifts required or the implementation of an equivalent circuit using standard Mach-Zehnder modulators (MZM) rather than individual phase-modulators as the basic building brick. After our latest investigations [4, 5], in this paper a methodology is presented that specifies the architecture required to meet specified design objectives such as the suppression of unwanted products (Fig. 1). Moreover, it is shown how to use the intrinsic phase relations between the ports of splitters and combiners and specifically multi-mode interference couplers to implement the static optical phase shifts required by these circuits, thereby avoiding the need to apply static DC bias to the electro-optic modulators and the associated drift issues that otherwise require complex stabilization circuitry. Circuits capable of single-side-band suppressed-carrier modulation and frequency octo-tupling show a simulation performance equal to or better than results reported in the literature

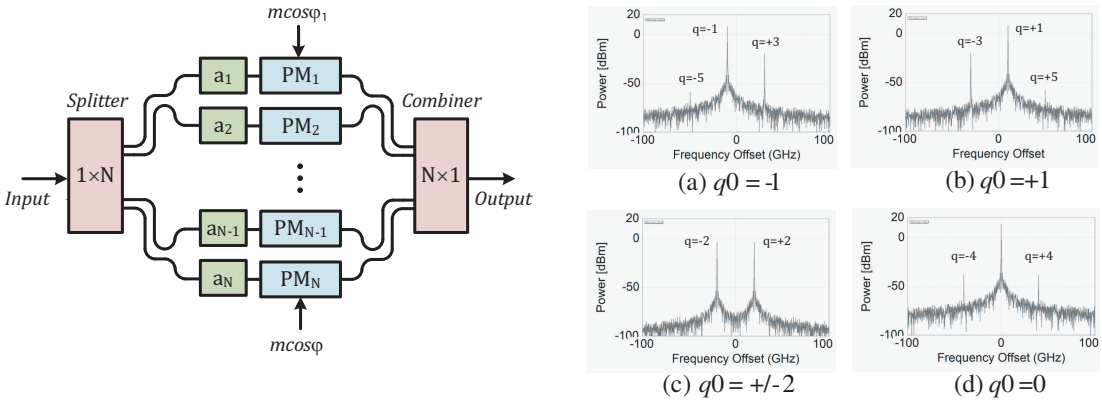

Figure 1: Schematic diagram of a GMZI and the output for various design conditions in a 4-modulator array.

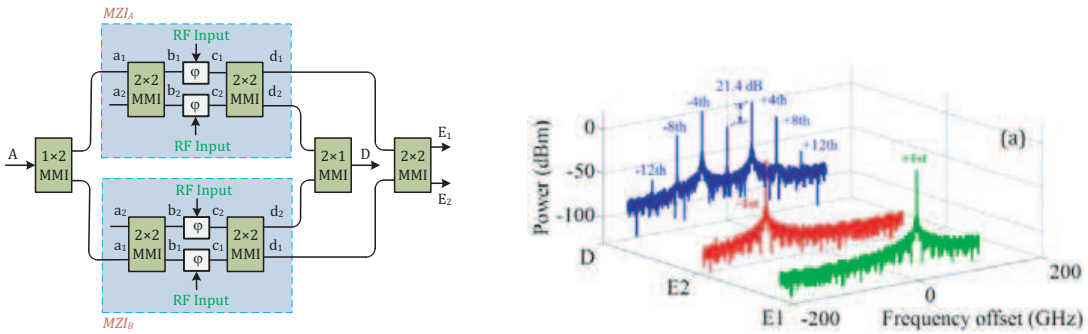

Figure 2: Schematic of a dual-function photonic circuit and output for frequency octo-tupling and single-side-band modulator.

(Fig. 2). In particular, a new cascade architecture implementation is reported that offers 50% lower optical insertion loss and 50% reduced RF power drive requirement compared to previously known circuits. While $LiNbO_3$ technology offers a mature solution to the small scale integration of MZM structures, this work anticipates photonic integrated circuits based on Si and/or InP material integration platforms emerging as the preferred choice. In this context the continuous advances made in improved speed, linearity, footprint, and energy consumption of electro-optic phase modulator devices in both material platforms augurs well for the future.

Design of a Printed Antenna for Mobile Terminals

Hui Liu[1, 2], **Youhuan Guo**[2], **Ping Yu**[2], **and Xueman Wu**[2]

[1]Centre for Optical and Electromagnetic Research, Academy of Advanced Optoelectronics
South China Normal University, Guangzhou, China
[2]Computer Science and Engineering Department, Guangdong Peizheng College, Guangzhou, China

Abstract— A printed mobile terminals antenna with multi operating bands for the 2G/3G/4G LTE (long term evolution) is presented. The antenna has three operating bands covering low band of 900 MHz, middle band 1900 MHz and high band 2600 MHz for GSM 900 MHz, UMTS 1900 MHz and LTE 2600 MHz. The antenna occupies a ground clearance of 54 mm × 19 mm and has a thin of 1 mm. The antenna comprises radiating branches to generate multi operating bands. Dimensions and working principle of the antenna are discussed.

A Wideband Circularly Polarized Antenna with Wilkinson Feed Network for Worldwide UHF Band RFID Reader

Bingjie Wang, **Zhibin He**, **Hui Liu**, **Yoichi Okuno**, **and Sailing He**
Centre for Optical and Electromagnetic Research, Academy of Advanced Optoelectronics
South China Normal University, Guangzhou 510006, China

Abstract— A radio frequency identification (RFID) reader antenna with circular polarization (CP) radiation is proposed to operate at worldwide UHF band which covers 840–960 MHz. The size of the antenna is $0.555\lambda_0 \times 0.553\lambda_0 \times 0.099\lambda_0$. A micro-strip patch with truncated corners as the main radiation patch is placed between the wilkinson feed network layer and the parasitic patch layer. The ground plate is placed on the top of the feed network layer. The feed network is connected with the main radiation patch via two metal cylindrical probes which produce two orthogonal signals of equal amplitude and 90 degree phase difference. The proposed antenna has wideband circularly-polarization characteristics. The truncated corners on the main radiation patch can increase 3 dB axial ratio (AR) bandwidth while improving the best axial ratio. And the parasitic patch can adjust the radiation direction of the antenna while increasing its gain. The simulation results show that the proposed circularly polarized UHF reader antenna has an input impedance matching bandwidth ($S_{11} \leq -10$ dB) of 456 MHz (675–1131 MHz), the band of reflection coefficient $S_{11} \leq -20$ dB covering 842–955 MHz, 3-dB axial ratio bandwidth of 296 MHz (741–1037 MHz), minimum axis ratio reaching 0.33 dB, and the highest gain reaching 3.53 dBi in the operating frequency band. Both the impedance bandwidth and the axial ratio band cover the entire UHF band of RFID systems.

A Small Printed Antenna for Bluetooth Wireless Communication

Abstract— A small printed inverted-F antenna, operating at 2.44 GHz, for Bluetooth system is designed in this paper. The RF system diagram and PCB layout are drawn by Cadence Allegro. The small printed antenna, integrated in the PCB, is modeled by HFSS and both the simulation and experimental results verify of its suitability for the Bluetooth wireless communication.

Measurement of the Dielectric Properties of Micaceous Minerals Using Scattering Parameters

I. F. Dos Anjos[1] and S. E. Barbin[2]

[1]UFPB-Federal University of Paraiba, João Pessoa, Brazil
[2]USP-University of São Paulo, São Paulo, Brazil

Abstract— The determination of the dielectric properties of materials is very important in the development of microwave heating systems. In this case, the dielectric properties of the materials to be processed are the key point in order to achieve a good efficiency of the system. In the present study it is presented the determination of the complex permittivity of vermiculite that is a hydrated phyllosilicate. In a previous work the dielectric constant of vermiculite has been determined using a TDR based probe. In this study dielectric constant has been determined through the measurement of the volumetric water content and the refractive index. Although the method has demonstrated a good accuracy, it was not possible to determine the complex permittivity of the mineral due to the characteristics of the equipment used. So, in order to determine the complex permittivity using an accurate and non-destructive method, the scattering parameters has been chosen. The method is based on the usage of a microstrip line and through the measurement of the S-parameters by a VNA the data has been processed in MATLAB® code. The results were very close to the ones obtained with the TDR probe, but now with the determination of the complex permittivity and loss tangent. The dataobtained with the present studyshow that the determination of the dielectric properties of materials such as vermiculite using S-parameters is a good accurate and non-destructive method.

Abstract— As optical metasurfaces become useful for practical applications, the possibility of dynamically controlling their optical properties becomes increasingly important. For plasmonic metasurfaces, considerable efforts have concentrated on tuning and switching their optical properties using liquid crystals (LCs) [1–3] utilizing either the strong temperature dependence of the LC optical anisotropy or their realignment in an external electric field. However, plasmonic metasurfaces suffer from strong dissipative losses of metals at optical frequencies. A solution to this problem is provided by all-dielectric metasurfaces consisting of two-dimensional arrangements of high-permittivity dielectric nanoparticles with tailored optical properties, which allow for controlling a wavefront at the nanoscale with near-unity efficiency [4]. However, to date dynamic control of all-dielectric metasurfaces remains an open challenge and experimental realizations are still missing.

In our work we use a silicon nanodisk metasurface featuring two pronounced resonances in the spectral range of interest — an electric and a magnetic dipole resonance. The metasurface is integrated into a 170 µm-thick LC-cell. The samples are fabricated via electron-beam lithography and reactive-ion etching on silicon-on-insulator wafers. We use the 'Licristal E7' LC from Merck that features a strong optical anisotropy along the axis of the LC molecules in its nematic phase. In order to demonstrate dynamic resonance tuning originating from the temperature-dependent refractive-index change of the LC and symmetry switching of the optical response, we measure the sample's transmittance when increasing the LC temperature from $T = 20°\mathrm{C}$ (nematic phase) above its phase transition point at $T \geq 58°\mathrm{C}$ (isotropic phase). The maximum spectral tuning range realized in our experiment is approximately 40 nm with a maximum relative transmittance change of up to a factor of 5. Importantly, for temperatures above $T = 58°\mathrm{C}$ the optical anisotropy of the metasurface is removed and the high symmetry, i.e., the isotropy of the sample's optical response is restored. Our experimental observations are in excellent agreement with numerical simulations. We believe that this first demonstration of tuning of dielectric metasurfaces will open the way for a new generation of efficient and tunable ultra-thin devices based on optical metasurfaces. Specifically, we will discuss three application examples of dielectric metasurfaces from our recent work, namely wavefront manipulation, shaping of photoluminescence spectra of quantum dots, and nonlinear frequency generation.

Tunable Multilayer Graphene Metamaterials for Terahertz/Infrared Waveguide Modulators

Irina Khromova[1], **Andrei Andryieuski**[2], **and Andrei V. Lavrinenko**[2]

[1]University Colledge London, UK
[2]Technical University of Denmark, Oersteds pl. 343, KongensLyngby, DK-2800, Denmark

Abstract— Active development of terahertz (THz)/infrared (IR) science and technology has created a growing demand for new electronic and quasi-optical devices. In particular, the promising opportunities for broadband high-speed terahertz communication require new techniques for real-time manipulation of radiation. Various approaches have been proposed for THz/IR amplitude, phase, spatial and temporal profile modulation, including the employment of metamaterials [1] and, recently, one-atom-thick graphene [2].

Most of the proposed modulators, including graphene-based ones, are developed for free-space propagation configurations. However, high-speed THz/IRcommunication channels will unlikely be based on such architectures — atmospheric absorption peaks and small wavelengths (from submillimeter to tens of micrometers) imply strong free-space attenuation. It is therefore preferential to apply waveguide-based modulation platform similar to those used in telecom photonics. Due to specific properties constrains it is natural to consider metamaterial (structured) approach to satisfy simultaneous demands for low losses and high tunability in the waveguide configuration.

We study and classify the electromagnetic regimes of multilayer graphene-dielectric artificial metamaterials. The interplay between interband and intraband transitions in graphene allows converting the structure into a transparent and/or electromagnetically dense artificial medium. The gate voltage can be used to electrically control the concentration of carriers in the graphene sheets and, thus, efficiently change the dispersion of the whole structure. Placed inside a hollow waveguide, a multilayer graphene/dielectric metamaterial provides high-speed modulation and tunable bandpass filtering. The absence of scattered radiation enables dense integration of such THz waveguides and modulators without influencing their neighboring elements.

We exemplify the employment of graphene-dielectric metamaterial for waveguide-integrated modulators with three examples of tunable devices. The first one is a modulator with excellent ON-state transmission and very high modulation depth: $> 38\,\mathrm{dB}$ with only $70\,\mathrm{meV}$ graphene electrochemical potential change. The second one is a modulator with extreme sensitivity towards graphene Fermi energy. The third one is a tunable waveguide-based passband filter. The narrow-band cut-off conditions around the ON-state allow the latter to shift its central frequency by $1:25\%$ perevery meV graphene Fermi energy change.

We believe that graphene-dielectric multilayer metamaterials will constitute the functional platform for THz-IR waveguide-integrated devices.

Stimulated Brillouin Scattering: Limitations and Possibilities in Integrated Optical Waveguides

C. Wolff[1,2], **M. J. Steel**[1,3], **B. J. Eggleton**[3], **and C. G. Poulton**[1,2]

[1]Centre for Ultrahigh Bandwidth Devices for Optical Systems (CUDOS), Australia

[4]School of Physics, University of Sydney, Australia

Abstract— We investigate Stimulated Brillouin Scattering (SBS) in the context of integrated optics. We examine the necessary conditions on material properties, waveguide symmetry, and waveguide dimensions that are required to obtain technologically useful SBS gain, as well as potential limitations on the amount of gain achievable. We discuss the technological possibilities for the harnessing of SBS for optomechanical applications.

Introduction: Stimulated Brillouin Scattering (SBS) is a coherent interaction between the electromagnetic and acoustic waves that occurs in optical waveguides [1]. Although traditionally associated with optical fibres, there has been a recent surge of interest in applying SBS in the context of integrated optics; thus far a broad range of capabilities have been demonstrated, from on-chip slow and fast light to high-frequency pulse generation [2]. These on-chip SBS experiments open the door to the exploitation of SBS in fully integrated photonic environments [2–4].

SBS in Integrated Waveguides: The basic physical processes of SBS can be derived from thermodynamics: this gives a connection between scattering processes (including the photoelastic effect and scattering from boundaries) and force-like processes, which include electrostriction and radiation pressure. These processes lead to necessary conditions on material properties for acoustic and optical guidance, symmetry, as well as dielectric contrast that must be met in order to achieve sufficient gain. We outline the possibilities for achieving SBS in various material platforms at different wavelengths, from communications frequencies to the mid-IR (see Fig. 1). We also explore the effects of both optical and acoustic loss, and see how fabrication imperfections such as waveguide roughness can lead to a reduction in gain in the same regimes that the effects of radiation pressure cause SBS enhancement. Finally, we examine the effect of finite lengths on achieving desired levels of gain in realistic SBS structures.

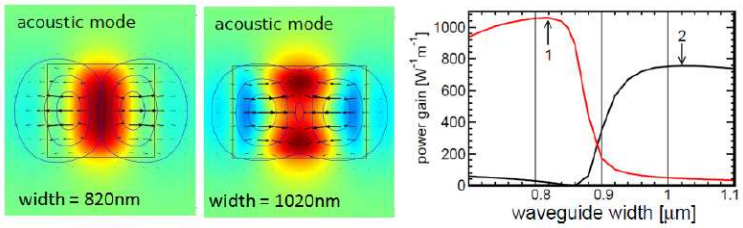

Figure 1: SBS acoustic mode and gain computations for a mid-IR waveguide [5].

Abstract— We have studied ultrafast effects in magnetoplasmonics by observing nontrivial evolution of transversemagneto-optical Kerr effect within 45-fs pulses reflected from an iron-based magnetoplasmonic crystal. The effect takes place for resonant excitation of surface plasmon-polaritons (SPPs), has opposite signs of time derivative for different slopes of the resonance, and is addressed to magnetization-dependent dispersion relation of SPPs.

One of the most prominent opportunities of using SPP nanostructures is to shape femtosecond laser pulses. The mean lifetime of SPPs in nanostructures varies from several femtoseconds to several hundreds of femtoseconds. A femtosecond laser pulse interacting with such a short-living excitation gets coherently modified as indicated in many preceding works. Recently, temporal shaping of femtosecond laser pulses by plasmonic nanostructures was observed both for the intensity and polarization state. it was shown that external quasistatic magnetic field can be used to control dispersion of SPP in magnetic media [1]; despite immense number of works on magnetoplasmonics emerged during the last years, magnetoplasmonic effects have been considered static so far. In this work, we experimentally demonstrate manifestations of time-dependent transverse magneto-optical Kerr effect (TMOKE) within ultrashort femtosecond laser pulses reflected from a one-dimensional iron-based magnetoplasmonic crystal. The sample of one-dimensional magnetoplasmonic crystal based on a commercially available digital versatile disk polycarbonate template having periodic corrugation with the depth of approximately 50 nm and the period of 750 nm. The dielectric template was covered by a 100 nm layer of polycrystalline iron deposited by magnetron sputtering and protected by a 20 nm-thick silica layer from the top. To obtain information about time-resolved TMOKE, the correlation function measurement setup was used. A train of 45-fs laser pulses from a Coherent Micra Ti:sapphire oscillator was precompressed at a chirped-mirror assembly to account for dispersive optics in the setup. The pulses were split into two beams, where one was the signal beam that contained the sample and the other was a gate beam with a 3-fs step delay line. Two electrically serial electromagnets placed around the sample were used to apply a quasistatic magnetic field in the TMOKE configuration, i.e., in the plane of the sample perpendicular to the plane of incidence. The magnets were driven by an ac source at a frequency of 117 Hz and provided approximately 30 mT of magnetic flux density,which was sufficient to saturate the magnetization of the iron in the sample. Manifestations of time-dependent transverse magneto-optical Kerr effect are experimentally demonstrated in fs-laser pulses reflected from a iron-based magnetoplasmonic crystal. Kerr effect evolution is shown to have either positive or negative time derivative depending on the position of the incident pulse carrier wavelength with respect to the SPP resonance. Proper grounds are given for this effect within the Lorentzian spectral line shape approach. Being a subwavelength-thickness tailorable nanostructure, the iron-based plasmonic crystal under study is a promising tool for manipulating femtosecond laser pulses with the external magnetic field that is to find applications in the novel active plasmon-based telecom devices [2, 3].

Three-wave Frequency Mixing in Stacks of Binary Nonlinear Dielectric and Semiconductor Layers

A. Schuchinsky
Queen's University Belfast, ECIT, Queen's Road, Queen's Island, Belfast, BT3 9DT, UK

Abstract— Nonlinear metamaterials have been a subject of increasing interest over the last few years. Owing to their capability of independent control of both the nonlinear properties and the linear characteristics, such as dispersion and phasing, they are attractive for a variety of diverse applications. Majority of the studies performed to date have been concerned with the metamaterials intended to improve the efficiency of harmonic generation. Combinatorial frequency generation (CFG) has been another direction where the purposely tailored metamaterials can be particularly instrumental for shaping and localising fields and controlling the phase coherence in distributed wave interactions rendering the three- and four-wave processes of mixing two or more pump tones. Uncovering the fundamental mechanisms of CFG in metamaterials proved to be of the special significance for the opposite aim — highly linear response of the medium and mitigation of spurious intermodulation effects.

Majority of metamaterials and metasurfaces are nowadays manufactured by layer-by-layer deposition or growth. To identify the main mechanisms of CFG in such kind of structures, it is instructive to examine first the nonlinear wave interactions in the canonical planar arrangements with the basic constitutive elements comprised of stacked binary dielectric and/or semiconductor layers. Both periodic and quasi-periodic (Fibonacci and Thue-Morse) structures have been analysed in this work to assess the qualitative effects of the lattice disorder on CFG in the finite stacks illuminated by a pair of plane waves of frequencies ω_1 and ω_2, incident at different angles. Stacks of semiconductor layers have been modelled in the self-consistent problem formulation taking into account the nonlinear dynamics of mobile carriers. A unified methodological framework based upon the modified transfer matrix method has been developed and applied to the CFG analysis in the finite stacks of binary layers. It has been demonstrated that the quasi-periodic stacks of Fibonacci and Thue-Morse types can be treated as the perturbed periodic stacks with the defects located in the positions determined by the respective quasi-periodic sequences. The results of numerical simulations have provided important qualitative insight in the mechanisms responsible for the performance of the stratified metamaterial structures and a means for controlling frequency mixing and CFG.

The main features of CFG in periodic and quasi-periodic stacks will be discussed and illustrated by examples of the simulation results for combinatorial frequencies $\omega_3 = \omega_1 + \omega_2$ generated in the three-wave mixing process. The effects of the stack linear reflectance, and the constituent layer anisotropy and losses on the CFG efficiency will be addressed in the talk.

Characterization of Chiral Nanostructured Plasmonic Surfaces with Second Harmonic Generation

Ventsislav K. Valev
MultiPhoton NanoPhotonics, Department of Physics, University of Bath, United Kingdom

Abstract— Because of its high surface and interface sensitivity, the nonlinear optical technique of second harmonic generation (SHG) appears as a designated method for investigating nanostructured metal surfaces. Indeed, the latter present a high surface-to-volume ratio, but, even more importantly, they can exhibit strong near-field enhancements, or "hotspots". Hotspots often appear as a result of geometric features at the nanoscale or of surface plasmon resonances, which are collective electron oscillations at the surface that, on the nanoscale, can readily be excited by light. In addition, SHG is a symmetry-sensitive technique and, due to the recent development of nanofabrication techniques, it has become possible to endow nanostructured metal surfaces with virtually any possible symmetry. As a consequence, SHG based techniques have gained popularity at both the microscopic and the macroscopic level [1]. One particular symmetry related property that has benefited a lot from the developments in nanofabrication is chirality.

Because of its high surface and interface sensitivity, the nonlinear optical technique of second harmonic generation (SHG) appears as a designated method for investigating nanostructured metal surfaces. Indeed, the latter present a high surface-to-volume ratio, but, even more importantly, they can exhibit strong near-field enhancements, or "hotspots". Hotspots often appear as a result of geometric features at the nanoscale or of surface plasmon resonances, which are collective electron oscillations at the surface that, on the nanoscale, can readily be excited by light. In addition, SHG is a symmetry-sensitive technique and, due to the recent development of nanofabrication techniques, it has become possible to endow nanostructured metal surfaces with virtually any possible symmetry. As a consequence, SHG based techniques have gained popularity at both the microscopic and the macroscopic level [1]. One particular symmetry related property that has benefited a lot from the developments in nanofabrication is chirality.

Chirality, the handedness of nature, constitutes a fundamental concept throughout the universe. Entire galaxies can be chiral, just as well as the smallest amino acids. Chiral plasmonic nanostructures are emerging as a very promising branch of nanophotonics, with numerous potential applications [2]. Recently, so called "superchiral" electromagnetic configurations have been demonstrated, whereby the pitch of the electric field of light is shorter than that of circularly polarized light. These configurations have lead to enhanced chiroptical interactions with matter. In addition, it has also been reported that negative refractive index can be achieved in chiral metamaterials. Furthermore, due to the favorable power-law scaling of near-field enhancements, new nonlinear optical properties, for instance in SHG, are emerging in chiral nanomaterials as well.

Chiroptical (chiral-optical) effects in SHG are usually three orders of magnitude larger than their linear optical counterparts. Therefore, upon using superchiral excitation, nonlinear nanomaterials are anticipated to achieve record-high chiroptical values compared to those of natural materials and consequently to serve as highly sensitive probes for exploring chiral molecular chemistry. At the moment though, little has been done towards fulfilling these high expectations. Basic understanding of the nonlinear chiroptical properties of nanosurfaces is also lacking; for instance, it is not clear how the chiroptical effects of nanosurfaces would be affected upon expanding to more pronounced 3D geometries.

Among other developments, a surprising direct relationship between superchiral light and SHG has been reported [3]. By varying the dimensions of nanostructures, superchiral light can be tuned to optimize material dimensions for enhanced nonlinear chiroptical response. The use of superchiral elements as building blocks opens very interesting possibilities in both 2D and 3D nanomaterials.

Ultrafast Kerr Nonlinearities in Multimodal Plasmonic Metamaterials: Elliptic, Hyperbolic and Epsilon-near-zero Regimes

S. Peruch, **A. Neira**, **G. A. Wurtz**, **and A. V. Zayats**
Department of Physics, King's College London, Strand, London WC2R 2LS, United Kingdom

Abstract— The ability to actively manipulate optical signals at the nanoscale represents an essential tool in modern and future nanophotonics. This can be achieved all-optically exploiting optical nonlinearities in metals, which are some of the fastest available. Plasmonic metamaterials represent an ideal platform to implement active functionalities, given their capability to support complex field distributions, which are geometry-controlled and impact the metamaterials ultrafast nonlinear response. Thus, enhanced optical nonlinearity can be engineered at the required wavelengths.

Previous work [1] has shown a strong, ultrafast response from metamaterials based on plasmonic nanorod assemblies, with sub-ps transient change in transmission reaching 80%. This exceptionally strong and fast response was assigned to the nonlocal behaviour of the metamaterial in the vicinity of the epsilon near zero (ENZ) frequency, where the real part of the effective permittivity vanishes and its wavevector-dependent contribution may become strong [2–4].

Here we present a full-vectorial microscopic model to study the Kerr-type, ultrafast nonlinear response of a plasmonic metamaterial consisting of an array of vertically aligned gold nanorods, with the plasmonic (Au) components of the metamaterial considered as the source of the optical nonlinearity.

We have performed a numerical study of the transient nonlinear response of the metamaterial taking into account the effects of both control illumination conditions and induced non-equilibrium electron temperature distribution in the Au nanorods forming the metamaterial. The nonlinear response of the Au nanorods is governed by a polarization-induced electron temperature change driven by the femtosecond optical excitation. We describe the evolution of the position-dependent electron temperature in the metal via the two temperature model (TTM) [5], keeping the phonons temperature effectively constant. The nonlinear absorption is then modelled via the temperature dependent Au permittivity [1].

We found that the nonlinear response of the system is stronger when exciting in the vicinity of the ENZ frequency. We also show that the enhancement of the nonlinear response depends on the spatial distribution of the electromagnetic energy density induced by the pump pulse . Considering these effects, the magnitude and time response of the metamaterial is further studied, in different dispersion regimes of the metamaterial.

Wavefront Shaping in Cavities: Waves Trapped in a Box with Tailored Boundaries

M. Dupré, M. P. Del Hougne, M. Fink, F. Lemoult, and G. Lerosey
Institut Langevin, ESPCI Paris Tech & CNRS, France

Abstract— Usually cavities of a given shape and dimensions support definite eigen frequencies and modes. They are used in a vast number of fields of research and frequency ranges, from microwave ovens to masers, from QED to electromagnetic compatibility. The eigenmodes of a cavity are always modified and tuned through mechanical parts, like mode stirrers in reverberation chambers in electromagnetic compatibility or screws in masers and quantum electrodynamices. Nevertheless, thanks to integral theorems, tailoring the boundaries of a cavity permits to design at will its eigenmodes and therefore the fields inside it. Here we show that this is possible to do so by using electronically tunable metasurfaces that litteraly modify locally the boundaries of cavities, switching them from electric to magnetic conductors. We prove that it permits, contrary to intuition, to focus waves at desired locations inside cavities. Using a binary tunable metasurface as a spatial microwave modulator (SMM) [1, 2], we show that we can control those eigenmodes up to some point which depends on one hand of the number of modes inside the cavity N given by the losses and the mean level spacing, and on the other hand on the number of degrees of freedom p which is also the number of elements of our SMM. We show experimentally, with the set-up shown on Figure 1(a), and theoretically that different behaviours of the cavity with a SMM inside can be expected. We explain the physical mechanism underlying the concept, which allows us to give a criteria that ensures that a cavity can be turned into a completely different one as in Figure 1(b) and contrary to Figure 1(d), by modifying parts of its boundaries. We finally show that this can even permit, in a cavity of given shape, to position at will the eigenfrequencies and corresponding eigenmodes as shown on Figure 1(d).

We believe those results will have application in fields requiring mode stirrers, optimizing transmission or frequency filters such as EMC, microwave ovens, or telecommunications.

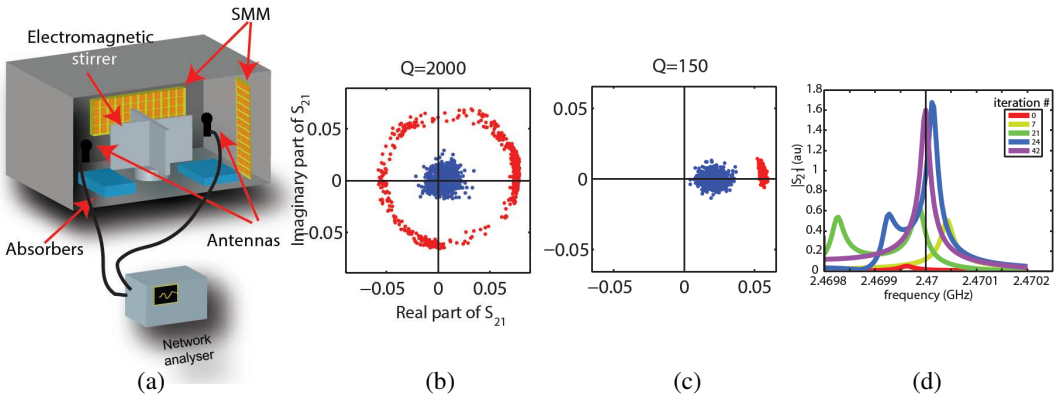

Figure 1: (a) Experimental set-up. (b), (c) Two different behaviours of the transmission between two antennas in a cavity for different Q factors when the configuration of the SMM is changed. Blue points correspond to initial measured transmission and red points correspond to optimized transmission points. (d) Spectra obtained numerically of the transmission between two antennas in the cavity, for different steps of the optimization procedure.

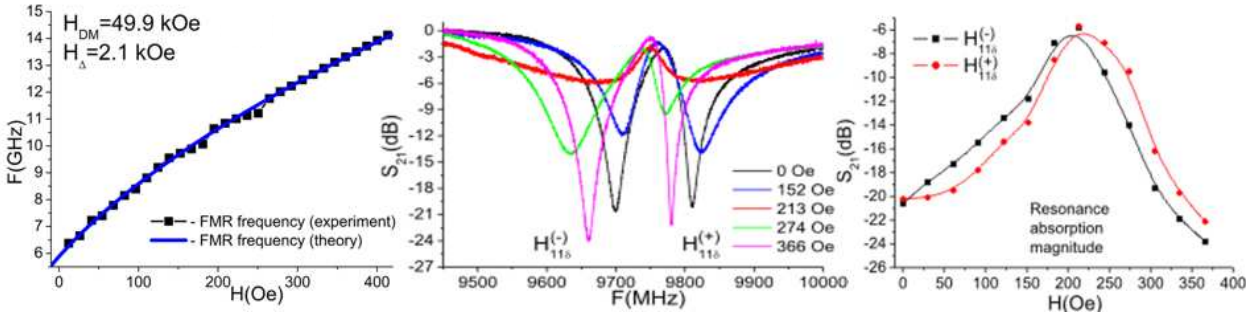
Abstract— Dielectric resonator based UHF filters, which are the key elements of the modern transceiver equipment [1], have one major drawback — they lack dynamical tuning of their characteristics. Since utilization of resonators with electronically tunable electrodynamic characteristics can greatly increase the functionality of microwave devices (for instance, in reconfigurable matched filters), in this paper we present a new concept for magnetic field tunable device, based on the electrodynamically coupled dielectric and weak ferromagnet resonators.

Weak ferromagnets are of special interest, since their typical quasi-feromagnetic resonance (FMR) frequencies can easily reach Ku- and K-bands for extremely small bias fields H_0 of few hundreds Oe [2], due to the presence of Dzialoshinskii-Moriya effective field H_{DM}, whereas quasi-antiferromagnetic excitations lays on the borderline between mm and sub-mm wavebands.

Here we investigated a $2.1 \times 2.3 \times 0.1\,\mathrm{mm}^3$ high-quality sample of iron borate ($FeBO_3$), a well-known weak ferromagnet [2]. It was grown by us from solution in melt. As a first step, a sample was characterized, by placing it atop of coplanar transmission line and measuring FMR frequency for in-plane bias magnetic field, in range from 10 to 400 Oe. After fitting resulting curve with model equation [2]

$$\omega_F^2 = \gamma^2 \left(H_0 \left(H_0 + H_{DM} \right) + H_\Delta^2 \right)$$

magnetic parameters of $FeBO_3$ were successfully determined (see Fig. 1(a)). Next, this sample was epoxy bonded to the disk dielectric resonator (commercially grade microwave ceramics) and put inside the rectangular metallic $23 \times 10\,\mathrm{mm}^2$ waveguide. Composite resonator was positioned at the middle of the wide wall, with $FeBO_3$ in direct contact with metal. Dielectric resonator was excited on $HE_{11\delta}^{(\pm)}$ modes (due to the lack of cylindrical symmetry of waveguide section, the frequency degeneracy was removed) and FMR oscillation in iron borate acted as a perturbation. Results on transmission characteristics modification with external in-plane bias magnetic field are shown on Figs. 1(b), (c). The strongest effect is observed when magnetic field tunable FMR frequency coincides with that of either of $HE_{11\delta}^{(\pm)}$ modes.



(a) (b) (c)

Thus, we have shown that inclusion of weak ferromagnet constituent leads to possibility of electronic control over a composite resonator amplitude and phase transmission characteristics, and have potential for both K-band and (in perspective) sub-mm wave device applications.

Abstract— We study microwave response of the individual meta-atoms of a superconducting metasurface formed by a two-dimensional array of Superconducting QUantum Interference Devices (SQUIDs). In our experiment, RF currents in the metasurface are directly imaged by using Laser Scanning Microscopy (LSM) technique. We tested a sample with 21×21 SQUID array in a waveguide cavity designed to achieve a uniform microwave distribution over the entire array. The demonstrated tunability of 2D SQUID metasurface resonance frequency by external magnetic field is about 56%, covering 8–12.5 GHz range. The obtained LSM images of the RF current distributions over the SQUID array confirm a high degree of coherence of the entire metasurface.

Introduction: A two-dimensional array of SQUIDs is an example of a tunable superconducting metasurface [1]. Here the SQUIDs are playing a role of magnetically coupled meta-atoms, tunable with external magnetic field [2]. Recently the microwave response of SQUID arrays has been studied theoretically [3, 4] and also experimentally [5, 6]. In published experiment it is difficult to estimate the actual number of the SQUIDs involved in synchronized RF response. We are using a cryogenic LSM [7] in order to observe the responses of the individual SQUIDs in the array, and to characterize the spatial distribution of the coherent response of the array to microwave signal.

Experiment and Results: In the test setup, the probing microwave signal should be uniform and have magnetic field component directed orthogonal to the plane of the SQUID array. To achieve this, we place the SQUID array sample in the plane of symmetry of a rectangular waveguide, where the magnetic field of the fundamental TE_{10} mode is perpendicular to the sample plane. The designed waveguide test section has two coaxial adapters for the broadband connection to the network analyzer. The LSM access is made via a small hole in the waveguide wall, with the size much smaller than the cutoff wavelength for RF. The test sample is an array of 21×21 SQUIDs, where each SQUID is a Nb thin-film rectangular loop, with outer dimensions of $70 \times 50\,\mu m^2$, interrupted by a single Nb/AlO_x/Nb Josephson junction.

In transmission experiment with the SQUID array, the array collective response is visible as a resonance peak tunable over 56% band (8.5–12 GHz). The resonance peak is narrow, about 20 MHz wide, and resembles a response of a single resonator. We used LSM to visualize the RF currents in the individual SQUIDs at the resonance frequency of the array. The LSM imaging shows that about 50% of the SQUIDs in the array are resonating coherently.

Conclusion: Our experimental study of superconducting metasurface with 21×21 SQUID array indicates a nearly synchronized resonant response of the array and a broad frequency tuning range of the metasurface. The LSM imaging of the currents in the individual SQUIDs shows a partial uniformity, where about 50% of the SQUIDs participate in the coherent response. The spatial structure of the SQUID array response will be discussed. SQUID-based metasurface has low losses and a good frequency tunability, and can be useful for designing compact cryogenic RF systems.

Abstract— Functional plasmonic nanostructures made of noble metals owing to their unique optical and spectral properties are currently of great scientific interest. A number of promising applications in such areas as plasmonics, nanophotonics, biosensing, etc. were theoretically predicted and experimentally demonstrated. For these applications it is often necessary to fabricate both single element at a given point and sufficiently large ordered arrays of nanostructures, which can be realized by a number of relatively expensive or time-consuming techniques. Laser material processing potentially provides the easiest and cheapest way to fabricate single and large ordered arrays of different functional metallic nanostructures through initiating various hydrodynamic instabilities excited on the metal film surface under nano- and femtosecond pulse irradiation.

In present paper we report on rigorous experimental study of various nanoscale surface hydrodynamic instabilities on the thin Au and Ag films induced by tightly focused single femtosecond and nanosecond pulses. Each type of laser-induced hydrodynamic instabilities results in the formation of corresponding resolidified surface relief nanostructure: nanojets, nanocrowns, self-organized nanoparticle's chains or hybrid structures (a nanojet surrounded by a nanocrown). The hybrid structures as well as the nanoparticle chains are reported for the first time. The thickness of the metal film, pulse energy and duration were found to be the key parameters determining the type as well as the geometrical shape of the resulted surface nanostructure. Underlying physical mechanisms responsible for the formation of all these laser-induced nanostructures are also discussed in this paper. Possible implementation of the fabricated nanojets, nanocrowns, nanoparticle's chains and hybrid structures as promising plasmonic elements for SERS signal enhancement in molecular sensors, hot electron generation in solar cells and light localization at nanoscale are also discussed in this paper.

Three Dimensional Ablation Flow Produced by Ultrashort Laser Pulse from Perfectly Flat Target

Abstract— We consider laser peeling and structure formation of thin and thick films on substrate. Let us present shortly a general picture of laser structuring. It is known, that the structuring of materials by short laser pulses with duration in the range of 10 fs–1 ps has many important technological applications. But underlying physics is not well understood. On our view, the corresponding processes are interplay of plasmon enhanced absorption from one side and a thermomechanical triplet from the another side, where the triplet is: (i) spallation, (ii) capillary deceleration in tandem with (iii) diffusion limited freezing. Particular morphology of structures depends on absorbed fluence and number of pulses. Formation of the structures is usually attributed to plasmon activity, which leads to the LIPSS (laser induced periodic surface structures, ripples). On our opinion, plasmons only dominate in the interplay if absorbed fluences are small and the multiple repetition regime is used. Indeed, the chaotic (not ripples) structures are produced by X-ray pulse where plasmon excitation is not possible. Therefore the wavelength should be added into the list of parameters governing the final morphology of an irradiated surface. It was shown that for the small number of pulses, either large fluences or short wavelength the chaotic structures different from ripples are formed. Another important governing parameters are connected with geometrical limitations. They are a radius of a focal spot on an irradiated surface and thickness of a film. Indeed, surface structures have the finite lateral sizes (submicron scales). Therefore for tightly focused optical light pulses, when diameter of a focal spot is smaller than lateral spatial scales, definitely will influences the surface structures. Those problems are analyzed in the report.

Abstract— Nanofabrication of single and multiple near- and sub-100-nanometer surface nanofeatures — nanoholes [1, 2], nanospikes (solidified nanojets) [2, 3], as well as intermediate submicron bumps [2–5] — by tighly focused nanosecond and femtosecond laser pulses appears to be driven interfacial or sub-surface boiling in thin films, or thick films and bulk materials, respectively. The necessary prerequisites for such buried evaporative phenomena is strong picosecond evaporative cooling of the fs-laser heated surfaces [6] and heat conduction laterally or to the bulk [1–5], which both leave the transient temperature maximum at the corresponding transient heat conduction length. Furthermore, when the peak subsurface temperature exceeds the boiling temperature of the laser-heated material [7], spontaneous nanoscale elementary single-bubble boiling, formation of sub-micron buried vapor cavity, or nanoscale melt expulsion occur, yielding in sub-100-nanometer nanoholes, bumps and nanospikes, respectively.

Abstract— Absorption of intense electromagnetic pulses gives rise to various non equilibrium processes in condensed matter resulted in ablation of irradiated materials. Here the ablation processes are analyzed in the framework of molecular dynamic simulations combined with continual description of electron subsystem in metals. At nanosecond pulse duration in metal (Al) film targets with 48 and 430 nm thickness which in liquid states with temperature 6400 K four different ablation regimes are observed depending on electromagnetic pulses intensities: surface evaporation, explosive (volume) boiling, spinodal decomposition and supercritical fluid expansion [1–3]. At shorter (picosecond) pulses spallation effect (see, e.g., [4, 5]) due to negative pressure values generated in the thin film is also observed. Appearance of explosive (volume) boiling in metals irradiated with intense electromagnetic pulses is not evident beforehand because of high values of thermal conductivity and small radiation penetration length. Nevertheless, the explosive boiling process at absorbed radiation intensity $I = 44\,\mathrm{MWt/cm^2}$ is clearly visible in Fig. 1(a) which shows several flying away target fragments formed after explosions at earlier moments 1.16 ns, 1.5 ns and 1.79 ns. The fragments with initially well defined boundaries then become thinner and disintegrate due to surface evaporation process. Remnants of the first fragment which was formed due to the first explosion at 0.71 ns are not visible here. Fig. 1(b) shows spinodal decomposition regime where density fluctuations have no such distinct boundaries as in the explosive boiling case. Initial thickness of the explosive boiling fragment is of the order radiation penetration length (about 10 nm). This result means, in particular, that in theoretical description of the explosive boiling process in irradiated metals [6] it is necessary to take properly into account finite value radiation penetration length.

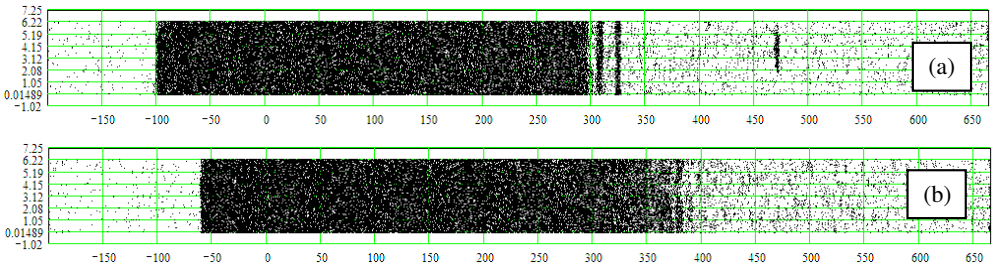

Figure 1: Snapshots of irradiated (from the right) metal film at $t = 1.82$ ns after the radiation pulse with constant intensity $I = 44\,\mathrm{MWt/cm^2}$ is switched on (a), and (b) at $t = 0.73$ ns with $I = 88\,\mathrm{MWt/cm^2}$.

Femtosecond Laser Ablation of Thin Films on Substrate

N. A. Inogamov[1], **V. A. Khokhlov**[1], **V. V. Zhakhovsky**[2], **Yu. V. Petrov**[1,3], **K. V. Khishchenko**[2], **and S. I. Anisimov**[1]

Abstract— In many applications an ultrashort laser pulse irradiates films deposited onto a dielectric substrate. E.g., microbumping phenomena caused by blistering of the irradiated film are important for laser bio-printing and LIFT technology [1–3], for formation of arrays of nanoholes [4], and for nanophotonics (creation of nanoantennas [5]). The case with a film on substrate is interesting. Indeed, a system with a thin film between a substrate from the one side and vacuum from the other side is very different from a case of bulk targets and from a case of a freestanding film. In the report the systems "film on substrate" are considered in details. Modern model of two-temperature (2T) physics is used [6, 7]. We show that for 40–100 nm thick thin films the conductive leveling of electron temperature across film thickness takes few picoseconds in gold, copper, and silver. The duration of the leveling is small in comparison with the electron-ion temperature equalization time t_{eq} [6, 7] and is small in comparison with acoustic time t_s defined by thickness of film and speed of sound. At the same time values t_{eq} and t_s are comparable. Thus electron-ion coupling coefficient and 2T equation of state [6, 7] are important ingredients of 2T physics since they define a rate of electron cooling and dynamic significance of electron pressure. Interplay of rarefaction waves in a film and dynamic interaction between the film and the substrate control a process of film separation from substrate. Finite size of a heated spot on a film surface is included into consideration. Velocity of a film after its separation from substrate has a maximum at the axis of a beam in case of Gaussian distribution of pulse intensity across a cross-section of a laser beam [1–4]. That's why the film after separation from the substrate expands having a shape of cupola. An area of surface of a target under the cupola is defined by a radius of a laser beam. Absorbed fluence is above a melting threshold in our applications. Therefore the shell of the cupola is made from molten metal. Surface tension plays the decisive role in a stopping of expansion of cupola. Tension focuses mass ow inside a shell in direction to the axial region forming a jet and droplets. Mutual action of capillary effects and cooling/freezing process define a final shape of a cupola.

Abstract— We demonstrate new simple methods of all-laser fabrication of nanoantenna (nanojet) with an additional elements for coupling/focusing of surface plasmon-polaritons (SPPs).

The first method is realized by using an aluminum plasmonic lens irradiated by linear polarized femtosecond laser pulses at fluences higher than the ablation threshold of aluminum. These plasmonic lenses are surface rings with tunable mean diameter in the range of 1.0–2.5 μm, which are easily fabricated by a single fs-laser pulse over the whole laser spot via self-organization processes. Following the first fs pulse, the next one irradiates these plasmonic lenses and initially excites quite intense SPPs which are focused in their center. The remaining part of the pulse interferes with the focused SPPs, resulting in field enhancement in the very center of the lenses and causing strong local (nanoscale) heating. The resulting plasmonic lenses contain single nanojets in their centers owing to melt expulsion in the locally heated area [1]. Such surface structure resembles a parabolic antenna, which has a receiver and focusing reflector.

The second method is based on double-shot femtosecond laser nanoablation of thin supported metallic (Au) film. The first fs-laser pulse produces nanojet, standing on bump of microscale diameter. Irradiation by spatially shifted (on several microns) second laser pulse results in the bump removing, transition of nanojet into nanosphere and formation of concentric periodical semi-rings. Resulted surface structure represents nanoantenna (gold nanospere), surrounded by plasmonic lens, delivering more incident energy to the nanoantenna [2].

The proposed new principle of all-laser nanoantenna fabrication is very simple and high-productive technology to be applied in nanophotonics soon. For instance, we showed almost 30-fold enhancement of fs-laser induced ultrafast electron emission from such nanoantennas, which is promising for time-resolved electron microscopy [1].

Abstract— We present a low-index polymeric three-dimensional photonic crystal, rod-connected diamond structure, created via direct laser writing, showing a partial photonic band gap at near-infrared wavelengths in both P and S polarization, measured by angular resolved Fourier image spectroscopy. We show initial tests of backfilling with high refractive index material aimed at achieving a full photonic bandgap in the near-infrared.

Rod connected diamond (RCD) [1], which is known to exhibit the largest full PBGs among all photonic crystal designs with the same index contrast [2], has been investigated but remains a significant challenge to create [3]. Here we use the direct laser writing method to fabricate a polymeric ($n = 1.52$) RCD template and characterize its band structure via angular-resolved spectroscopy. We first calculate the RCD bandstructure using MPB software around wavelengths of interest using the results to optimize lattice parameters (Fig. 1(a)). We then fabricated a structure and measured transmission (reflection) at normal incidence along the X' symmetry direction where we see a clear 20% dip (peak) in transmission (reflection) with center wavelength around 1500 nm (Fig. 1(b)). We then measure reflection spectra mapped as function of angle (Fig. 1(c)) showing good agreement with the bandstructure features seen in Fig. 1(a).

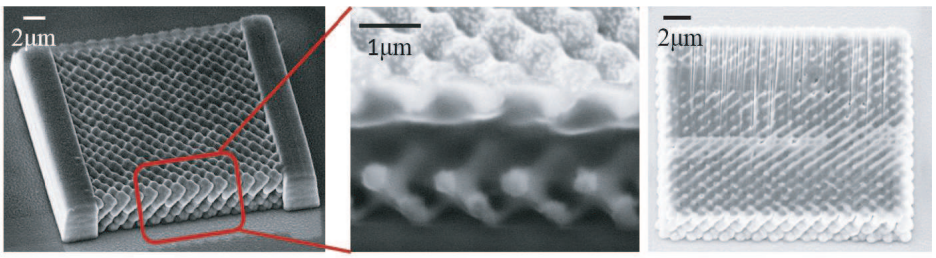
Figure 1: (a) MIT photonic-bands (MPB) calculation of RCD band structure at our measurement range, the insert defines the Brillouin zone of RCD and the principle directions (X', U', L), (b) transmission and reflection measurements at normal incidence, the insert show dimensions of structure, (c) measurement of reflection spectra against collection angle, incident with S polarized light.



(a) (b) (c)

Figure 2: (a) Overview of a backfilled RCD structure, (b) cross section and (c) top peel showing good back fill quality, bright parts are chalcogenide material and dark parts are polymer templates.

Having successfully made polymeric RCD, we can then backfill this template with high refractive index ($n = 2.4$) chalcogenide material [4] to form high refractive index contrast (2.4:1) photonic crystal with full photonic bandgap. Our preliminary backfilled sample is shown in Figs. 2(a)–(c). By removing the polymer templates in a further process we can achieve high refractive index contrast. In the conference we will show our latest measurement results for these full photonic band gap RCD structures.

Simulation of Intense Laser Irradiation of Silicon and Diamond

T. Apostolova and B. Obreshkov
Institute for Nuclear Research and Nuclear Energy, Sofia 1784, Bulgaria

Abstract— The processes of photo excitation of band gap materials by intense pulsed laser radiation taking place on a femtosecond time scale is modeled by time dependent Schrodinger equation. The subsequent time evolution of the dynamical system near the end and after the termination of the pulse due to impact ionization, auger recombination, exciton formation and electronphonon scattering are modeled by quantum-kinetic Boltzmann type equation.

We apply our theoretical approach to investigate ripple formation and graphitization in laser irradiated silicon [1] and diamond [2] crystals.

Formation and Properties of 3D Metamaterial Composites Fabricated Using Nanometer Scale Laser Lithography

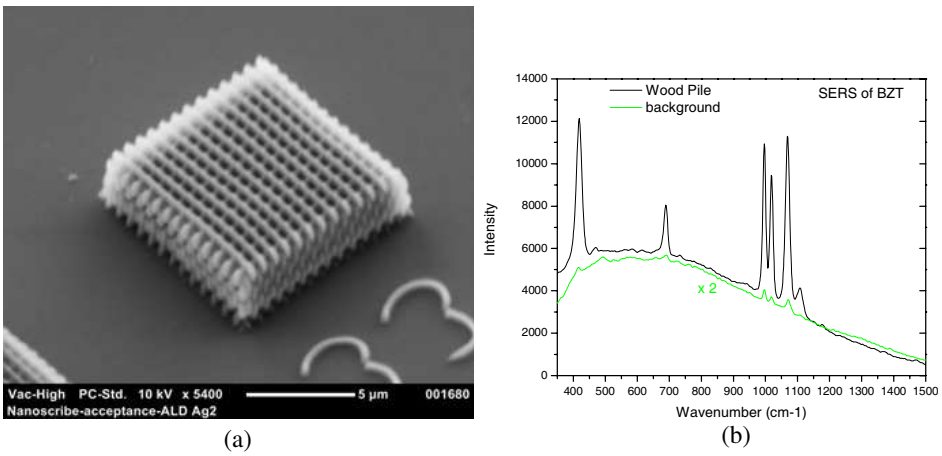
S. M. Prokes[1], **F. K. Perkins**[1], **O. J. Glembocki**[1], **and T. Larrabee**[2]

[1]US Naval Research Lab, USA
[2]NRC post doctoral Fellow, USA

Abstract— Metamaterials are engineered composite materials containing subwavelength arrangements, which often exhibit properties not available in nature or traditional synthetic materials. The field of metamaterials has brought about novel designs, since researchers have been able to overcome the constraints associated with conventional materials and explore entirely new concepts with a much larger range of material parameters available through structured media.

The key aspect of these materials is that they are artificially engineered, and although some of these structures can be formed by the use of appropriate deposition or growth techniques, most must be formed by patterning. To design a metamaterial in the terahertz or longer wavelengths, the patterning does not require much effort, since current optical lithography or pattern transfer techniques suffice. For metamaterials designed for the visible or near IR wavelengths, however, the patterning is much more of a challenge. To achieve this, techniques such as e-beam lithography are used, but it is slow, extremely difficult and can only produce 2D structures. An alternative technique to produce 2D and 3D structures involves laser fabrication using the Nanoscribe 3D laser lithography system. This is a direct laser writing technique which can form arbitrary 3D nanostructures and is based on multi-photon polymerization. The laser light is tightly focused in an ultra short pulse, so that the photoresist within the focused area is exposed by multi-photon absorption.

We are creating 2D and 3D metamaterials via this technique using a Nanoscribe proprietary acrylic-based negative-tone resist, and subsequently conformally coating them using Atomic Layer Deposition of oxides and Ag. The resolution of our Nanoscribe system is 80 nm, measured by writing a 2D grating structure. We also recently developed a novel plasmonic material, based on Plasma Enhanced Atomic Layer Deposition (PEALD) of Ag [1], which results in strong plasmonic properties of flat Ag films. We have modeled the ALD-Ag film using FDTD and FEM full wave E-M simulations, representing the film as a ring shaped air gap in Ag. The results show a very strong confinement of optical fields in the air gaps with an enhancement $> 10x$. When PEALD Ag is combined with an active plasmonic material, such as dielectric core nanowires, the additional field enhancement over the plasmonic material can be $> 100x$. This behavior is due to these air gaps, which are an inherent property of the PEALD growth of Ag. This unusual plasmonic behavior is very similar to what would be expected in hybrid spoof plasmonics and suggests that PEALD Ag is a metamaterial. Thus, we are now able to form a composite metamaterial by conformally coating an engineered 3D structure fabricated by laser lithography with a 2D naturally forming Ag metamaterial deposited by PEALD. An SEM image of such a 3D composite and its SERS



(a) (b)

Figure 1: (a) 3D composite "wood pile" structure formed in photoresist/ALD Ag and (b) SERS of BZT showing $30x$ enhancement.

response are shown above. Note that the SERS is $30x$ stronger than the ALD Ag background. We will discuss the optical properties of these novel composite structures and their potential for dual resonant metamaterials.

Two-temperature Heat Conductivity of Gold

Yu. V. Petrov[1], **N. A. Inogamov**[1], **and K. P. Migdal**[2]

[1]L.D. Landau Institute for Theoretical Physics RAS, Russia
[2]All-Russia Research Institute of Automatics, Russia

Abstract— Data on thermal conductivity in states with hot electrons are necessary for the simulations of ultrashort laser pulse-metal interaction. We develop a new analytical approach describing a coefficient of heat conductivity within a broad range of two-temperature phase diagram including the melting curve. This is a region in the three dimensional space defined by electron temperature, ion temperature, and density. Coefficient of thermal conductivity is an order of magnitude larger than the room temperature value of this coefficient if electrons are hot — electron temperature is one — few eV. This large increase in the heat conductance is due to a sharp increase of a heat capacity of carriers (electrons) when they are significantly heated because electrons partially lose their degeneracy. The developed model is based on a solutions of the kinetic equations. The model also is based on experimental data and on calculations of the electronic spectrum. Electronic spectrum was calculated using the density functional theory (DFT). The model works well also at low electron and ion temperatures. This is significant since for applications it is necessary to describe the cooling process of molten metal down to melting temperature and below the melting temperature.

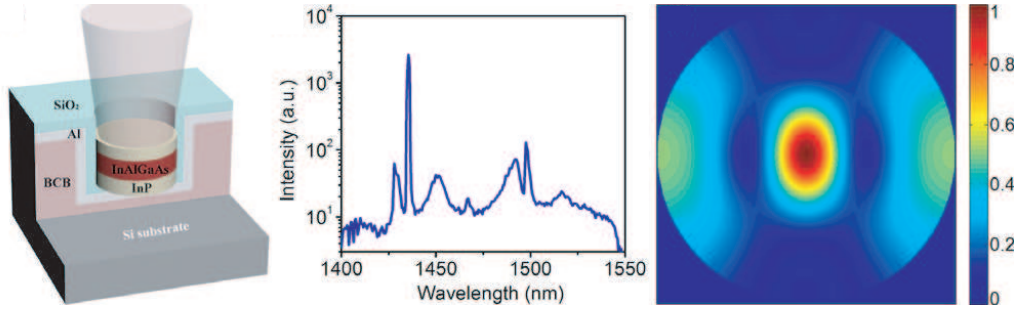
Abstract— Semiconductor nanolasers with subwavelength sizes are greatly demanded for their potential applications in photonic integrated circuits, optical interconnection, data storage and imaging [1–4]. Here we demonstrate an aluminum/silica coated InAlGaAs/InP circular subwavelength laser, which is bonded on a silicon wafer using a benzocyclobutene (BCB) layer. Room temperature lasing operation is observed for the nanolaser with the semiconductor core height of 800 nm and the radius of 740 nm. Resonant modes in the subwavelength laser are analyzed by 3D finite-difference time-domain (FDTD) simulation, and the simulated spectrum agrees well with the observed lasing spectrum. Meanwhile, the far-filed characteristics of the resonant modes in the subwavelength laser are also investigated by 3D FDTD method.

Figure 1(a) shows the schematic figure of our fabricated subwavelength laser, which consists of a circular cross-section semiconductor core coated by silica/aluminum on the bottom and sidewall. Eight pairs of compressively strained InAlGaAs multiple quantum wells (MQWs) are used as the gain material of the laser. The height and radius of the semiconductor core are about 800 nm and 740 nm, respectively. The fabricated laser was tested at room temperature by a micro-photoluminescence setup with a pumping source of a 976 nm pulsed laser. A 40× objective lens was used to focus the pump laser beam on the laser sample and collect the emitting light of the laser at the same time. Fig. 1(b) shows the typical above-threshold spectrum of the fabricated laser. As shown in Fig. 1(b), a lasing mode with peak wavelength of 1436 nm and some other resonant modes of the laser were observed. The mode spectrum of the fabricated laser was simulated by 3D FDTD technique and compared with the observed spectrum. In addition, the far-field characteristics of the resonant modes in the laser were also investigated by 3D FDTD technique. Fig. 1(c) shows the calculated far-field pattern of the mode $TE_{1,4,1}$ (the three indices represent the azimuthal, the radial, and the longitudinal mode numbers) in the laser.



(a) (b) (c)

Figure 1: (a) Scheme of the fabricated subwavelength laser. A circular semiconductor core is coated by silica/aluminium layers, and then bonded on a silicon substrate by using a BCB layer. (b) Measured lasing spectrum of the fabricated laser at room temperature. (c) Calculated far-field pattern of the mode $TE_{1,4,1}$ in the laser.

We demonstrated a metallic confined InAlGaAs/InP circular subwavelength laser. Single lasing mode with peak wavelength of 1436 nm and linewidth of 1 nm was observed. The mode spectrum of the laser and the far-field patterns of the resonant modes were investigated by 3D FDTD method.

Calculations Concerning the Variable Size of Protons and Other Nuclei

Konstantin Meyl
Faculty of Computer and Electrical Engineering
First Transfer Center of Scalar Wave Technology (1.TZS)
Furtwangen University, Germany

Abstract— 30 years ago already, the then nuclear research center in Karlsruhe publicized experimentally determined dimensions and shapes of various nuclei. Apart from the obvious spherical shape, cylindrical and elliptical nuclei had also been found. Such experimental results have to be compared with calculations. Not only the number of p^+ and n° involved, but also spin, direction of rotation, and nuclear cohesion through magnetic moment need to fit together. The mathematical basis can already be found in the work from 1755 by the founder of the modern field theory, Prof. Roger Joseph Boscovich. According to his assumption is calculated, as an example, that the radius of a particle is dependent on the field and, ultimately, on the mass of all particles involved in the measurement. Thus the radius of the proton is reduced by muons about 5% in contrast to electrons. The factor, widely confirmed by recent measurements, is calculated. This should also apply to other atoms measured by the help of muons, when for this purpose the corresponding particle mass is influencing the calculation. At the end of the paper mathematically justified predictions are given.

Dissipative Magnetorotational Instability: Wavelength Asymptotic Saturation

F. E. M. Silveira
Centro de Ciências Naturais e Humanas, Universidade Federal do ABC, Santo André, Brazil

Abstract— When a plasma, which rotates differentially about a fixed center, is subjected to a magnetic field, perpendicular to the plane of rotation of the fluid, the coupling of the current with the field (the Lorentz force density) may be disruptive if the angular velocity of the gas decreases with the increase of the radial coordinate. This phenomenon is commonly referred to as the magnetorotational instability (MRI). For a perfectly conducting, inviscid plasma (ideal approximation), the problem can be treated analytically. Such an approach is particularly useful for the description of the dynamical evolution of accretion disks, astrophysical structures consisting of ionized gases which rotate about compact objects (black holes, neutron stars). In this case, the flow is assumed to exhibit a Keplerian profile, thereby leading to a dispersion relation which is biquadratic in the growth rate of the MRI. However, the associated instability condition implies the perturbative wavelength increases with the increase of the radial coordinate [1]. This means that, as the radial coordinate decreases, the perturbative frequency increases with no limit. Recently, there has been some progress towards an analytical formulation of the MRI by including dissipative effects for the rotating plasma [2, 3]. In this work, by introducing both finite resistivity and viscosity for a Keplerian accretion disk, it is found that the growth rate of the instability may satisfy a quadratic equation and become suppressed by a term which depends on the magnetic Prandtl number. It is also shown that, when resistive effects dominate, the perturbative wavelength saturates asymptotically to a minimum value which does not depend on the radial coordinate.

Abstract— The paper describes the connection of a hydrogen circuit to a 24 V experimental smart grid. The principle of the proposed design consists in improving the stability of the current grid and enabling maximum exploitation of the electric energy produced by renewable sources (micro-hydropower plant, photovoltaics, and wind power plants). In this respect, the authors present a very important module to save the energy and show an efficiency calculation of the hydrogen circuit.

Our hydrogen circuit consists of an electrolyzer (hydrogen generator) with a purifier; the second part is a hydrogen storage, in our case the storage presents a metal hydride canister with a valve system to switch between a charge operation and consumption, and the third one is a fuel cell. A hydrogen generator is based on an innovative alkaline membrane technology and produces 100 sl of hydrogen per hour. The generator produces hydrogen on demand from water, directly compressed, dry and pure using a patented electrolytic process. It contains 5 l water tank.

OvonicTM Solid Hydrogen Storage Canisters are used to store pure gaseous hydrogen in a solid form and under a low pressure level. The stored hydrogen can be used by a fuel cell system or by other hydrogen consuming systems.

Fuel cells with a polymer electrolyte membrane are characterized by a high current density, which allows the construction of a low weight and small dimensions. The solid electrolyte membrane simplifies sealing in a chemical process, reduces corrosion and increases the life of the cell.

Advanced Methods of UHF EM Diagnostic of Discharge Activity in High Voltage Transformers Dielectric

Abstract— The reliable and economical production and distribution of electrical energy and safety impacts of these processes are crucial aspects of sustainable development in industry and generally the human society. The energy production and distribution chain comprises of various blocks with specific functions and the safety and reliability of each of the blocks are under intensive monitoring. The key component of the chain is the block transformer in the power plant. It is carrying high electrical power under very high voltage conditions. Therefore, the condition of its oil dielectric is carefully watched in order to prevent the development of partial discharges (PD). PD in oil represents an electrical discharge activity at the microscopic nonhomogeneities — e.g., released microbubbles of dissolved gasses. The oil degeneration due to PD activity rapidly deteriorates its insulating properties which can lead to subsequent intensive arc and catastrophic transformer failure.

Various methods have been developed over time. Currently the most advancing is the ultra-high frequency (UHF) method which is based on the real-time detection of electromagnetic radiation generated by PD. Moreover, this approach allows also the time-difference-of-arrival (TDOA) localization of PD source. We have previously reported the development of PD diagnostic system based on the UHF method, including TDOA localization and we have presented results of real field measurement on the nuclear power plant's transformers. Despite of the common view of the UHF method, which assumes excellent sensitivity due to transformer's vessel shielding properties against outer interference, we have noted low-level signal detection difficulties. They are caused by the influence of discharge activity in the encapsulated feeding lines which connect the transformers with turbo-generator system. We have developed a new method for weak PD signal detection which utilizes discrimination of disturbed signal acquisitions. The method was verified by field measurement of very weak injected artificial pulse signal. The results indicate that the sensitivity down to tens picocoulombs can be achieved.

In the proposed article we would like to report the results obtained be the new detection method application. The steps of procedure of method application will be described also. Further advances of the method represents the discharge radiated signal filtration with the goal of separation of the frequency band which are typical for rapid PD and the suppression of frequency bands occupied by components of different electrical discharge types. This advancement further enhances the sensitivity and reliability of the UHF method with discrimination of disturbed signal acquisitions approach.

Numerical Model and Analysis of a Graphene Periodic Structure

Abstract— The aim of this paper is to present the particulars of new research in special numerical models of structures used for nanoapplications. These models can be advantageously used in the evaluation of electromagnetic parameters, thus helping researchers and designers to solve problems related to nanoelements and nanotechnology. The first numerical model of large peridodic structure is designed to test electromagnetic wave propagation in a graphene composite structure. According to the interpretation of the results, the basic design will be prepared for experimental fabrication of the functional sample. There are the results of a numerical analysis of simple nano-electric line.

Introduction: It is obvious from the research presented in papers [1, 3] that the periodic structure of graphene should exhibit certain interesting electrical and electromagnetic properties regarding the propagation of an electromagnetic wave. Thus, new horizons could be opened for the use of graphene in electrical engineering (EMG) and electronics. The referenced articles nevertheless do not provide a clear conclusion that would facilitate prospective application of periodic structures with extreme properties in the field of electromagnetic wave propagation; these structures can be based on either natural or artificial materials.

The authors of this paper have developed the idea to set up a simple numerical model and to propose an experiment suitable for the related verification. Fig. 1 shows the known concepts of carbon nanostructures [2, 3] and layered polymer. The numerical model enables us to evaluate the propagation of an electromagnetic wave along the surface consisting of a periodic structure (such as graphene or metamaterial) and the surrounding dielectric environment The aim of the model is to evaluate the components of both the EMG wave and the power flux density in the time domain; thus, based on our knowledge of today's manufacturing technologies, it would be easily possible to define the applicability of the periodic structure for specific purposes in electrical engineering and electronics. Examples of periodic structure arrangements can be found in several studies, for instance in the referenced paper [2], Fig. 1.

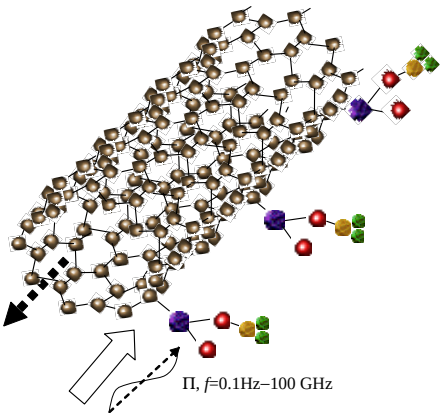

Figure 1: Geometrical structure of the numerical analysis of surface wave propagation.

Magnetic Field Shaping with Quasi-Periodic Resonators

D. Nespor and P. Drexler
Department of Theoretical and Experimental Electrical Engineering
Brno University of Technology, Technická 3082/12, Brno 616 00, Czech Republic

Abstract— Metamaterials are composite structures which have electrical and magnetic parameters (permittivity and permeability) which don't exist in the nature. Metamaterials are composed of small segments. For example, they compose of long parallel conductors or planar coils. In fact, metamaterials aren't homogenous. But if we use an electromagnetic wave with wavelength much larger than the size of metamaterial segment, we can consider the metamaterial as homogenous. Generally, metamaterials with negative parameters represent the media which has negative value effective permittivity ε_{ef} or permeability μ_{ef}. These materials are known since 1960s but only theoretically.

It is possible to manipulate electromagnetic field by means of dielectric materials. Electromagnetic field will be affected due to values of dielectric constant ε_r and permeability μ_r. Viktor Veselago has defined theoretically the usage of material with negative parameters (metamaterial) as an electromagnetic lens. If we put metamaterial between transceiver and receiver, we can see an increase in detected energy. It appears that the metamaterial behaves like an electromagnetic lens.

Negative permeability can increase magnetic coil range. It means that metamaterial with negative permeability behave as an electromagnetic lens. Negative effective permeability can be created by Split Ring Resonators (SRR). The resonator is constructed as a concentric metal ring with interspaces. These rings are deposited as regular matrix on dielectric substrate. For better homogenous of magnetic the field it is possible to designed Kvasi-Periodic Resonators (KPR). KPR are composed from SSR. The subject of this work is design and measuring of KPR.

Abstract— The paper discusses the control of a specific LUNG simulator. This model was created for education and it is used for the simulation of required respiration wave. These simulations may be used on either rubber substitute lung or real lungs. The simulator can simulate breathing during various diseases or detect different lung properties (e.g., stiffness, puncture).

The simulator consists of several parts. They are piston, lung and box, where is connection for lung. The whole process in simulator was described by equations and created a simulation model in Matlab for the suitable design of controller. In this model are taken into account various distractions such as leak of box.

Control of simulator is programmed in LabVIEW and implemented in the real-time platform CompactRio. The simulator program has several modes. User can choose one mode and set parameters of this mode. They are the generating of required speed and feedback control. The CompactRio is used for reading the sensor values and control the pump and the piston movement. The values which are read from input can be divided into two parts: safety sensors and sensors for control. Values from the pressure sensor and the limit motion sensor are safety sensors and values of flow sensors are used to control. These values are processed in the CompactRio and the he PWS signal is sent to output for the control of bellow speed. Safety sensors are used for switching the vacuum pump and checking of the bellow position. The result is a simulator that realizes the required course of respiration curve.

Future Ultra-low Latency Flexible and Programmable All-optical Interconnect Architectures for High-capacity Datacentre Networking

Emilio Hugues-Salas
University of Bristol, UK

Abstract— Increasing number of Internet applications are migrating to the Cloud. In addition, High-Performance Computing (HPC) applications, big data storage/processing along with multi-tenancy, impose new requirements that challenge current data centre networks (DCN) infrastructure with warehouse-scale datacentres (DCs) being deployed in order to support these DC new services. To overcome these challenges, optical-based components are foreseen as promising DC technologies since such devices inherently offer high-bandwidth, low-latency and flexible intra-DCN interconnections. In this invited talk, recent research progress on datacentre interconnect architectures is reviewed in terms of the advanced optical fibres and components used, beyond the state-of-the-art all-optical equipment, programmable flexible high-speed electronics and various multiplexing techniques for datacentre connectivity. On one hand, spatial-division-multiplexing (SDM) transmission is proposed to provide a large quantity of optical links between top-of-the-racks (ToRs) and the function programmable cluster switch. Multicore or multi-element fibres (MEFs) are SDM fibre alternatives to achieve these functionalities. On the other hand, Hollow-Core Photonic Band-Gap Fiber (HC-PBGF) is suggested as another kind of interconnection fibre link to offer significant propagation delay reduction. With regards to equipment, the use of high-port count fibre switches and reconfigurable spectrum selective switches provide important flexibility and adaptability to the DCN architecture to combat the unpredictable DCN applications and services. With respect to DCN interfaces for chip-level access, high-speed electronics based on field-programmable gate arrays (FPGAs) ameliorate the bottleneck whenever optical-to-electronic (O/E) conversion occurs. Finally, different multiplexing techniques, such as Time Division Multiplexing (TDM) and Wavelength Division Multiplexing (WDM), together with SDM, are discussed as ways to achieve high scalability and connectivity amongst systems and subsystems of the DCN as well as in between DCNs.

Golomb Ruler Sequences Optimization for FWM Crosstalk Reduction: Multi-population Hybrid Flower Pollination Algorithm

Prince Jain, **Shonak Bansal**, **Arun Kumar Singh**, **and Neena Gupta**
PEC University of Technology, Sector-12, Chandigarh, India

Abstract— The adverse nonlinear effects degrade the performance of optical wave length division multiplexing (WDM) systems. One of the performance degradation effects is four wave mixing (FWM) crosstalk, a serious problem for WDM systems and can be reduced by unequal channel spacing [1]. Here, we present an unequal channel allocation scheme based on the optimal Golomb ruler (OGR) sequences [2]. It allows the reduction of FWM crosstalk signals preserving the effectiveness of optical channel bandwidth. Recently, the Golomb ruler, a class of non-deterministic polynomial (NP)-complete problems, has been solved by multi-objective, nature-inspired based optimization algorithm [3].

An improved version of Multi-Objective Flower Pollination Algorithm (MOFPA) [4] is proposed to solve the OGR sequences. The modified algorithm called MHMOFPA divides the entire population into several sub-populations/multi-populations at each iteration. All the sub-populations exchange the best solutions by applying the differential mutation strategy. This enhances the ability of original MOFPA algorithm and attains the balance between exploration and exploitation abilities in the search space preserving the solutions diversity in the population.

The proposed algorithms are executed 20 times until optimal sequences are found. The experimental results demonstrate better and efficient generation of OGRs in a reasonable computational time compared to its original forms. Figures 1(a) and (b) show the reduction in the ruler length computation time and total channel bandwidth occupied, respectively.

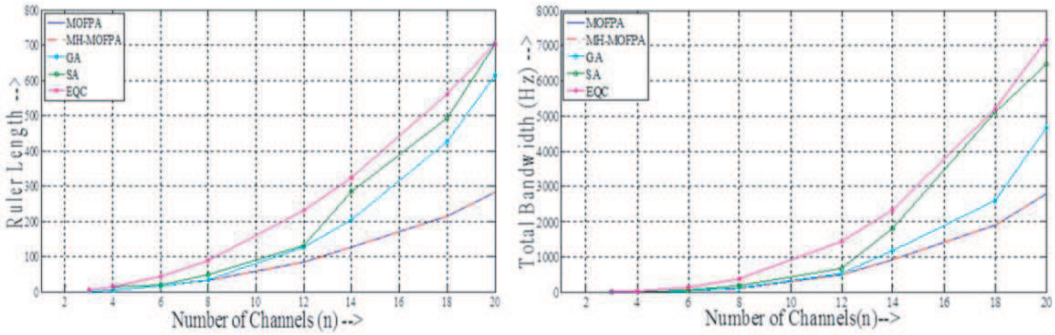

Figure 1: The proposed algorithm demonstrates the significant reduction in (a) ruler length and (b) total channel bandwidth in comparison to the existing algorithms.

Photonic Microwave Amplification for Radio-over-Fiber Links Utilizing Semiconductor Lasers at Stable Locking Dynamics

Kun-Lin Hsieh[1] and Sheng-Kwang Hwang[2]

[1]Department of Photonics, National Cheng Kung University, Tainan, Taiwan
[2]Advanced Optoelectronic Technology Center, National Cheng Kung University, Tainan, Taiwan

Abstract— The radio-over-fiber technology has attracted considerable attention in the last two decades since it enables the distribution of microwaves over long distances through optical fibers. The simplest scheme to superimpose microwaves on optical carriers is direct or external modulation of semiconductor lasers. However, due to their low modulation efficiency, especially at high frequencies, low optical modulation depth is typically generated. This leads to low microwave power after photodetection at a remote base station and therefore limits the distance of microwave radiation. The most straightforward approach to enhance the microwave power is to increase the optical power received by the photodetector, which however may induce unnecessary fiber nonlinearity and may also result in severe detector damage. To overcome these problems, a variety of different approaches based on, for example, optical filtering, fiber Bragg grating, and Brillouin scattering have been proposed for microwave power amplification under a fixed optical power received by the photodetector through improving the modulation depth of a microwave-modulated optical signal. These approaches rely on considerable power suppression of the optical carrier and therefore require optical amplifiers to compensate for the optical power loss. In this study, the stable locking dynamics of semiconductor lasers are applied to achieve modulation depth enhancement through sideband enhancement, instead of carrier suppression, without significant power dissipation. Under proper continuous-wave optical injection, while the optical oscillation of a semiconductor laser is stably frequency-locked to the injection, the lower sideband of its relaxation resonance becomes resonantly enhanced due to the red-shift of the cavity resonance. By taking advantage of such a resonant enhancement characteristic, the modulation depth of a microwave-modulated optical signal can be considerably enhanced by sending it into the laser under the same operating conditions. As a result, the power of the photodetected microwave is amplified by more than 17 dB under the same received optical power. Accordingly, the sensitivity of the phtodetection is significantly improved by more than 8 dB. The phase quality, such as linewidth and phase noise, of the microwave is preserved after amplification. The amplification system can operate for microwave frequency ranging from less than 12 GHz to more than 60 GHz by properly controlling the operating conditions or by choosing proper lasers.

[4]Trinity College Dublin, Dublin, Ireland

Abstract— Long reach-passive optical networks (LR-PON) are being proposed as a means of enabling ubiquitous fiber-to-the-home (FTTH) by massive sharing of network resources and therefore reducing per customer costs to affordable levels. To be ubiquitous the solutions must be suitable for sparse rural areas and also must cater for very high capacity links (∼100-Gb/s) for large business customers. The difficulty for conventional PON designs in sparse rural areas is connecting a sufficient number of customers to the PON system in order to get adequate sharing of the physical infrastructure and therefore achieve a low cost per customer. A further problem is the longer distances between splitter nodes and customers, which requires longer cable lengths with higher fiber count which also increases cost per customer. Also the size of small rural communities can be much less than the total LR-PON split which would mean that the conventional "lollipop" design, with long feeder and large split within a relatively small fiber reach < 10 km, can be underutilized which directly increases the cost per customer. In this paper, we consider the use of "chained" cable and amplifier solutions to improve LR-PON utilization in rural areas. The amplifier nodes for a single LR-PON are presented in a chain configuration with 4 fibers required between the amplifier nodes for each LR-PON chain, while only 2 fibers are required from the primary and secondary metro-nodes to the closest respective amplifier nodes. This solution shares one optical line terminal (OLT) working and one protection OLT for all the amplifier nodes in the chain, it maintains full wavelength availability at all amplifier nodes and also works for single wavelength entry solutions. We analyze the chain solutions at 100-Gb/s point-to-point transmission using dual polarization-quaternary phase shift-keying (DP-QPSK) modulation. The numerical analysis shows that with appropriate finite impulse response (FIR) filter designs, 100-Gb/s transmission can be achieved with at least 512 way split and up to 160 km total distance which is sufficient for many of the optical paths in a practical situation (e.g., private circuits across large metropolitan area) for a point-to-point link from one LR-PON to another LR-PON through the optical switch at the metro nodes and across a core light path through the core network without regeneration.

Photonic Microwave Generation and Stabilization Using Semiconductor Lasers at Period-one Dynamics

Kai-Hung Lo[1] **and Sheng-Kwang Hwang**[1, 2]

[1]Department of Photonics, National Cheng Kung University, Tainan, Taiwan
[2]Advanced Optoelectronic Technology Center
National Cheng Kung University, Tainan, Taiwan

Abstract— Photonic microwave generation using optically injected semiconductor lasers at period-one dynamics has attracted great research attention owing to its promising broadband frequency tunability and all-optical approach. However, due to the intrinsic laser noise, the 3 dB linewidth of such generated microwaves is typically of the order of megahertz, which is disadvantageous for many application purposes. Therefore, several linewidth reduction schemes have been proposed, including direct modulation, optoelectronic feedback, and optical feedback. The last scheme is particularly attractive since no electrical microwave source is necessary, making the scheme all-optical and therefore bypassing severe electronic limitation and parasitics for high frequency microwave generation. In this study, research work is conducted to study how the microwave linewidth varies as a function of the feedback level and time, which shall provide important guidelines in operating the system for better linewidth reduction. If the feedback level is high except for extremely short feedback delay times, the optical feedback can actually suppress the period-one dynamics and excite other more complex dynamics. However, within the range of the period-one dynamics, the optical feedback can stabilize the period-one dynamics in such a manner that significant reduction of microwave linewidth and phase noise is achieved, up to more than two orders of magnitude. A high feedback level and/or a long feedback delay time are generally preferred for such microwave stabilization. However, considerably enhanced microwave linewidth and phase noise happen periodically at certain feedback delay times, which is strongly related to the behavior of locking between the period-one microwave oscillation and the feedback loop modes. The extent of these enhancements reduces if the feedback level is high.

IMDD Formats for High-speed Data Center Interconnect Applications up to 80 km

H. Griesser[1], **A. Dochhan**[2], **N. Eiselt**[2], **J. L. Wei**[2], **and J.-P. Elbers**[1]

[1]ADVA Optical Networking SE, Campus Martinsried
Fraunhoferstraße 9a, Martinsried, Munich 82152, Germany
[2]ADVA Optical Networking SE, Märzenquelle 1-3, Meiningen, Germany

Abstract— Services like cloud storage, video streaming, and on-demand computing moves big data centers into the focal point of the internet. A large part of internet traffic is just between data centers and not to the end user. Regionally close data centers with massive interconnections form a single distributed data center, driving the need for many cheap 100 GbE and 400 GbE connections over a single fiber up to 80 km distance. This application is not covered by the IEEE P802.3bs 400 GbE Task Force which defines objectives for multimode fiber (MMF) and for single mode fiber (SMF) including 500 m, 2 km and 10 km length of SMF.

While coherent DP-16QAM with two wavelengths could be used to transport 400 GbE over 80 km such a solution most likely will not meet the stringent requirements on cost, power and footprint for these short distances. DP-64QAM on a single wavelength would be more appealing, but currently the performance is dominated by the low resolution of the converters and the limited bandwidth of the electrical components. Therefore, intensity-modulated and directly-detected (IMDD) formats might be an interesting alternative to potential coherent solutions. In the paper we present an overview on interesting modulation formats currently considered for WDM transport of 400 GbE signals over metro distances promising lower costs compared to long-haul implementations. DP-64QAM with coherent reception is compared to the IMDD formats PAM4 and DMT, with regard to reach, form factor, and energy consumption. Although an IMDD format most probably requires eight wavelengths for the application under consideration it might benefit significantly from the ecosystem and the economy of scale of the 400 GbE client interface.

Numerical Analysis of Artificial Neural Network and Volterra-based Nonlinear Equalizers for Coherent Optical OFDM

Abstract— Coherent optical orthogonal frequency-division multiplexing (CO-OFDM) is a high spectral-efficient modulation technique able to virtually eliminate inter-symbol interference caused by chromatic dispersion and polarization-mode dispersion. One major drawback of CO-OFDM that remains unsolved is its vulnerability to nonlinear fiber effects due to its high peak-to-average power ratio. Several digital signal processing (DSP) techniques have been investigated for the compensation of fiber nonlinearities, such as the traditional digital back propagation (DBP), nonlinear pre- and post-compensation and nonlinear equalizers (NLEs) based on the inverse Volterra-series transfer function (IVSTF). The main disadvantage of DBP is the extensive use of the fast Fourier transform, which results in high DSP computational load. Pre- and post-compensation algorithms are complex to implement and present a marginal performance enhancement (< 0.5 dB in Q-factor). IVSTF-based equalization has been considered as an effective method for combating fiber nonlinearities. Alternatively, nonlinearities can be mitigated using nonlinear decision classifiers such as artificial neural networks (ANNs) based on a multilayer perceptron (MLP). MLP-ANNs form a complex map with nonlinear decision boundaries between its input and output spaces, which helps in inverting the effects of nonlinear distortions. ANNs have shown promising results in wireless communications applications to reduce the effect of the nonlinear distortion of amplifiers in OFDM signals. In this paper, a novel reduced-complexity ANN-NLE for 16QAM CO-OFDM is analyzed. The capability of the proposed approach to compensate the fiber nonlinearities is numerically demonstrated for up to 100-Gb/s and over 1000 km and compared to the benchmark IVSTF-NLE. Results show that in terms of Q-factor, for 100-Gb/s at 1000 km of transmission, ANN-NLE outperforms linear equalization and IVSTF-NLE by 3.2 dB and 1 dB, respectively. Additionally, it is shown that both ANN and IVSTF NLEs offer $\sim$50% reduced computational complexity compared to the single-step/span DBP.

Quantum-dot Semiconductor Optical Amplifiers: Novel Technique for Gain Management and Noise Suppression

Hamed Baghban and Amir Hashemloo
School of Engineering-Emerging Technologies
University of Tabriz, Tabriz 51666-14761, Iran

Abstract— The saturation behavior of a quantum-dot semiconductor optical amplifier (QD-SOA) is governed by a complex combination of ground state and excited state replenishment in saturation condition. Also, due to inhomogeneously broadened gain of a QD-SOA, various spectral regions are coupled via the common quantum dot (QD) reservoir, i.e., wetting layer, and the barrier layer. Hence, a frequency domain model has been developed to effectively exhibit the saturation properties of a QD-SOA in this article. Based on performed experimental tests, and also, developed model we exploit gain dynamic, gain saturation characteristics and noise suppression capability at different SOA operation conditions. The effect of an external beam on different characteristics of QD-SOAs has been investigated experimentally when the applied beam is in the gain or transparency region of the amplifiers. Also, based on different external beam power levels, the performance of the discussed method is characterized in terms of signal-to-noise ratio at the input of the QD-SOA, and output quality factor, which directly quantifies the level of intensity noise. A comprehensive comparison is performed between the quality factor of noisy input bit stream and the output data which contains the pattern effect at higher bit rates. Finally, noise suppression specification of the device at different bias currents is discussed.

Figure 1 (left panel) illustrates the experimental setup utilized for gain characteristics measurement at the presence of the external holding beam (HB). Also, the noise suppression features at different bit rates in terms of the input and the output Q-factors along with the Q-factor-bit rate competition have been presented in the middle and right panel of Figure 1.

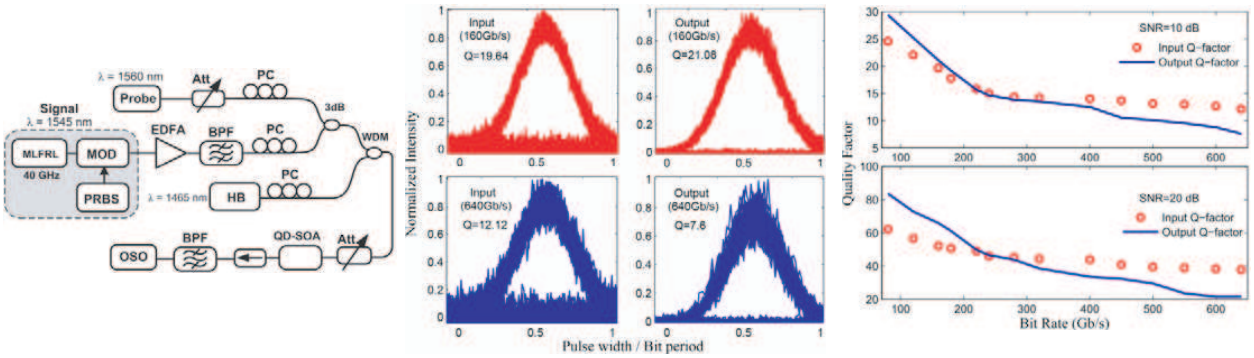

Figure 1: Experimental setup used for investigation of the effect of an external beam on QD-SOA gain and noise features as well as the noise characteristics obtained from the developed model.

Parameters Identification of Controlled Systems with Electrical Drives Using Genetic Algorithms

P. Brandstetter, J. Hajovsky, and M. Kuchar
Department of Electronics, VSB-Technical University of Ostrava, Czech Republic

Abstract— There are a lot of new approaches and principles which are based on a relatively new scientific discipline which is called soft computing. The main feature of soft computing is a departure from traditional modelling based on Boolean logic, analytical models, sharp classification and deterministic search. Among the main representative of soft computing we can include fuzzy logic, neural networks and genetic algorithms. Genetic algorithms solve optimization problems in different fields of the industry. In the field of electrical drives, the genetic algorithms can be used to identify the parameters of the controlled system, optimization of the controller parameters settings and optimization of the parameters adjustment of adaptive controllers.

The electrical controlled drives usually work with controlled systems that contain one or two large time constants and several small time constants, whose influence is replaced by approximately sum time constant. The large time constants is then compensated by a serial correction using a controller, while the sum time constant remains uncompensated. The quality of the control is assessed according to the response of the control loop to step change of input variable.

In the paper, there is used the genetic algorithm to identify the unknown time constants of the controlled system with electrical drive from the step response characteristics.

The most important part of the genetic algorithm is the fitness function — An equation describing searched problem. The first population is generated randomly from specified range of values. According to the results of the individual in the fitness function for each individual is assigned a fitness value that reflects how strong this individual is. The strongest individuals continue in the algorithm and the weaker die.

Next is applied operations of mutation and crossover of most powerful individuals. During the crossing parents remain and the population grows by the new offspring resulting from accidental crossing of chromosomes randomly selected individuals — parents. The newly formed individual may be stronger than parents or weaker and dies in the next generation. The next step is the implementation of a mutation. This creates new individuals by mutation of individuals randomly selected from the population. In the developed algorithm is mutation implemented by multiplication chromosomes and random value close to one. In the next step of the algorithm are randomly generated new individuals. If not to create new random individuals, the space would be poorly scanned and the algorithm would get stuck in a local extreme of fitness function. Add new randomly generated individuals ensures a random search of the entire area, allowing the algorithm to jump out of the field of local extreme. The population was thus extended by new individuals resulting from the crossing and mutation of new individuals, but also randomly generated individuals. The whole population progresses to the next generation, where the process is repeated again — determining of fitness values — selection — crossover — mutation — the emergence of new randomly generated individuals. This process is repeated continuously till not reached the desired number of generations or until the individual is sufficiently mature — high enough fitness value.

The measured points and the function which describe the controlled system are loaded to the application. Chromosomes of the individual are function parameters and function values are calculated in measured points. Differences between measured and calculated values are calculated and summed. Total sum of the deviations then indicates how the individual is strong. The lower sum of differences means that the individual is stronger. The aim therefore is to find the parameters of the function to function as close as possible to the measurement points.

Summation of differences has the consequence that in this case the behaviour of the function exactly intersects some points and some points are disproportionately away. Sum of differences is the lowest in this case. Even during the fitting function all points can provide the sum of squared differences. The sum of squared deviations is smaller number than the large square of one difference.

The sum of the differences is exactly interleaves the most points and ignores points outside the course of function. The sum of the deviations quadrates create graphs of functions uniformly interleaved all points.

All measurements generally are flawed and because of this error sometimes it is not possible to achieve sufficient results by substituting into the equation, or by inserting of the measured points in to the system of equations and solve the equation parameters. In case of an inaccurate measurement should be measured points evenly interspersed by curve.

Model of Voltage Source Inverter for Estimation Methods with Observers

P. Brandstetter, **J. Hajovsky**, **O. Petrtyl**, **and R. Sulak**
Department of Electronics, VSB — Technical University of Ostrava, Czech Republic

Abstract— AC motors are often preferred choice in variable-speed drive applications. For high performance, it is possible to use vector control or direct torque control of the AC motor. The pulse-width modulation (PWM) inverters are most commonly applied in such AC drives. The PWM voltage source inverter, based upon IGBTs, has gained a dominant position in the AC drives market due to its ease of application, good power factor and potential to provide good dynamic performance.

At present, the importance of the so-called sensorless control of AC drives is growing. More common sensorless methods are methods working with the mathematical model of machines. Mathematical models of the AC motor that are used in sensorless control methods with different types of observers and estimators require knowledge of stator currents and voltages.

The essence of the model based methods is the use of a particular algorithm for calculation of the speed and rotor position from known or measured variables such as stator currents and voltages. The values of stator currents and voltages can be obtained by direct measurement using current and voltage sensors at the terminals of the AC motor.

For the measurement of the phase stator currents, the situation is simpler because we can measure directly the value that we need. The stator voltage generated by the PWM voltage inverter causes a ripple of the phase currents. For the control, there is not necessary to know the current waveform during switching period. It is necessary to determine the mean value of the stator currents per PWM period, not per period of the stator current. The mean value can be easily obtained using the PWM module synchronization with the AD converter. The stator currents should be scanned at the same time. From the viewpoint of the current control, there is appropriate to measure stator currents just before entry into the current control loop algorithm. Then we have actual data at disposal.

The stator voltages can be estimated direct or indirect. The direct measurement requires high quality voltage sensors. At indirect method, there is used simpler voltage sensor that is connected to DC link. This voltage sensor measures DC voltage with a low frequency voltage ripple. The stator voltages are calculated using the DC link voltage and actual switching combination of the voltage source inverter. It is known that the voltage source inverter represents generally non-linear system. A relationship between the control voltage and the output supply voltage of the voltage source inverter is not linear. The non-linearities are caused mainly by the dead-time and real properties of the power switching devices, for example a voltage drop on the power switching device. By neglecting these non-linearities, it is obvious that the calculated stator voltages are not correct at indirect method. However, the observers need correct terminal voltage of the AC motor.

The mathematical model of the machine and the entire control structure of the AC drive neglect non-linearities, or replace these non-linearities by linearized dynamic members. Then the observer or estimator which is composed of these blocks will be linear. When we use the distorted stator voltage at the input of the linear observer, we will not obtain on its outputs correct estimated values of quantities. After closing feedback control loops, behaviour of the AC drive can be very unstable. The easiest way is the mentioned non-linear effects to compensate.

The paper deals with the possibility of the compensation non-linear effects such as dead-time and the voltage drop on a power switching device.

Model of Power Electronics Used for Electric Vehicles Contactless Charging

M. Košík, **R. Fajtl**, **K. Buhr**, **and J. Lettl**
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technická 2, 166 27 Prague 6, Czech Republic

Abstract— This paper deals with modeling of adverse effects of Contactless power transfer (CPT) system to its surroundings and supply AC line. The CPT system is used for electric vehicle charging.

The first chapter of the article mentions basic equations which describe parameters of CPT. The CPT transformer is the main component of CPT and most of the equations describes its operation principle.

To increase CPT transmission efficiency, CPT has to operate at high frequency. But high operational frequency means also high value of reactance power. The second chapter of the paper lists four basic electric circuits used to compensate reactance power and thus increase the CPT transmission efficiency. This part also expands the CPT basic equations of compensation influence and adds equations for calculation of transfer efficiency, optimal operational frequency, compensation capacitor values, etc..

The third chapter of the article describes power electronics used in CPT for creating desired waveforms of current and voltage. Power electronics must meet specific requirements given by operation at frequencies about 100 kHz and with transferred active power in order of kW.

In the fourth chapter is described CPT model used for electric vehicle charging. Main focus of the model is to simulate power electronics operation. The CPT power electronics has to be able to transform waveform of electric energy distributed by AC line to high frequency waveform which is transferred by CPT transformer and then to waveform needed for electric vehicle batteries charging. Simulation shows current and voltage waveforms at every CPT component. This chapter also discuss how CPT affects AC line and other electric devices in CPT surroundings. Without magnetic core CPT transformer has low no-load losses (magnetization losses occurs only in coil conductors). As shown in simulation, due to low no-load losses the high current values are taken by CPT during device turn-on process. This phenomenon causes increased electromagnetic noise during device turn-on. The simulation shall be used for outlining of increased noise elimination method.

In conclusion, this article reminds basic principles of contactless power transfer used for electric vehicles charging. The main part of the paper focuses on simulation of power electronics, its operational functions and CPT operation effects on AC line.

Elimination of Undesirable Transients in Direct Torque Control of Induction Motor

P. Brandstetter, M. Kuchar, and J. Hajovsky, and T. Verner
Department of Electronics, VSB — Technical University of Ostrava, Czech Republic

Abstract— For a direct torque control (DTC) of induction motors, several methods were developed in the past. Among the oldest known, Depenbrock's method (D-DTC) and Takahashi?s method (T-DTC) are included. In an effort to improve or simplify these methods of the direct torque control, there was also developed several other methods, for example modified Takahashi?s method (M-DTC), a twelve-sector method (TS-DTC), a method with direct calculation of the voltage vector (DVC-DTC). In some applications, it is advantageous to achieve a constant switching frequency of a voltage inverter which basic principles of the direct torque control do not allow. For these applications, a pulse-width modular has to be integrated into the control structure of the direct torque control (PWM-DTC).

In case of the direct torque control, undesirable transients can easily occur in the process of the induction motor excitation and torque reversation. To eliminate or to reduce the undesirable transients, different ways are utilized. In the paper, there are some methods for the elimination of these undesirable transients described and experimentally verified on a laboratory stand with the induction motor drive.

An induction motor start by simply running the DTC algorithm is problematic. In general we can say that all described DTC methods allow the start of the induction motor. This start process is not in any way optimal.

The DTC algorithms require a special subroutine for the motor excitation. By running DTC methods without the special subroutine for the induction motor excitation, it is possible to describe two different transients during the motor excitation:

In the case of D-DTC and M-DTC, there is a linear increase of a stator flux in the direction of the switched active voltage vector. The time constant of the stator flux increase is greater than the time constant of the stator current. Therefore, when the stator flux modulus becomes its reference value, the stator current reaches already relatively large value. This transient is prohibited and may lead to a reaction of the voltage inverter protection, or even it can damage it. The methods T-DTC, TS-DTC, DVC-DTC and PWM-DTC have a helical increase of the stator flux. This is also accompanied by an unacceptable increase of the stator currents, but the maximum value is smaller than in the previous case.

The best way that ensures the reliable excitation of the induction motor and limits the stator currents is an application of the pulse-width modulation. The motor start is practically performed so that the subroutine is executed before starting the DTC algorithm that switches between the selected active voltage vector and one of the zero vectors. The average value of the stator current during the induction motor excitation can be set by selecting the switching ratio of the active and zero voltage vectors.

A direction change of the motor rotation is achieved by changing the sign of the desired torque. The induction motor speed begins to decrease with the steepness according to the desired torque and then the induction motor is running in the opposite direction. Some mentioned DTC methods are able to perform this reversation without any undesirable transient, for example T-DTC, M-DTC, TS-DTC and PWM-DTC. This means that there are not the over currents even a torque overshoot. Their switching table (or algorithm for the calculation of the voltage vector in the case of PWM-DTC) is not depend on the direction of the induction motor rotation, i.e., these methods are able to maintain the motor torque at the desired value even when the rotation direction disagrees with the sign of the desired torque.

For methods with the switching table (or algorithm for the calculation of the voltage vector in the case of DVC-DTC), which depend on the direction of the motor rotation, it is necessary to use a special reversal subroutine. If the sign change of the desired torque and the replacement of the switching table are at the same time, then an uncontrolled torque overshoot occurs during the torque reversation. This overshoot increases with the speed value at the reversation time. Therefore it is necessary to insert to these DTC methods the subroutine that ensures the correct time course of the motor torque during the torque reversation.

Compensation of Disturbed Load Currents Using Active Power Filter and Generalized Non-active Power Theory

Jiří Lettl[1], **Petr Šimek**[2], **and Viktor Valouch**[1]

[1]Department of Electric Drives and Traction
Faculty of Electrical Engineering, CTU Prague, Czech Republic
[2]Institute of Thermomechanics, Academy of Sciences of the Czech Republic Prague, Czech Republic

Abstract— Today, the compensation of subharmonic, non-periodic, and stochastic disturbances in the electric power systems has emerged as a very serious problem to be solved. Diversity of the features of these disturbances makes their compensation quite difficult. The compensation devices based on power electronics converters must work in the real time, so the time domain approach to control algorithms for the compensation of non-periodic disturbances seems to be promising.

The original Fryze's theory of the non-active current may be extended using a general averaging time interval T_C that can be chosen either one-half fundamental cycle, one full fundamental cycle T, that is the same as that in Fryze's theory, or multiple fundamental cycles, depending on the character of the load current, compensation objectives and the energy storage capacity of a power electronics-based compensator.

If the current $\mathbf{i}(t)$ is the current of an unbalanced load, which may contain, in general, harmonic and also non-periodic or stochastic components, and the active current $\mathbf{i}_a(t)$ is the demanded source current, then $\mathbf{i}_n(t) = \mathbf{i}(t) - \mathbf{i}_a(t)$ is the non-active current that should be injected by a parallel compensator connected to the PCC (Point of Common Coupling).

By choosing $T_C \to 0$, the GNP (Generalized Non-active Power) theory gives the same results as those obtained by using the well-known IRP (Instantaneous Reactive Power) theory. If $T_C \to \infty$, the non-active component in the non-periodic load current is completely eliminated, so the source current is only active.

A principal and analysis of usage of this GNP theory for the parallel compensation of periodic and non-periodic disturbances is presented in the paper. A non-linear unbalanced load generating periodic as well as non-periodic stochastic currents connected to an unsymmetrical non-sinusoidal voltage source is considered.

The impact of the value of T_C on the magnitude rate I_{La}/I_L for different frequencies has been studied in the frequency domain (I_{La} is a residuum of the load current magnitude I_L remaining in the active current after applying GNP strategy). It was found that especially the interharmonic current components above 100 Hz are sufficiently suppressed for $T_C = (5-10)T$. As for subharmonics, the lower their frequency is, the higher the value of T_C should be used for a sufficient compensation. On the other hand, the compensation dynamics in case of transient processes is becoming worse for T_C increasing.

The effectiveness of the generalized non-active power theory to mitigate non-periodic current disturbances is demonstrated by simulations in the time domain on an example of a reactive, unbalanced load current with several harmonic and interharmonic components, additionally modulated either by the subharmonic component or the white noise signal.

Combined Magnetic Bearing

J. Vitner, J. Pavelka, and J. Lettl
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technicka 2, 166 27 Prague 6, Czech Republic

Abstract— Magnetic bearings are becoming more and more the object of interests to designers and producers of rotating machines. Their advantages, as ability to work in vacuum, in weightlessness, in chemical aggressive environment and alike, are demonstrable. Next advantage is the possibility to change their stiffness and damping and thereby to change the rotating system oscillation frequency.

From technical point of view magnetic bearings can be divided into passive bearings and active bearings. Passive magnetic bearings exploit repelling resp. attracting permanent magnets to create a force between their stator and rotor. It is known that it is not possible to obtain a stable equilibrium by using passive magnetic bearings only and therefore at least one direction has to be stabilized by means of a mechanical bearing or an active magnetic bearing. Passive magnetic bearings operate without consummation of electric energy but low stiffness and low damping are their disadvantages. Active magnetic bearings exploit attractive force of magnetic flux in an air gap between their stator and rotor. This force, that can be controlled by the stator winding exciting current, has only attractive character and therefore two electromagnets located on opposite sides must be used for one axis. The resulting force is determined as difference of the both forces.

The paper deals with sorting active magnetic bearings according to their principle of function. Their abilities, advantages and disadvantages, as well as functional principles are discussed. Further the detailed design, development and rotor stabilization process of the combined magnetic bearing placed in the laboratory of the Department of Electric Drives and Traction FEE CTU in Prague are demonstrated. During the development applied mathematical proposal of the combined magnetic bearing, calculation of the magnetic circuit parameters, as well as calculation of the 3-phase winding and determination of the force effects of the passive and active magnetic field are explained. Last part of the paper deals with control methods of the active magnetic field, the task of them is to stabilize the rotor. Measurement results of behaviour of the stabilization process and of the individual control components are presented, too.

Induction Motor Drive Predictive Control Method Analysis and Comparison with Fundamental Direct Torque Control Method

J. Lettl and P. Karlovsky
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technicka 2, 166 27 Prague 6, Czech Republic

Abstract— Thanks to their simplicity, low price and high reliability, induction motor drives are one of the most common in many applications nowadays. Many ways of their control strategies have been developed since launching of mass production of the modern semiconductor devices of high power at high switching frequency. These methods include not only standard frequency control but also modern techniques of field oriented control or direct torque control.

The fundamental direct torque control method of induction motor drive, using two hysteresis controllers to maintain the asked stator flux amplitude and generated torque values, is simple and efficient, however, in some applications relatively high torque ripple can be seen as its disadvantage. That is why various modifications of the method, such as direct torque control with space vector modulation, multilevel inverter application or some forms of predictive algorithms have been performed reduce the torque ripple.

The paper presents suggested predictive direct torque control method of induction motor drive based on predicting the most suitable inverter output voltage vector for the next control step. The prediction calculation is proceeding from torque and stator flux reference values, motor parameters, and actual values estimated from voltage and current measurements. In the paper theoretical analysis of the method is performed, mathematical description of the system is created and the functionality of the proposed control algorithm is verified both by simulation in MatLab/Simulink environment and by measurement on the real induction motor drive. Comparison of the designed predictive control method with the fundamental direct torque control method developed by Takahashi is presented, too.

Electric Vehicle Control Based on GPS and GSM Path Parameters

T. Haubert, P. Mindl, Z. Čeřovský, P. Mňuk, and J. Lettl
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technicka 2, 166 27 Prague 6, Czech Republic

Abstract— Minimizing of energy consumption is important task which is solved at all vehicles. In the case of electric vehicles (EV), energy stored on board in chemical accumulators must be used very effectively. For this purposes mathematical model of EV and real journey data used for energy consumption calculation must be used. On the basis of journey regime optimization lower energy consumption will be achieved.

Optimal journey regime is calculated by means of known road data, obtained by means of GPS and GSM navigation system. From the road horizontal and vertical data basic route elements are calculated. Basic route elements are compared with needed torque, generated by driver's pedal. All this information is processed, optimized, and needed mechanical torque is transmitted to the control unit of electric drive.

For model implementation the dSPACE DS1103 has been employed. The DS1103 dSPACE platform is used as a simulator of the electric vehicle in laboratory and it is used for HIL (Hardware In the Loop) tests. The DS1103 device is covered in the AutoBox with Ethernet communication interface and Autoboot option enabling usage of Compact Flash card. The complete EV mathematical model is loaded in DS1103 device.

For laboratory verification special testing bench has been built. Testing bench consists of permanent magnet synchronous motor, power inverter and power sources. The load is substituted by the dynamometer. Both machines are controlled by master controller. Hardware structure of the laboratory stand is depicted below.

In the first step of journey simulation, the required torque of EV drive in the single path elements has been calculated. Real path data obtained within the journey were generated by means of GPS and GSM mobil-phone and stored in the memory.

Stored data were used as EV simulation model input data. Then values ofr needed driving torque, actual power and consumed energy are calculated. With respect to the obtained results optimized path elements strategy calculation has been developed.

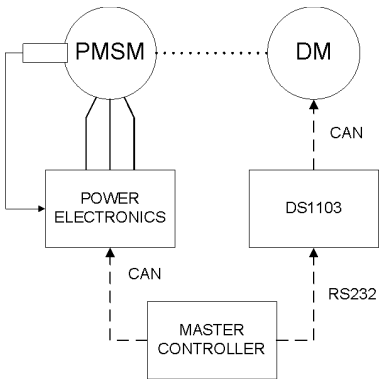

Figure 1: Hardware structure of the laboratory stand.

Railway Traction Vehicle Longitudinal Velocity Estimation by Kalman Filter

P. Pichlik, **O. Zoubek**, **J. Zdenek**, **and J. Lettl**
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technicka 2, 166 27 Prague 6, Czech Republic

Abstract— Important task of railway traction vehicles is to achieve maximal tractive effort in any conditions. For this purpose the vehicles have slip controllers. Some types of the controllers need the vehicle longitudinal velocity as input. The vehicle longitudinal velocity is typically derived from the wheel velocity or measured by Doppler radar in modern vehicles. It is difficult to measure the vehicle longitudinal velocity directly because the vehicle longitudinal velocity could not be directly determined from the wheel velocity. Wheel velocity is higher than vehicle longitudinal velocity when the wheel is driven because of the slip phenomenon. In the case of braking the wheel the wheel velocity is lower than vehicle velocity because of the skid phenomenon. In some cases the vehicle has some non-driven wheels that enable to measure the vehicle longitudinal velocity, but the measurement has higher level of noise. In any case the wheel velocity is influenced by vehicle dynamic motion that can change the measured actual velocity accuracy.

Railway traction vehicle wheel velocity is measured by incremental encoders that are mounted on wheelsets or on motor shaft. The locomotives with DC motors have the incremental encoders mounted on wheelsets. Locomotives with induction motors have the incremental encoders mounted on induction motor shaft. The encoder position was chosen due to the vector control of the traction induction motor. The used incremental encoders are typically of magnetic types with low number of pulses per revolution to be robust and reliable. The encoders are exposed to high mechanical stress and electromagnetic interference that have influence to the velocity measurement accuracy.

When the longitudinal velocity is determined from driven wheel velocity the actual longitudinal velocity cannot be calculated because the driven wheel velocity is higher than the longitudinal velocity. Therefore only approximate velocity could be determined. This is why methods for vehicle longitudinal velocity determination have to be designed. Methods are typically based on evaluation of the slowest wheelset velocity. The paper proposes railway traction vehicle longitudinal velocity estimation based on Kalman filter. The filter contains the vehicle model in state-space form and enables to estimate the velocity and an adhesion force that is difficult measurable value and that is needed for the slip controller, too. The proposed method has been verified using the actual data gathered from actual vehicle with a heavy train. The paper presents results obtained by processing this actual data with designed Kalman filter.

Analysis of the Electromagnetic Field of Electric Machines Based on Object-oriented Design Principles

National Technical University "Kharkiv Polytechnic Institute", Frunze 2, Kharkiv 61002, Ukraine
[2]Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technicka 2, 166 27 Prague 6, Czech Republic

Abstract— Object-oriented design — an approach to solve problems using models based on the concepts of the real world. Fundamental element is an object that combines the data structure with its behaviour.

One-sided approach to the problem of study and research of electric machines, characterized by a great variety of species and structural-functional classes, led to corresponding negative consequences. As in fact was permanently closed a way of using structural and systemic approaches to their study and setting goals of higher level of its generalization.

Regarding the numerous objects of Electromechanics, the problem is most clearly manifested in the way of explaining the principles of their structural construction, which determines the diversity of spatial forms of electrical machines, so that they can be considered as a basis for the development of generalized structural models. The present level of ideas in this area is based on the idea of forming a single improvement framework that would get all the other varieties of structures of electric machines using certain group of transformations.

Considering the theory of object-oriented design, assumes a basic (abstract or virtual) class of generalized electric machine, where its descendants are well-known types of electrical machines. By inheritance or added clipped of some characteristics that can lead to the synthesis of the specific model of the electric machine.

Maxwell's equations underlying the description of the processes occurring in electric machines can be formulated for all types of electrical machines with arbitrary geometric design.

In presented paper problem of finding common principles of synthesis of electromagnetic field models for the main types of electrical machines is solved. The main objective is to create field models of electric machines by inheritance of their characters from the original Maxwell's equations.

This will show the application of the object-oriented design principles in modelling of electric machines and its inextricable link with the basic principles of the theory of the electromagnetic field. An inverse problem — the synthesis of electric machines electromagnetic field equations using object-oriented design is solved, too.

Locomotive Wheel Speed Measurement under Wheel Slip Conditions

O. Zoubek, P. Pichlik, J. Zděnek, and J. Lettl
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technická 2, 166 27 Prague 6, Czech Republic

Abstract— Wheel speed of heavy freight train locomotive under non-ideal traction conditions was measured with very high resolution and fine precision. Many authors published papers in this area over a past century, but only recent advance in information technology enabled measurement in such extent and resolution at the same time.

Most modern locomotives have the speed sensor coupled with the traction motor. Unlike many other authors doing research in area of wheel-slip, in the presented case the wheel speed was measured directly on the wheel, not indirectly on the traction motor. This approach made it possible to observe the wheel speed directly, without the requirement to implement motor — wheel model, which can carry inaccuracies.

Thanks to an independent method of determining train speed using sensitive GPS receiver, wheel slip speeds were identified accurately regardless of synchronous slip phenomenon.

Despite the adhesion theory, three types of operation mode were identified: stable traction with negligible slip without oscillations, semi-stable traction with evident slip and oscillations and prominent wheel slip. As the wheel speed was measured directly on the wheel, much larger oscillations than ever published were revealed. The source of the oscillations is discussed in the paper.

A simple MatLab model of rotational masses was constructed and tuned to match the measurements. Eigenvalues and eigenvectors of the model are discussed, too. The model of rotational masses is completed with adhesion model to perform simulation. The simulation results are presented and compared to the results of measurement.

Abstract— In the study we investigate the impact of polar neutral atmosphere dynamics on the high-midlatitude ionosphere during sudden stratospheric warming (SSW) events. For this purpose the reanalysis data from ECMWF Era Interim and data from high-midlatitude chain of Russian ionosonde stations are used. The results show that the ionospheric response to the SSW events at high-midlatitudes depends on the position of the ionosonde stations relatively to the stratospheric circulation pattern. Two well pronounced effects were found in the study. First effect, observed in January 2009, is a negative effect in the critical frequency (f_oF2) and a positive effect in F2 layer maximum (h_mF2) above the border of stratospheric cyclone and anticyclone with northward flow direction. During six days the ionosphere had sharply inhomogeneous longitudinal structure when ionosondes, displaced on ~ 20 degrees longitude, showed differences ~ 1 MHz in f_oF2 and more than 50 km in h_mF2. Second feature, which was clearly observed in January 2013, implied a positive effect in f_oF2 (up to ~ 2.5 MHz) and a negative effect in h_mF2 (~ 10 km) above the centre of stratospheric cyclone. We suppose that for the first case the effect is caused by upward transport of molecular gas to the lower thermosphere above the region of interaction between two stratospheric jet-streams. In the second case we suggest effect is due to a pull-down forcing of molecular species above the low pressure zone inside the stratospheric cyclone. Changing of O^+/N_2 ratio in the lower thermosphere produced changing of O^+ recombination rate and corresponding variations of ionosphere parameters.

Institute of Solar Terrestrial Physics, SB RAS
Irkutsk p/o box 291, Lermontov st., 126a, 664033, Russia

Abstract— The experimental data of Irkutsk Incoherent Scatter Radar (IISR) pose the non linear inverse problem where the ionospheric parameters (such as electron density, electron and ion temperature, as well as drift velocity and ion composition) can be derived from the experimental autocorrelation functions or energy spectrums. Due to the presence of non linear core in integro-differential equation of IISR data processing this problem can be solved only by the least-square fitting or by statistical methods such as Monte-Carlo algorithms. In our recent research we suggest a new method for solving of multi-dimensional inverse problem for processes that are continuous in time and which have a pre-history of solutions. The typical IISR measurements have as a result the set of lag-products (or spectrums) which can be used for derivation of ionospheric parameters from the solution of a repeatable nonlinear inverse problem respectively to lag-product properties. When this problem is solving for full profiles of parameter, such as attitude profiles of electron density, electron and ion temperatures etc., we have a multidimensional problem which requires from $2N$ to N^2 calculations of objective function per dimension. This requires large computational resources and can be realized practically only on super computers.

In the present study we suggest a new approach to IISR data processing on the base of recently developed algorithm which solves the nonlinear inverse problem in the special projection space where any motion between the projection space noodles can be done along the multi-dimensional simplex grid. This kind of gradient conjugate algorithm has no a significant limitations on problem dimension, it require only $(N+1)$ calculations of objective function per dimension and it can be realized on any usual personal computer systems. The method called simplex-processor is realized on IISR for simultaneous fitting of few tens of spline coefficients that gives approximations for all parameters profiles mentioned above. The simplex-processor method can be implemented to variety of linear and nonlinear inverse problems in many experimental geophysical applications.

Analysis of Speed and Acceleration of GPS/GLONASS Phase in the Polar Ionosphere

V. V. Demyanov[1], **Yu. V. Yasyukevich**[2], **and T. V. Kashkina**[1]

[1]Irkutsk State Railway University, Irkutsk, Russia
[2]Institute of Solar-Terrestrial Physics, Irkutsk, Russia

Abstract— Currently polar ionosphere is of great interest. This is connected with creation of global model of ionospheric storms and providing stable navigation in polar region. Currently dual- and multi-frequency GNSS phase measurements have been utilized widely and these measurements combination yields us current TEC-values along all SV's line-of-sights in view. One of the main parameters is stability of phase measurements and their noise level.

We carry out the GNSS signal monitoring campaign under the polar ionosphere condition (in Taimyr cape, Russia) in 2013. JAVAD Delta-G3T receiver was used. We observed amount of the rapid and sharp phase acceleration variations. The absolute value of these variations were as much as 30–40% up to 2–2.5 times higher in comparison the background level for both GPS and GLONASS signals. In some cases we found a strong positive correlation between the phase acceleration variations and TEC variations in the variation frequency band of 0.08–1 Hz. It is well known that this frequency band relates to the 1-st Fresnel zone sized ionospheric irregularities. On the other hand we found some cases when there was no an obvious correlation between the 0.08–1 Hz TEC-variations and the phase acceleration variations. In these cases the phase acceleration variations could be inspired by the SV's reference oscillator frequency drift.

In order to separate all the observed phase acceleration variations according to they physical origin we arranged a new measurement campaign of both GPS and GLONASS signals in Norilsk (69°N, 88°E) and Irkutsk (52°N, 104°E). Additionally we used Moscow (55°N, 37°E) data. This report is devoted to discussion of the main results of the campaign data treatment.

[3]Lomonosov Moscow State University, Moscow, Russia

Abstract— Along with precision positioning and timing applications, Global Navigation Satellite Systems (GNSS) are widely used nowadays for remote sensing of ionosphere in equatorial, mid-latitude and arctic regions. While estimating absolute total electron content (TEC) using the combination of dual frequency code and phase measurements, a satellite and receiver dependent systematic error occurs. This error is associated with differential code biases (DCB) — the different, frequency dependent processing times of L1 and L2 signals in radio frequency paths, both for satellites and receivers. For example, a 1-ns DCB causes a $\sim$ 3 TECU error in TEC estimation. Due to these DCBs, TEC, in some cases, can obtain even non-physical negative values.

We analyze DCBs dynamics and errors in TEC estimations associated with satellites and receivers DCBs for 2000–2014. For such estimates, we used the CODE laboratory data [ftp://ftp.unibe.ch/aiub/CODE/] as well as the results of our own technique of DCB estimation based on single station data. The systematic variability of the TEC estimation errors associated with DCBs according to our results is about $\sim$ 1 TECU/year for GPS and three times greater ($\sim$ 3 TECU/year) for the GLONASS satellites. There are significant variations in TEC errors for GLONASS with amplitude up to $\sim$ 5 TECU compared to rather small variations for GPS.

Systematic DCBs change both for GLONASS and GPS frequency channels is observed significantly varying depending on the receiving station. For GLONASS and GPS frequency channels, seasonal variations in estimated TEC errors (up to $\sim$ 20 TECU) associated with DCBs are observed. We show that such strong variations could be associated with variations in the receiver environment, especially meteoparameters, such as temperature and humidity.

Variations of O+/H+ Transition Height over East Siberia from Joint Analysis of Irkutsk Incoherent Scatter Data and GPS Total Electron Content

Denis S. Khabituev and Boris G. Shpynev
Institute of Solar-Terrestrial Physics SB RAS, Irkutsk, Russia

Abstract— In the study we compare data on O+/H+ transition height (TH) derived on the base of Irkutsk Incoherent Scatter Radar (IISR) data and GPS Total Electron Content (TEC) with other topside ionosphere models. IISR-GPS technique of TH derivation based on the calculating of difference between TEC and ionospheric electron content derived from IISR Faraday rotation measurements. IISR and TEC data are assimilated in topside ionosphere model based on the modified Chapmen layer with assumption of different scale height for each ion components. Also, the model uses special transition scale height which describes the exponential changing of O+ and H+ ions concentrations.

According to this model we calculate the dynamics of O+/H+ transition height for Eastern Siberia region and compare our results with theoretical models and actual empirical models developed on the base of topside sounding ionosphere data. The comparison shows that practically all topside models have no satisfied agreement between each other especially for daytime conditions. Theoretical models usually overestimate O+/H+ transition height. IISR-GPS technique well agrees with topside sounding data models, but there are sufficiently differences between our results and theoretical models. Direct IISR measurements of transition height that available only below $\sim$ 700 km show that in night time IISR-GPS technique gives more realistic results then theoretical models. We suppose that TH overestimating in theoretical models results from incorrect account for meridional neutral wind effects and plasma flux between ionosphere and plasmasphere. In turn, the underestimation of daytime TH in IISR-GPS technique can be result of assumption that plasmasphere scale height is constant in altitude range above TH and below GPS satellites orbit.

The Study of the Ionospheric Dynamics during Strong Sudden Stratospheric Warmings in the Russia's Arctic Region

A. S. Polyakova, **M. A. Chernigovskaya**, **and A. A. Mylnikova**
Institute of Solar-Terrestrial Physics of Siberian Branch of the Russian Academy of Sciences
Irkutsk, Russia

Abstract— A sudden stratospheric warming (SSW) is a global phenomenon occurring in the winter stratosphere and covering a large area of hemisphere up to the polar latitudes. As a result of this phenomenon an essential breaking of the circumpolar vortex, determining largely the behavior of the lower and middle neutral polar atmosphere in winter, is occurred. Because the state of the high-latitude ionosphere during the winter period is partly determined by neutral processes, it is natural to expect that such global phenomenon as SSW may have an impact on it.

The behavior of the ionosphere in the Russia's Arctic region during periods of strong sudden stratospheric warmings was investigated using the data of the international network of phase dual-frequency GPS receivers, global ionospheric maps (GIM) of the total electron content (TEC) and vertical sounding data. Eight events of major stratospheric warmings that occurred in the Northern hemisphere in the last decade were considered. For identifying the possible response of the high-latitude ionosphere on SSW events the analysis of the total electron content and F2-layer critical frequency deviation from background level was done. Spatial and temporal distributions of the amplitude of diurnal variations of TEC were also studied. It is revealed that diurnal dynamics of high-latitude ionosphere at the points located near the SSW zone during periods of a warming differs significantly from regular. It is also identified that the events of strong SSW are usually accompanied by a decrease of the amplitude of diurnal variations of TEC during the SSW development stage and by an increase of the amplitude, which may be observed up to $\sim 75°$N latitude after the SSW peak.

Abstract— This study deals with ionospheric disturbances caused by the wave-like processes in the lower and middle atmosphere. The ionospheric data were obtained from continuous measurements made at the vertical sounding ionosondes in the high-latitude region of Eastern Siberia, Russia, in 2008–2010. We studied the seasonal variations of the high-frequency part of the $F2$ peak density variability caused by traveling ionospheric disturbances associated with gravity waves (GWs) propagation from the lower and middle atmosphere. The ionospheric disturbances referred to deviations of the maximum electron density N_mF2 from the median values, i.e., deviation of the observed value from a regular behavior.

We identified periods of large-scale wave-like motions in the stratosphere between November and February 2008–2010 based on the ECMWF ERA-Interim reanalysis data. These wave motions were associated with the jet streams at heights of the stratosphere, localized mainly at latitudes 50–80 °N. The waves propagated eastward, generally in latitudinal direction; however, sometimes meridional direction of the wave propagation was observed. It was shown these wave-like disturbances propagate upward from the stratosphere to the mesosphere, with the increase in the amplitude. Propagating up to the atmosphere the waves cause changes in the structure and internal dynamics of the lower thermosphere and ionosphere as travelling atmospheric and ionospheric disturbances.

A noticeable increase in the GWs activity was found at heights of $F2$ layer during the periods of stratospheric wave activity over analyzed region. Satellite temperature measurements MLS Aura confirmed the existence of variations in parameters of the stratosphere and mesosphere, which accompanied by increases in wave disturbances of the $F2$ layer.

Simulation of HF Ground Backscatter Measured by the Ekaterinburg SuperDARN Radar. Comparison with Observations

A. V. Oinats, **K. A. Kutelev**, **and V. I. Kurkin**
Institute of Solar-Terrestrial Physics SB RAS, Russia

Abstract— The Ekaterinburg SuperDARN radar (Ekb; 56.4N, 58.5E) operates in the high frequency band (HF) and can measures the echoes from the ranges of about 180 km to 3500 km. The Ekb antenna system represents a phased array which allows to form a narrow radiation pattern (azimuthal width of $\sim 3.24°$), called "beam", in the 16th azimuthal directions. The width of the radar field-of-view is about 50°. Radar scans sequentially all 16 beams in the standard operation mode. Duration of the whole scan is about 2 min. There are two types of the echoes in radar data: ionospheric scatter and ground backscatter. Ionospheric scatter is typically irregular, because it is caused by HF wave scattering by geomagnetic field-aligned plasma inhomogeneities of decameter scale. Ground backscatter is caused by HF wave scattering by ground surface roughness. Due to ground backscatter is mostly determined by regular change (diurnal and seasonal) of the ionosphere, its behavior is more predictable.

In the paper we study diurnal-seasonal pattern of the ground backscatter characteristics such as minimum slant range, corresponding elevation angle and skip distance. Also we study a behavior of true reflection height, slant range and ground distance to the ionospheric reflection region. Taking into account the Ekb technical parameters, simulation of the mentioned ground backscatter characteristics is carried out in the framework of waveguide approach as well as using ray tracing technique. Global international reference ionosphere model (IRI) is used as a propagation media. We compare simulation results obtained using different calculation techniques with observational Ekb data recorded during 2013–2014. Current study could be used for further correct interpretation of the Ekb data, and also it might be useful for improvement of IRI model predictions.

Correction of the Ekaterinburg SuperDARN Data Mapping Using Ionospheric Vertical Sounding

A. V. Oinats, **K. A. Kutelev**, **O. I. Berngardt**, **and V. I. Kurkin**
Institute of Solar-Terrestrial Physics SB RAS, Russia

Abstract— One of the effective tools to investigate the ionosphere dynamics are SuperDARN radars which operate in the high frequency band of 8–20 MHz. High temporal resolution and wide azimuthal field-of-view of SuperDARN radar allow us to perform effective monitoring of the ionosphere in large spatial region. However HF waves, propagating in the Earth's ionosphere, are strongly affected by refraction. Excluding the refraction leads to significant errors in the SuperDARN data mapping. The errors could reach the magnitude of tens or even hundreds kilometers with regard to the true reflection position. Such accuracy is insufficient for ionospheric dynamics investigations at the present level especially at high-latitudes (auroral and subauroral) where ionosphere is characterized by high degree of variability in both time and space.

In the current paper we study possibilities for the Ekaterinburg SuperDARN (Ekb; 56.4N, 58.5E) data mapping improvement in both quiet and disturbed geomagnetic conditions. To take into account refraction, we apply the simulation of the HF wave propagation using the techniques based on waveguide approach as well as ray tracing. Global international reference ionosphere model (IRI) is used as a propagation media. In order to overcome IRI shortcomings of high-latitude ionosphere representation, we adjust IRI prediction using ionospheric vertical sounding data recorded by a number of high- and mid-latitude stations (Arti, Norilsk, Amderma, Salekhard, Dikson). Different IRI adjustment and Ekb SuperDARN mapping techniques are compared and discussed.

Space Weather Variations and Corpuscular Ionization

Abstract— The ionospheric manifestations of space weather in the northwest Russia and Alaska are analyzed from the ionospheric images reconstructed by the satellite radio tomography (RT). The methods of ionospheric radio tomography based on the low-orbiting navigational satellite systems (LORT) are capable of reconstructing the two-dimensional (2D) distributions of electron density in the vertical plane (height-latitude) above the chain of ground receivers in a wide spatial sector covering a few thousand km. The ionospheric snapshots provided by LORT show the structure of the ionospheric plasma distribution in the studied spatial sector over an interval of 10–15 min. LORT spatial resolution is 20–30 km horizontally and 30–40 km along the vertical.

The geomagnetic storms belong to the most striking phenomena impacting the space weather. A series of the complex ionospheric patterns resulting from various space weather factors were revealed by the RT methods during the geomagnetic storms. We discuss the series of RT images for strongly disturbed geomagnetic conditions during the 23rd and 24th solar cycles. The RT reconstructions demonstrate a number of the features both inherent in all or most of the considered events and specific to the local spatiotemporal conditions. The first group includes complex patterns of the ionospheric plasma distributions with numerous extrema, rapid rearrangement of the ionospheric structure, variations in the position and shape of the main ionization trough, wave and wavelike disturbances, increased ionization in the night-time ionosphere compared to the quiet periods, etc.. The second group comprises rapidly emerging and dissipating isolated irregularities with different shapes and spatiotemporal scales, the ionospheric manifestations of particle precipitation, etc..

We present and discuss the examples of qualitative comparison between the RT cross sections of the ionosphere and the data on the ionizing particle fluxes measured by the DMSP satellites. Based on the comparison of the RT data with DMSP observations, we analyze the effects of corpuscular ionization of the ionosphere. During the periods of the strong geomagnetic storms, the spatial scales of the fluxes of corpuscular injections widely vary from a few to ten degrees along the latitude. The RT images for these periods demonstrate highly structured ionization patterns with numerous extrema and wavelike structures on the scales ranging from a few tens to a few hundred km. Our studies show that the spatial structure of the additional corpuscular ionization, which is observed in the RT ionospheric cross sections, qualitatively agrees with the latitudinal distributions of the fluxes of precipitating particles.

Arctic Ionosphere Imaging and GNSS Tomography

Abstract— For better understanding the nature and mechanisms of the physical processes that occur in the Arctic atmosphere and ionosphere it is vital to have the adequate experimental input for the research. Global Navigation Satellite Systems (GNSS) can be used as one of the sources of these data, whose processing and analysis enables the structure and dynamics of the ionosphere to be explored by different methods including the ionospheric radio tomography. At present, GNSS include the first-generation and second-generation satellite systems. The low-orbiting (LO) Transit and Parus systems belong to the first-generation GNSS. The second-generation systems comprise high-orbiting (HO) satellite constellations such as GPS and GLONASS systems, which are currently in operation; the European Galileo system, which is currently under development; the Chinese BeiDou, and Japanese QZSS satellite systems. The GNSS space segments together with the corresponding ground-based receiving networks make it possible to carry out sounding of the ionosphere along a system of the intersecting fan-shaped ray families and to apply radio tomographic (RT) approaches.

We show and discuss a series of the examples of RT reconstructions to illustrate a variety of the ionospheric patterns observed in different latitudes. For reconstructing these images, we applied the methods of the low-orbiting (LO) and high-orbiting (HO) RT. By combining the advantages of these approaches (the high spatial resolution of LORT together with the extensive spatial coverage and rather high time resolution of HORT), we identified and studied the structure and dynamics of the equatorial anomaly, ionospheric troughs, blobs, fingerlike irregularities and spotty plasma distributions with numerous local enhancements and depletions, patches, wavelike structures, travelling ionospheric disturbances (TIDs), ionospheric displays of the manmade impacts such as rocket launches, explosions, and artificial modifications of the ionosphere by high-power high-frequency radiation or, etc. We analyze the spatiotemporal ionospheric responses in relation to solar activity, natural geophysical impacts (e.g., earthquakes), and seasonal conditions. We present the examples of comparing the RT images with the measurements by the ionosondes.

Emphasis in our presentation is placed on discussing the results of the ionospheric radio tomography above the Arctic. These RT images illustrate various structures, events, and processes associated with the convection and other phenomena. We observed the characteristic ring-shaped irregularities encircling the North Pole, the tongues of ionization, antisunward drift of the ionization patches from the dayside to the night-side ionosphere, etc..

Recently, the input data for the ionospheric studies were expanded by the widely used 2D global ionospheric maps (GIMs) of the total electron content (TEC), which are generated from the IGS data with a thin sheet approximation. We present and discuss the results of comparison between GIMs and RT reconstructions.

Applications of EM Field in Biomedical Technique

Identification of Abnormal Blood Cells Using Scattering of a Focused Laser Beam by a Cluster

Hany. L. S. Ibrahim[1], **Elsayed Esam M. Khaled**[2], **and Ahmed Elsayed Esam M. Khaled**[2]

[1]Telecom Egypt Company, Qina, Egypt
[2]Electrical Engineering Department, Faculty of Engineering, Assiut University, Assiut, Egypt

Abstract—

Introduction: Normal mature red blood cells (RBCs) are shaped as biconcave oblate discs. These shapes can be deformed by several inherited disorders, e.g., spherical, crescent, oval, or any other abnormal shapes [1]. Therefore these deviations are sensitive remarks for various blood disorders and diseases, e.g., malaria and anemia, ... etc. [2]. For this reason, finding such shape deviations is an important research issue and has been studied considerably. In this paper analysis of the modified cluster T-matrix method, as introduced in a previous work [3], is used to calculate the angular scattering intensity of a cluster consists of healthy and abnormal cells illuminated with a focused Gaussian beam. This angular scattering can give good identification of the abnormal cells in the cluster. The technique combines the cluster T-matrix method with the plane wave spectrum method to model the incident beam. We think that this technique is a powerful one to define the diseased RBCs for more accurate diagnostics purposes.

Analysis and Results: Here the technique is applied to real life applications such as clusters of normal and abnormal RBCs. The computed angular scattering of a cluster composed from different cells as shown in Fig. 1(b) is compared with those of a cluster of normal biconcave RBCs shown in Fig. 1(a). Each biconcave particle is of size parameter $x = 10$, refractive index $m = 1.4$ and deformation parameter $\xi = 0.2$. Each abnormal cell presented in Fig. 1(b) (crescent shape) is formulated by a coated spherical cell of an offset core $l = 0.3\,\mu$m, coating parameter $R = a_c/a_s = 0.7$ (where a_c and a_s are the radius of the core and the shell respectively) and refractive indices for the shell and the core are $m_s = 1.4$, $m_c = 1.0$ respectively. The size parameter of the cell is $x = 2\pi a_s/\lambda = 10$. Both clusters of the normal and abnormal cells are illuminated with a Gaussian beam of wavelength $\lambda = 0.6328\,\mu$m and waist $w_0 = 2\,\mu$m. The computed angular scattering is illustrated in Fig. 2 for different cases of clusters.

The first case is for the cluster consisting of five normal biconcave cells. Then the cells are replaced in steps by abnormal cells. The second case is for a cluster consists of four normal (biconcave) cells and one abnormal cell at the edge of the cluster, and so on to sixth case is

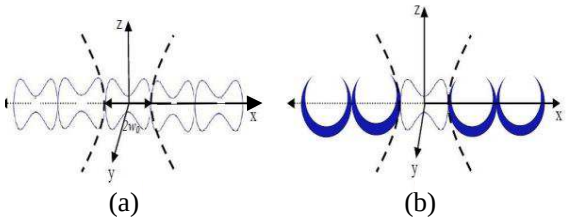

Figure 1: A cluster of different cells centered at the origin of a Cartesian coordinate system (x, y, z). The cells are illuminated with a focused beam of a spot size w_0, and propagating in the z-direction. The considered clusters consist of (a) a linear chain of five identical biconcave cells, (b) a linear chain of four identical abnormal cells, and one centered biconcave cell.

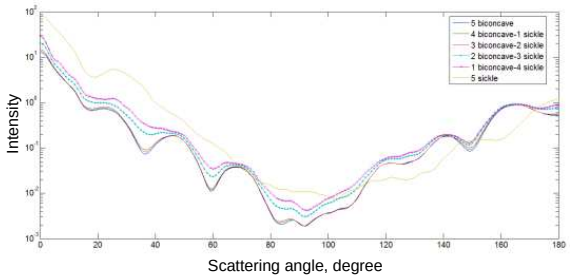

Figure 2: Angular scattering intensities as a function of the angle θ measured from the $+z$-axis for a cluster consists of a linear chain of (a): Case 1, five biconcave cells as illustrated in Fig. 1(a) (blue curve). Case 2, one abnormal cell in one side beside four biconcave cells (green curve). Case 3, two abnormal cells in one side beside three biconcave particles (red curve). Case 4, three abnormal cells in one side beside two biconcave cells (aqua curve). Case 5, two abnormal cells in both side of a centered biconcave cell as illustrated in Fig. 1(b) (purple curve). Case 6, five abnormal cells (yellow curve).

for a cluster of five abnormal cells. The results in Fig. 2 illustrate that the angular scattering intensity of a cluster contains more than 50% of abnormal cells (for example cases 5 and 6) deviate from the intensity distributions of the cluster contains normal cells (case 1). As the number of abnormal cells increases in the cluster of the sample compared with the normal RBCs the angular scattering distributions get more deviation from those of the sample of normal cells and the ripples get smaller. For the cluster of five abnormal cells, the angular scattering intensity has greater front scattering amplitudes compared with those for a cluster of normal RBCs as shown in Fig. 2 (yellow curve).

Emergence of a Traveling Wave Regime on an Unmodified Clinical 3T MRI

Abstract—

Introduction: Traveling wave (TW) MRI holds both promise and challenges to tackling B_1 field inhomogeneity at ultra-high MRI fields [1], which are well above the clinically relevant field strength. At conventional clinical field strength ($< 4\,\mathrm{T}$), TW concept is not easily applied due to the relatively small bore diameter to wavelength ratio (< 0.5). A few earlier demonstrations at 3T includedthe use of coaxial [2], metal plates [3] waveguides, and high dielectric inserts in quasi-static regime [4]. Here, we demonstrate an emergence of TW regime in a large cylindrical phantom at 3T using a simple loop-coil as transmit-receive probe. Using this approach, we generated MR images of a phantom with a large field of view (FOV) and with an SNR comparable to traditional near-field approach. Compared to quasi-static regime, we demonstrate that there is no longitudinal decay of B_1 field over the maximum achievable FOV as limited by the linearity of the gradient coil. The TW concept at clinical fields offers the potential to adapt far-field ideas into clinical applications such as larger FOV imaging, accessing deep region of interest, and mode manipulations via multi-channel TW excitations for B_1 field shaping and homogeneity.

Methods and Materials: Our experimental setup consists of unmodified bore based on a standard unmodified GEMR750 (Waukesha, Wisconsin) 3T scanner with an RF shield that serves asa waveguide ($D = 64\,\mathrm{cm}$), a cylindrical acrylic tube filled with distilled water ($D = 20\,\mathrm{cm}$, $L = 1\,\mathrm{m}$), and a 15 cm-diameter Tx/Rx loop-coil as a probe for mode coupling into/from the guide system (Fig. 1). Such a partially filled cylindrical waveguide allows propagating hybrid EH modes inside a dielectric phantom, or pure axially symmetric TE (TM) modes [5]. In addition to a simple loop coil, we used a modified circular polarized (CP) probe that consists of two loop-coils ($D = 15\,\mathrm{cm}$) placed orthogonal to each other so that each B_1 field is also orthogonal to B_0 [6]. The loop-coils are mounted on an acrylic frame to ensure that they remain orthogonal, hence ensuring that they are completely decoupled with isolation between the loops to measured as $-18\,\mathrm{dB}$. The loops are driven in quadrature using a quadrature hybrid splitter, which divides the transmit signal and recombines the MR signal, connected to the inputs of the coils. A balun is present at each coil input to minimize currents flowing on the cable shields. We obtained images of the phantom placed at is ocenter with a single loop-coil or quadrature coils placed 5 cm from the edge of the phantom and 55 cm away from isocenter. Data were acquired using a GRE pulse sequence, TR/TE = 100/6.8 ms, bandwidth = 15.6 kHz, FOV = 48 cm, 5 mm slice, skip 1.5 mm, 256×256, nex = 8, 7 slices, with a total imaging time of 3 : 28 min; an dB_1 MAP pulse sequence: 25 slices, TR/TE = 46/13.2, bandwidth = 15.6 kHz, FOV = 48 cm, 10 mm slice, skip 10 mm, 128×128, nex = 1, with scan time of 5 : 05 min; GE-EPI sequence: TR = 2 s, TE = 30 ms, bandwidth = 250 kHz, FOV = 30 cm, 10 mm slice, skip 10, 64×64, 8 nex, 0 : 16 min. To confirm the concept and predict the observed mode and B_1 field profile we carried out simulations using FEM eigenmode simulator (COMSOL Multiphysics, Burlington, MA).

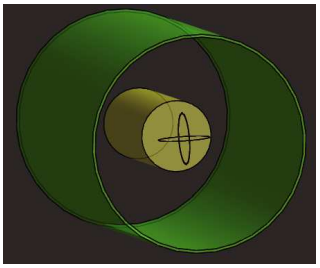

Figure 1: Experimental setup with two possible orientations of single coil, or quadrature coils.

Results and Discussions: Figure 2 shows the experimental and simulation results for our MRI experiment with a cylindrical phantom. For the MRI experiment, we utilized various probe setup geometries: single loop oriented in sagittal, coronal, and tilted by $\sim 20^\circ$ to coronal planes, as well as quadrature coil setup, in order to study how the B_1 field orientation affects the efficiency of RF coupling and the mode inside the cylinder. All the setups produced the same single axially symmetrical mode (TM_{01}) showed in Fig. 2(a) with its distinct feature of a null in the center, contrary to the regularly observed central brightening effects in dielectrics at high fields. The highest SNR of 220 corresponds to the single loop oriented at an angle of approximately 20 degrees to coronal plane and located 5 cm away from the edge of the phantom. All the axially symmetric loop-coil configurations including CP quad-coil, which could be thought as magnetic dipoles, are generally effective for TE mode excitation and less effective for the observed TM mode. The other feature of the observed field pattern is non-decaying propagation of the field along z-axis over the full FOV (48 cm), indicating TW regime. While the persistence of a single,but not the lowest,mode is somewhat surprising from the electrodynamics point of view, the clinical scanner setup is distinctive from the typical screened dielectric waveguides with variety of modes, where the metal screen is adjacent to the dielectrics. In our case, the relatively small diameter dielectric (20 cm) is less coupled to the metal screen, and the pure dielectric waveguide has larger effect on the modes. The B_1 field map shows (Fig. 2(b)) the mode structure with the center null pattern. Our 3D eigenmode simulations (Fig. 2(c)) producea B_1 field that supports the experimental results. The vector map of the field corresponds to TM_{01} mode with a small decaying constant of $\alpha = 1.7 \times 10^{-4}$ that is inherent to complex hybrid modes inside high dielectric materials [5]. We also show that our TW concept is capable of generating relatively high quality images with other clinical sequences such as GE-EPI as shown in Fig. 3.

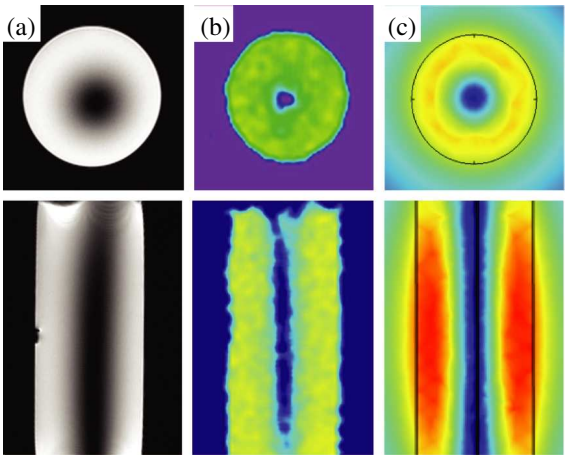

Figure 2: Images of TM_{01} mode in cylindrical phantom (FOV = 48 cm): (a) experimental MRI; (b) experimental B_1 field map; (c) simulations of B_1 field, axial — top row, sagittal — bottom row (arb units).

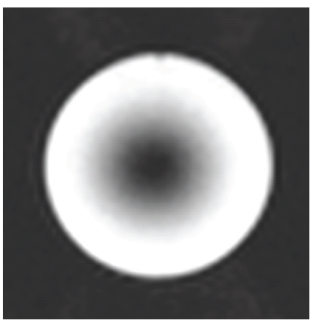

Figure 3: EPI axial TW-MRI image of cylindrical phantom.

Conclusion: We have demonstrated MR imaging with TW concept using an unmodified clinical 3T MRI scanner as an under-moded RF waveguide. The MRI images of a large cylinder are comparable to the ones obtained with TW imaging at ultra-high field strength (7T) [1] and with an SNR comparable to conventional near field coils. Our demonstration of TW in a dielectric

waveguide applicable to aclinical field strength (3T) may result in a more robust large FOV imaging acquired in relatively less time in a clinical setting, as well as new applications in deep tissue imaging of hard to access areas. The presented analysis is relevant to understanding high field artifacts in human torso observed with similar scanning conditions. Future directions include designing probes and guide structures for high efficiency excitation of TW in the bore, mode propagation in human body, and RF field profile control with meta-materials or artificial dielectrics.

Waveguide Hyperthermia Applicator with Circular Polarisation

I. Merunka, O. Fiser, L. Vojackova, and J. Vrba
Department of Electromagnetic Field, Czech Technical University in Prague, Czech Republic

Abstract—

Introduction: In this contribution we present a circular waveguide applicator with circularly polarized wave at its aperture. In our previous contributions, where we studied UWB antenna and its application to microwave hyperthermia [1], we observed polarization of dielectric on the interface between spherical phantom of tumour and phantom of human breast in numerical simulations. This phenomenon causes hotpots on the interface while the temperature inside of the tumour does not even reach the therapeutic level. Using of a circularly polarized hyperthermia applicator could at least partially solve this issue.

Materials and Methods: Circular waveguide was virtually filled by distilled water and designed to work perfectly on frequency 434 MHz [2]. In order to get circularly polarized wave at the aperture, polarization plate was inserted into it [3]. Waveguide hyperthermia applicator was facing to the water bolus ($\varepsilon_{\mathrm{rel}} = 80$, $\sigma = 0\,\mathrm{S/m}$) of thickness of 2 cm followed by human breast phantom with average dielectric parameters ($\varepsilon_{\mathrm{rel}} = 10$, $\sigma = 0.8\,\mathrm{S/m}$). Moreover, there is also spherical phantom of tumour ($\varepsilon_{\mathrm{rel}} = 49$, $\sigma = 0.79\,\mathrm{S/m}$) with radius of 1 cm placed 0.5 cm under the breast phantom surface. This configuration can be seen in Fig. 1. Numerical simulations of electromagnetic field were performed in SEMCAD X 14.8.6 Aletsch (Schmid & Partner Engineering AG, Zurich).

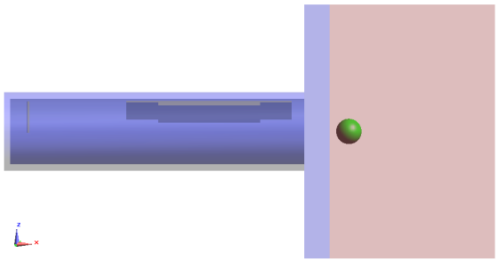

Figure 1: The applicator and configuration of numerical model.

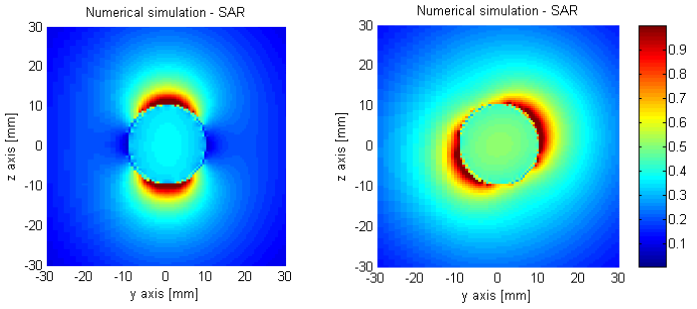

Figure 2: SAR [W/kg] in the cross section of the tumour phantom. (a) Without polarizer, (b) with polarizer.

Results: Specific absorption rate (SAR) in the cross section of the tumour is depicted in Fig. 2. There is a comparison between the SAR obtained by applicator with the polarizer and without the polarizer. Circularly polarized field helped to cover the tumour by SAR from all directions. On the other hand, the effective penetration depth decreased and the ability of focusing microwave power by using a multi-antenna array is also limited with this kind of hyperthermia applicator.

Study of Hot Spots by Oncological Patients with Metal Implants in Head and Neck Region

Ondrej Fiser, Ilja Merunka, Lucie Vojackova, and Jan Vrba
Department of Electromagnetic Field, Faculty of Electrical Engineering
Czech Technical University in Prague, Czech Republic

Abstract— The purpose of this contribution is to study the risk of unwanted hotspots around metallic implants in head and neck area of the new waveguide applicator system and thereby to increase the safety for patients with metallic implants. Metallic implants may interact with the EM field. The reaction rate depends on the implants dimensions [1]. The next objective is to find solution how to reduce hotspots around metallic implants.

Applicator System: We developed a new applicator system intended for microwave hyperthermia in head and neck area (see Figure 1). The applicator system is constructed from four equal waveguide applicators. They are water filled waveguide applicators with strip line horn aperture. The suitable working frequency for this type of applications is 434 MHz. By amplitude and phase combination of each applicator we are able to steer the field and cover the most of treated tissue.

Methods: Metal implants like wires, titan screws or stents are often considered as contraindication for microwave hyperthermia. We choose three different metal implants, which are commonly used in surgery.

- Stent in esophagus or in carotid artery;
- Screws in cervical vertebras;
- Cochlear implant.

In the numerical model the considered metal implants in different positions were inserted. An example model is shown in the Figure 2. For numerical simulations SEMCAD X Aletch 14.8 and human model part of the SEMCAD X models database [2]. For our purposes the human model Ella from Virtual Family 1.2 was utilized. All dielectric and thermal parameters of the model were taken from IT'IS foundation materials database [3]. For comparison and evaluation specific absorption rate [W/kg] and temperature [°C] analysis in human body are used.

Conclusion: In this contribution a study and reduced solution proposal of potential hot spots around metal implants of new type applicator system are performed.

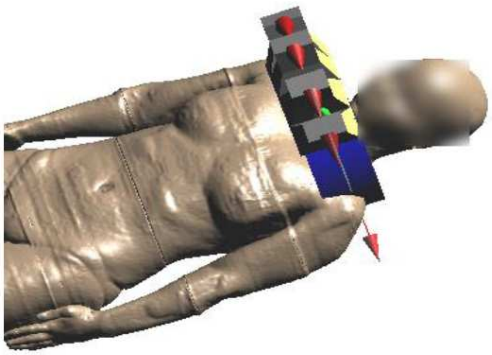

Figure 1: Applicators position.

A Couple of Methods for Power Focusing of Vector Felds in Non-homogenous Media

D. A. M. Iero[1], **L. Crocco**[2], **and T. Isernia**[1, 2]

[1]DIIES-Università Mediterranea di Reggio Calabria

Abstract— Power focusing in non homogeneous media is a canonical problem relevant in many applications such as hyperthermia [1] and targeted drug delivery [2]. In these cases, the overall intensity of the electric field has to be focused in a given target point while possibly keeping the field intensity as low as possible elsewhere.

In this communication, we report about two different strategies we have developed to tackle the problem of focusing transverse electric vector fields, when the primary sources, fed by monochromatic signals, surround the 2D region under test. These approaches apply to generic vector fields so that they can be easily extended to tackling the electromagnetic focusing problem in 3D scenarios.

One of the developed focusing method relies on the well known Time Reversal (TR). TR is a spatial/temporal re-focusing technique, which was originally developed to focus ultrasonic (scalar) fields [3] and recently extended to electromagnetic (vector) fields [4, 5]. An overlooked aspect of electromagnetic TR is the influence of test source polarization, used during the sensing phase, on the overall focusing performance. The common choice of a linearly polarized test source (along the x or y axes) is, indeed, equivalent to focusing just one component of the field and, hence, it affects the focusing performances as the other component does not cooperate to the field focusing phenomenon. Therefore, using a suitable elliptically polarized test source is advisable as it corresponds to a proper combination of the two field components and can produce a better focused field. In this respect, we have developed a simple, general and efficient procedure aimed at optimizing the selection of the test source polarization according to the application requirements.

Although the above method outperforms the more usual TR version, it still cannot guarantee that the field intensity is below assigned (application induced) bounds in the regions outside the target area. To this end, we have developed an extension to vector fields of the focusing technique applied to scalar fields, presented in [6, 7]. It is interesting to note that the method can be interpreted as a (constrained) optimization of the field polarization in the target point. More details on the two methods and some comparisons will be shown at the conference.

Biological Signals Transmitted by a Resonant L-C-oscillator; Transmission Controlled by Measuring the Growth of Plants

Konstantin Meyl[1] **and Heide Schnabl**[2]

[1]Faculty of Computer and Electrical Engineering
First Transfer Center of Scalar Wave Technology (1.TZS), Germany
[2]Institut für Molekulare Physiologie und Biotechnologie der Pflanzen (IMBIO)
Universität Bonn, Germany

Abstract— In the experiments presented the effects of transmitting information derived from the growth hormone gibberellic acid (GA) to peas over a distance of some meters have been measured. Transmission of the biochemical characteristics of GA was achieved through a carrier wave of approximately 6.78 MHz running along a copper wire comparable to a strip line from the gibberellic acid as the source of information to the exposed peas, which reacted by a statistically significant enhanced root growth. The measured averages of the germinating pea root lengths were compared to control values, i.e., values corresponding to untreated peas. While continuous GA transmission resulted in an average increase of root length by approximately 50–60%, a singular burst of 15 minutes could increase roots' length by an additional 42%, raising the increase relative to the control group by as much as 125% in total. Both values could be established with very high statistical significance. In a third experimental setup, the peas were treated instead of a GA-signal, with an apoptotic signal produced in *two* different ways: with a pulse carrying the information of peas (a) either stored anaerobically (48–100 hours) or (b) peas macerized and therefore decomparmented. The almost total inhibition of root growth showed, again with high statistical significance, that an information transmission must have occurred remotely. The molecule hypothesized should be *cytochrome c*, released by the stress occurring during the apoptotical process. Some hypotheses in technical as well as in biological respect are being discussed.

Novel Microwave Applicators Inspired by Metamaterials for Hyperthermia Treatment of Cancer

D. Vrba and J. Vrba, Jr.
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— In this paper, three novel microwave applicator prototypes based on zero-order mode resonators are proposed for use in hyperthermia treatment of cancer. The ability of all three applicators to homogenously irradiate muscle tissue-equivalent phantoms is demonstrated with results of numerical simulations, and relative performance of the applicators is compared.

Based on previous research [1], it can be stated that metamaterial (MTM) Zeroth-Order mode resonators (ZOR) can provide improved thermotherapy for cancer in several ways, by improving the homogeneity of electromagnetic (EM) power absorption, the depth of EM wave penetration, and offering the possibility of either homogeneous treatment of very large areas or conversely focusing EM power into well-defined small areas [2].

New capabilities include, among others, the creation of electrically small applicators that can work without water filling. This could facilitate the delivery of microwave hyperthermia treatment simultaneous with 3D monitoring of temperature distribution in the patient with Magnetic Resonance (MR) thermal imaging.

Another advantage of MTM technology is that this phenomenon enables the creation of a special kind of resonator whose physical length is completely independent of the classical resonance condition (wavelength). This allows us to design the applicator with dimensions matching the clinical need and as a result of the spatial arrangement of MTM resonators we are able to radiate an almost perfect electromagnetic plane wave into the treated area. This improvement in wave propagation produces the advantage of optimizing homogeneity of power deposition within the target tissue region resulting in an improved temperature distribution throughout the treated area.

All three applicators are designed for use at 434 MHz and have similar working principle. Thanks to the excitation of zero-order mode, vectors of surface current density in all inductive parts of the proposed applicators show approximately the same magnitude and phase. The radiated contributions from the all inductive parts of the applicator are in good superposition as they exit the front aperture of the applicator and combine in phase in tissue. This allows the Huygens principle to be applied to describe the resulting EM field distribution in tissue.

ACKNOWLEDGMENT

Phased Arrays Pre-treatment Evaluation in Antitumoral Hyperthermia

Piero Tognolatti[1] and Fernando Bardati[2]

[1]Department of Industrial and Information Engineering and Economics, University of L'Aquila, Italy
[2]Department of Civil Engineering and Computer Science, University of "Tor Vergata", Rome, Italy

Abstract— There is general consensus that quality of hyperthermia treatment is a key factor for clinical effectiveness. A correlation between clinical outcome and thermal dose parameters has been shown. The optimal treatment is defined by efficient tumor heating without patient discomfort by hot spots. To improve hyperthermia treatment quality, optimization of SAR or temperature distribution in the tumor by hyperthermia treatment planning (HTP) is considered before or during treatment. HTP procedures start with tissue map acquisition, then various heating modalities are explored and compared by solving the appropriate electromagnetic (or ultrasound) problem, depending on the equipment in use. Finally the temperature distribution is found for treatment pre-evaluation. However, due to the more complex thermal characterization of vascularised tissues and organs, temperature increase modeling is generally omitted and the optimum problem is formulated in terms of SAR. As the robustness of electromagnetic solvers has increased importantly over recent years, the presently available systems provide excellent opportunities to perform SAR characterization as a start point for SAR optimization. Radiating systems that are currently used to heat deep seated tumors include phased arrays of elementary radiators (dipole, waveguide or microstrip antennas) for which SAR-optimization based HTP is pursued by amplitude and phase setting.

Objective functions have been proposed for SAR optimization according to various quality indicators. They include maximum absolute SAR and SAR homogeneity in the target both to be optimized as well as hot spots to be minimized. The power deposited in the tumor as a fraction of the generators power and of that delivered to the patients body are further indicators. For given array, patient and lesion to be heated, evaluating whether or not the array is able to heat the lesion in accordance with prescribed quality indicators is a somehow different problem a solution of which logically precedes HTP. Only in case of positive answer the search for optimal feed settings will be meaningful. The purpose of this paper is to propose means to exploit in this pre-evaluation. Since the electromagnetic solvers decompose the whole body exposed to radiation (both tumor and healthy tissues) into elementary cells, it is natural to treat each cell as a target and to evaluate the maximum SAR deliverable by the array to that cell. At this stage it is sufficient to know that a feed setting exists that is able to deliver such a maximum SAR to that cell. Repeating this for all cells of the body provides maps of *heatability* that can be used to investigate maximum SAR and SAR uniformity, if the cells belong to a tumor, or to delineate hot spots. Since power deposition is limited by the largest available power from amplifiers referred to as *nominal power*, the latter will be included in the optimization problem.

The paper is organized as follows. Two optimization methods with the constraint on amplifier nominal power are presented. Quality parameters related to systemic heating, tumor heating uniformity and hot spot are introduced. Then a voxel-based numerical analysis is performed for 8 dipoles on two rings, positioned around a head/neck volume within a distilled-water bolus

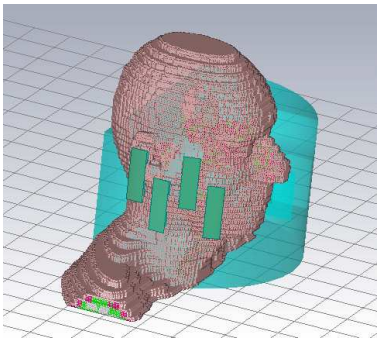

Figure 1: Array of 8 dipoles on 2 rings around a head/neck phantom.

(Fig. 1). Then an extended target, i.e., a 60 ml sphere in central position (oropharynx), is considered. Amplitude and phase settings that are obtained by optimizations are compared on the basis of the maximal absolute power delivered to the target and the other quality parameters that have been previously defined.

Some generators are kept off during a treatment due to unavailability or maintenance of amplifiers or even to awareness that a subset of the available radiators suffices to heat a target. In conclusion, heatability will be discussed in presence of such array thinning.

Complex Permittivity Measurement in Hyperthermia Treatment Planning

Jaroslav Vorlíček[1], **Ladislav Oppl**[2], **and Jan Vrba**[2]

Czech Technical University in Prague, Technicka 2, Prague, Czech Republic

Abstract— The goal of hyperthermia cancer treatment is to raise the temperature of the targeted tissue area. Thus, temperature can be maintained above 43°C for up to one hour. To evaluate the expositions of microwave radiation from thermo-therapeutical microwave applicators, we need to know the dielectric properties of the tissues. This can be performed using measure of the complex permittivity of the tissues in the desired area of the treatment. For this purpose, we constructed a sensor based on the coaxial transmission line for measuring the complex permittivity. Measurement method on an open-ended coaxial line is based on the reality that the reflection coefficient of an open-ended coaxial line depends on dielectric parameters of material which is attached to the coaxial line. For calculation of biological tissue dielectric parameters from the measured reflection coefficient, it is necessary to use an equivalent circuit of an open-ended coaxial line. The values of elements in the equivalent circuit depend on the dielectric properties of the material attached to the end of coaxial line.

To determine the values of elements in an equivalent circuit, we use calibration by means of material with known dielectric properties. Open-ended coaxial probe has a capability of broadband measurements and simple sample preparation. Also, its nondestructive nature and capability for in-vivo measurements provide open-ended coaxial probes with a significant advantage over other techniques for biological applications. There have been many techniques to correlate the measured input admittance to the complex permittivity of the sample material, which resulted in significant improvement in the extraction process. Accurate measurements of the complex permittivity of biological tissues gain great importance in both basic and applied research.

The performance of this system was evaluated by measuring of the deionized water. The measured data were compared with the value calculated by Debye's model. The relative errors between the measurement and the calculation were less than ±4%. The reliability of this method was confirmed by the measurement of deionized water in wide frequency range.

Feasibility Study of Microwave Interstitial Applicator Array for Treatment Pancreatic Cancer

Lucie Vojackova, Jan Vrba, Ondrej Fiser, Ilja Merunka, and Katerina Cervinkova
Department of Electromagnetic Field, Faculty of Electrical Engineering
Czech Technical University in Prague, Czech Republic

Abstract— The aim of this paper is to check a possibility of usage of interstitial helix applicators for a treatment pancreatic cancer by microwave hyperthermia. The typical characteristics of pancreatic cancer are little chance for a complete cure, high mortality and in the majority cases a tumor is considered inoperable due to local spread or presence of metastatic disease. The finding a new possible alternatives to a classical approach is highly important. Thus, this work is focused on the simulation of the hyperthermia treatment.

The simulation for three different frequencies 434, 915 and 2450 MHz were performed in the simulation program of electromagnetic field SEMCAD X [1]. As the applicators were considered interstitial, the first requirement for helix applicators design was made them thin as much as possible. For the later possible realization thin enough coaxial cable was chosen. Simultaneously the coaxial should be sufficiently "thin" to allow wind the turns of helix antenna on the dielectric coaxial cable without necessity to use a special winding technique.

A diameter of helix was clearly established by the choice of coaxial cable. For the individual frequencies only a length of helix and number of turns were changed. The second step, after selecting the suitable coaxial cable was the impedance matching of helix applicator for the aforementioned frequencies. First, the only one helix was placed in a simple homogeneous phantom with dielectric parameters of pancreatic tissue. The checked characteristic was the impedance matching respectively SWR (Standing Wave Ratio). For achieving the best SWR the length of helix and number of turns were changed gradually for single frequencies. It means, every frequency had its helix with specific dimensions after the optimization.

In the next step were done the simulations of SAR (Specific Absorption Rate), already by using the matrix of helix for frequency 434, 915 and 2450 MHz. The first SAR simulations were performed in a simple homogeneous phantom with dielectric parameters of the pancreas as well as by detecting the SWR. After obtaining satisfactory results for so called simple homogeneous model, another simulation of SAR was done for anatomical model. For simulation procedure was used "High-Resolution Human Models for Simulations: Virtual Population" which, together with the dielectric parameters, comes from the pages IT'IS Foundation [2]. In our case it is a virtual family member "Duke" — 34 year old man. For the simulations were considered only bodies in the immediate vicinity of the pancreas, as the proposal for frequencies assumed location 4 applicators around the pancreas. Using SAR values allows us to calculate very precisely extent of the exposure of biological tissue. By different frequencies respectively the lengths of helixes it was possible to affect approximately the size of the area and its volume, which would achieve the highest temperatures respectively the greatest heat.

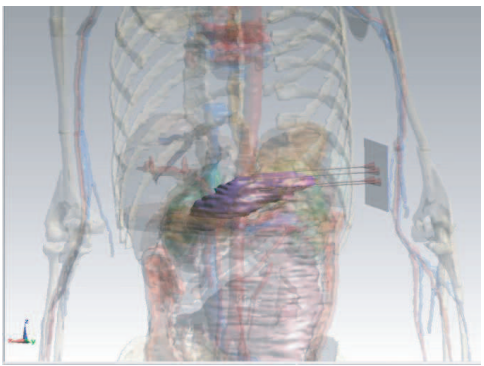

Figure 1: An anatomical model with the highlighted pancreas (violet) and the applicators.

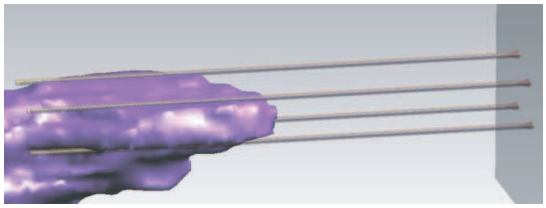

Figure 2: Detail of placing the helix applicators around the pancreas.

Microstrip Antennas and Defected Ground Structure (DGS) Filters

A Microstrip Line with Additional Capacitive and Inductive Effects Loaded

Jongsik Lim[1], **Kyunghoon Kwon**[1], **Seungwook Lee**[2], **Seok-Jae Lee**[1], **Sang-Min Han**[1], **Dal Ahn**[1], **and Yongchae Jeong**[2]

[2]Chonbuk National University, Republic of Korea

Abstract— Microstrip line depicted in Fig. 1 is one of representative transmission lines, and its characteristic impedance (Z_o) is proportional to the ratio of the equivalent inductance (L) to capacitance (C) per unit length with the mathematical expression of ($Z_o = \sqrt{L/C}$). If a perturbation structure is added to the normal microstrip line, the additional parasitic inductance and capacitance arise and make the characteristic impedance change from the normal value. The changed characteristic impedance depends on the property of the added perturbation structure, so Z_o would increases or decreases depending whether the perturbation is an inductive or capacitive structure, respectively. Fig. 2 shows SIAD (substrate integrated artificial dielectric) structure proposed by Coulombe et al. in 2007. This structure has a lot of metalized via-holes through the second dielectric substrate. One of major effects of SIAD falls on the increased equivalent capacitance. The realizable limitation of the characteristic impedance goes down further to the lower side if SIAD is added. This means when a specified characteristic impedance of microstrip line is required after SIAD has been combined, the line width maybe much thinner than normal one, so sometimes it is necessary to compensate the line width. Fig. 3 is a defected microstrip structure (DMS), which has the additional equivalent inductance per unit length. If a DMS pattern is inserted alone on the microstrip line, characteristic impedance increases. It means one need to enlarge the line width to keep the same specific characteristic impedance. When SIAD and DMS structures are combined to a normal microstrip line as illustrated in Fig. 4, the characteristic impedance and line width are preserved similarly to the normal ones while the advantages of adding perturbation structure such as the increased slow-wave effect and enlarged electrical length. These advantages are fruitful in reducing the physical length of a fixed specific electrical length. Fig. 5 shows dimensions of DMS as example in this work. One can compare the physical lengths of four microstrip lines for the same frequency (1 GHz) and fixed electrical length ($\lambda/4$) in Table 1.

Applications of Artificial Magnetic Conductors to the Innovative Design of Various RFID Tag Antennas

D. Kim
Department of Electronic Engineering, Sejong University
209 Neungdong-ro, Gwangjin-gu, Seoul 143-747, Korea

Abstract— We propose a new and advanced design method of RFID tag antennas. The proposed approach is very simple and differentiated from conventional design ways that mostly need highly complicated geometry of tags in order to obtain good impedance matching between RFID chips and the tags.

In our method, we exploit distinctive phase behaviors of reflected waves from versatile artificial magnetic conductors (AMC). As is well known, one of the most attractive characteristics of the AMC is its readily controllable response of reflection phase. As a matter of fact, we can obtain any required phase values between $+180^\circ$ and -180° by changing dimensions of the AMC, which can be directly integrated into our tag design.

According to target applications, we categorize our design approaches into three types; low-profile tags, tags for long reading distances, and those for dual frequency bands.

For the low-profile applications, we install the tag with a RFID chip right on the AMC that is used as a ground plane. Therefore, the low-profile tag is inherently platform tolerant, which means the tag is directly attachable on the various target objects including metal and high-dielectrics with almost no degradation in its performance.

The other two tags are built in metallic cavities with an AMC ground, in which we use coupling effect among the tag, the cavity, and the AMC ground plane so that we can acquire good impedance matching. Consequently, we can avoid figurational complexity of tags. In addition, for the dual-band application, we use two symmetric phase values with respect to the zero phase, at which there is no difference from $+180^\circ$ or -180°, respectively.

All the tags show relatively good agreement between prediction and experiment, which proves that our proposal is practically useful in the design of RFID tag antennas.

Design of the Wide-tuning-range Notch Filter with Wide Constant Absolute Bandwidth

C. W. Tang and W. M. Chuang
Center for Telecommunication Research, Advanced Institute of Manufacturing with High-Tech Innovations
Department of Cmmunications Engineering, National Chung Cheng University, Taiwan

Abstract— Recently, due to the rapid development of wireless communication systems, there are growing demands for filters with good performance of filtering. Moreover, in order to track the operating frequency, frequency-tunable filters are often used for the multiband communication systems, wide-band radar systems, and measuring instruments. Compared with the conventional filters, tunable filters are more functional. Moreover, the same hardware can be utilized for various bands.

Bandstop filters can easily suppress spurious responses and distinguish weak signals from the interference. Moreover, with the tunable bandstop filter, the requirement for high selectivity of the bandpass filter can be diminished. Therefore, the tunable bandstop filters have gained a lot of attention. Because the channel bandwidth is usually fixed even with varying carrier frequencies, the constant absolute bandwidth is crucial for the filter design. The bandstop filters with multi-staged T-shaped cell have been studied. It is found that the more the LC resonator pairs there are, the wider the stopband bandwidth there is. However, when tuning the central frequency, a constant absolute bandwidth cannot be sustained with the T-shaped structure adopted for the bandstop filter. On the contrary, a wide and constant absolute bandwidth is obtained in this paper because the π-shaped circuit is employed for the design of the bandstop filter. This tunable filter is composed of two varactor-tuned resonators, shunted at input/output ports separately, and one quarter-wavelength transmission line connecting two varactor-tuned resonators. These two varactor-tuned resonators are arranged symmetrically, and realized by a varactor and an inductor with series connection. Moreover, the varactor is introduced to control the central frequency within the stopband. Significantly, we provide easy methods to increase the absolute bandwidth of the stopband by enlarging impedance of the transmission line section and adopting larger values of the ripple in this study. Moreover, the higher the order of the bandstop filter is, the sharper the roll-off stopband will be.

A Simple Tunable Filter Antenna Design with No Bias Lines

M. Al-Husseini[1, 2], K. Y. Kabalan[2], and A. El-Hajj[2]

[1]Beirut Research & Innovation Center, Lebanese Center for Studies & Research, Lebanon
[2]Electrical & Computer Engineering Department, American University of Beirut, Lebanon

Abstract— Existing tunable antenna designs are complex and many of them use a large number of switching elements. Even the less complicated ones still require external DC bias lines to control the employed RF switches or varactors. The design of these bias lines is a daunting task since their presence affect the antenna properties.

In this work, a simple design of a tunable filter antenna is presented. The design uses a single varactor and does not require any external DC bias lines. The design is based on a basic ultra-wide-band antenna with a microstrip line feed, a partial ground plane, and a rectangular patch with rounded corners. A rectangular ring slot is etched in the ground plane beneath the feed line. One varactor is mounted over the ring slot, transforming it into a single-ring complementary split-ring resonator (CSRR). In this configuration, the CSRR causes a tunable band notch whose frequency depends on the varactor's capacitance value. A narrow cut is then made to the feed line, which acts as a capacitor and transforms the band stop caused by the CSRR into a band pass. A shorting is made, through the substrate, to connect the section of the feed before the cut and the inside of the CSRR in the ground plane. This shorting serves to improve the band-pass behavior and to relay the DC voltage to the CSRR's varactor. A DC voltage is applied at the antenna's feed, mixed with the RF input using a DC bias tee. Due to the shorting, the inside of the CSRR is at this same DC voltage level, putting the varactor between two different DC voltage regions. The capacitance value of the varactor is thus controlled by changing the DC voltage at the bias tee input. The cut in the feed prevents the DC current from flowing into the patch.

A prototype antenna is fabricated and tested. Its geometry is shown in Fig. 1 and the measured reflection coefficient is given in Fig. 2 for several reverse DC voltage values. Clear frequency tunability is achieved, in this case over a 1 GHz band. The antenna has good gain values and omnidirectional patterns. The detailed configuration and results will be presented in the full paper.

The Golden Spiral Antenna

Bhaskar Harsha, **G. S. Kartikeya**, **Praveenkumar Patil Kedar**, **and Gowda N. G. Monish**
Antenna Research Laboratory, BMS Institute of Technology, India

Abstract— In this paper the possibility of a golden spiral antenna which is derived from the Fibonacci series is applied to a patch antenna and is investigated. It was found that for the substrate dimensions of 14.4 cm × 8.9 cm (144 being the 11th successive number of the Fibonacci series) 13 resonating bands in the range of 1 GHz to 8 GHz without the application of the EBG structure was found. The return loss graph for six different iterations of different substrate dimensions based on the successive numbers of the Fibonacci series is investigated. For the substrate dimensions of 14.4 cm × 8.9 cm mentioned above, Electromagnetic Band Gap (EBG) structures are positioned in the ground plane of the golden spiral antenna. Slotted EBG structures are used to enhance the gain at a particular frequency. As a consequence of this it was found that gain of the Golden Spiral antenna from 1.09 GHz to 2.5 GHz and 6.0535 to 6.25 GHz was increased by the addition of the EBG structures. A peak gain of 15 db and 9.2 db was found at 1.98 GHz and 6.18 GHz respectively.

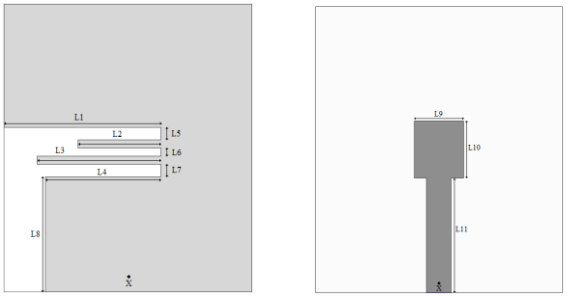
Abstract— Electromagnetic Band-Gap (EBG) Structure is an area of study in which researchers are growing interested and are investigating. Loading EBG to antennas imparts, to the antennas, many properties including surface wave suppression, band rejection or increased gain. But there has not been much research on fractals loaded as EBG. The amalgamation of these two areas of research is yet to be explored. Implementation of Sierpinski Gasket Fractals as Electromagnetic Band-Gap (EBG) Structures on a multiband planar patch antenna, for WLAN/WiMAX applications, is investigated in this paper. An L Slot Patch Antenna is selected as the test antenna for the fractals to be loaded as EBG. This antenna has a FR4 epoxy substrate of thickness 1.6 mm with a dielectric constant 4.4 and loss tangent of 0.02. The overall dimension of the patch antenna is 35 mm × 30 mm × 1.6 mm. Fig. 1 shows the top and bottom view of the antenna along with the point of excitation represented by X in the figure. Initially, the gain of the patch antenna over the frequency range of 2 GHz to 5 GHz is measured for reference and comparison. Before introducing the EBG structures, the gain of the patch antenna is measured to be 2.38 dB. Later, different iterations of the fractals are loaded as EBG onto the antenna in different configurations. The results obtained, with and without EBG structures, are compared and studied. A peak gain of 2.51 dB is obtained after introducing the fractal structures in the antenna, in one of the various proposed designs which is shown in Fig. 2. The results obtained are depicted in Fig. 3. Thus, this paper illustrates a novel approach of Sierpinski Gasket Fractals to be loaded as EBG.



(a) Top View (b) Bottom View

Figure 1: $L1 = 19$ mm, $L2 = 10$ mm, $L3 = 15$ mm, $L4 = L8 = L11 = 14$ mm, $L5 = L7 = 1.5$ mm, $L6 = 1$ mm, $L9 = 6$ mm, $L10 = 7$ mm.

Antenna Design:

Fractals loaded as EBG around the patch: Fractals were arranged around the patch on the bottom plane of the substrate. Parametric analysis is done and the side length of the fractals is varied from 3 mm to 4.5 mm, the gap between the fractals is varied from 7 mm to 11 mm and the orientation of the fractals is changed from 0° to 180°. The design is shown in Fig. 2.

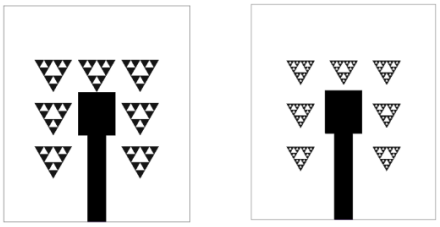


Figure 2: Fractals loaded, around the patch, on the bottom of the antenna.

Results and Discussion:

Fractals loaded as EBG around the patch: The third iteration of the fractal structures are analyzed in this design. After the parametric analysis, it is found that the peak gain of the third iteration fractal loaded design is 2.51 dB.

Improvement in Planar Array Antenna Performance by Using Center-fed Coaxial-to-SIW Transition and UC-EBG Structure for 60 GHz Wireless Communication

Ehsan Ghahramani, Ramazan Ali Sadeghzadeh, Mahmood Karami, and Behzad Boroomandisorkhabi
Faculty of Electrical and Computer Engineering, K. N. Toosi University of Technology, Tehran, Iran

Abstract— Microstrip patch antennas (MPA) are widely used in modern communication systems, because of low profile, conformability to planar or curved surface, low cost and light weight. Therefore, they are a good candidates for low cost Microstrip millimeter wave (MMW) applications. But these antennas have low efficiency and low gain because of having small size and high conductive losses. To overcome this problem, the waveguide resonance slot antennas are employed. These antennas have high gain, high cross-polarization and low side lobe levels. But there are some disadvantages with these antennas. Heavy weight and high price are two of these disadvantages. By using substrate integrated waveguide (SIW), these problems can be solved. In this paper, the performance of a conventional two-layer 2×2 SIW-fed MMW MPA array is improved using new center-fed coaxial-to-SIW transition and UC-EBG structure. In recent years, Electromagnetic band-gap structures have become more interesting because of having desirable properties. Suppressing undesired surface waves on the antenna, increasing the antenna gain and reducing mutual coupling between antenna radiation elements are some of these properties. In this paper, first, process of substrate integrated waveguide (SIW) transition line designing is discussed and then a novel coaxial to SIW transition structure introduced since employing microstrip line for feeding millimeter wave antenna in commercial use is not appropriate because of internal losses. Finally, the gain and side lobe level of proposed antenna are improved by using surface wave suppression properties of EBG structure in antenna. If antenna center frequency has been in the UC-EBG band-gap areas, mutual coupling, antenna gain and side lob level will be improved effectively. Presented antenna model is offering good impedance bandwidth (900 MHz) and boresight Gain (> 11.7 dB). The proposed configuration is simulated using CST Microwave Studio.

S-band Proximity Coupled Patch Antenna Based on TiN/Ag Multilayer Material

Abstract— One of the challenges in the development of antennas is their resistance to the environment and corrosion, which is extreme on shore or cost region due to humidity and corrosion agent such as chlorine and sulphides. On the other hand, there is a trend and increase use of planar antennas due to their low profile, integration capability and size for high frequency and wideband applications. The conventional structures for these antennas consist of a dielectric substrate and two separate conducting layers. The latter are implemented with copper and a resin protection cover. However, this structure is not always convenient to endure the stringent conditions of a costal city. For this purpose, it is well known that Titanium nitride (TiN) has important properties as high hardness and high corrosion resistance. Nevertheless, its electrical resistance is high and not convenient for antenna use. Due to this, a multilayer material consists of TiN and silver was grown on Alumina substrate by using DC magnetron sputtering, resulting in a conductive material with corrosion-resistance properties.

In this paper, a first antenna design with this TiN/Ag multilayer material is demonstrated. Since the patterning of this material by photolithography is not simple, neither it cannot be soldered to coaxial connectors nor bonding wires easily, a proximity electromagnetic coupling method is employed for this design. To this purpose Keysight EMPro program was used for the simulation of this antenna, which structure is shown in Fig. 1. This antenna comprises an Alumina substrate (with the grown TiN/Ag layers) on top of a baquelite substrate, where the microstrip feeding line is patterned. This antenna was measured showing a central frequency of 3.3 GHz with 100 MHz of bandwidth, and a gain of 5.6 dBi.

Analysis of High Gain Dual Beam Pentagonal Patch Antenna Array

R. Anand[1], **Jesmi Alphonsa Jose**[1], **and Sreedevi K. Menon**[2]

[1]Amrita Center for Wireless Networks and Applications, Amrita School of Engineering, Amritapuri, India
[2]Electronics and Communication Engineering, Amrita School of Engineering, Amritapuri, India

Abstract— In this paper, a high gain pentagonal patch antenna array with dual beam is presented. The pentagonal geometry is inspired from a rectangle patch antenna and a triangle patch antenna. The architecture of the antenna resembles an irregular pentagon comprised of a triangle placed on top of a rectangle. FEM is used to analyze the antenna design.

We used the characteristics of an inset feed rectangular patch antenna and an inset feed triangular patch antenna, with resonant frequency at 2.45 GHz, as a reference. The reference antennas had a directional radiation pattern with a gain of 6.88 dBi and 5.33 dBi, respectively. The geometry of the single element pentagonal antenna was designed by placing the triangle on top of a rectangle shape. The pentagonal antenna gave good reflection and radiation characteristics with a 2 : 1 VSWR bandwidth of 8.1% at resonant frequency. As we combined the geometry of a rectangle and a triangle for the pentagonal design, the single pentagon patch antenna radiated two directional beams with a peak gain of 6.1 dBi at resonant frequency. In the entire operating bandwidth, the gain was better than 5.8 dBi with HPBW of 40°/30° (for the two directional beams) in the azimuth plane and 70° in the elevation plane. Even though the pentagon patch had slightly less gain than the rectangular patch, it had an additional advantage since it radiated in two directions. The proposed pentagonal antenna architecture can be used in applications where there is a need to produce a dual beam without the need of any additional circuits for switching.

To enhance the gain of the pentagonal patch, we designed a 2×1 linear array with pentagonal elements. The spacing between the array elements and the feeding mechanism were optimized to achieve maximum gain. The array elements were spaced at a distance of 0.5λ. The pentagon array was fed by a $50\,\Omega$ impedance line. The line was split into two $100\,\Omega$ impedance lines for each of the elements of the pentagon. The 2×1 linear pentagon array produced dual beams with a peak gain of 9.27 dBi. In comparison, the rectangle 2×1 linear array and the triangle 2×1 linear array produced a single beam with a peak gain of 9.86 dBi and 7.03 dBi, respectively Thus, the 2×1 linear pentagon array with dual beams achieved a similar gain as the 2×1 linear rectangular array with a single beam.

We further enhanced the gain of the antenna system by constructing a 4×1 linear pentagon array, which produced a dual beam with a gain of 10 dBi The gain of the antenna was similar when compared to a 4×1 single beam rectangle array and a 4×1 single beam triangle array, whose gains were 11.24 dBi and 8.39 dBi, respectively. The simulated results obtained for the pentagonal antennas were validated by the network analyzer. Therefore, the proposed pentagonal antennas with dual beams can be applied in areas such as object detection, RF ablation, MIMO among others.

Bandpass Filters with Mixed Hairpin and Patch Resonators

Yi Wang, Eugene Ogbodo, and Predrag Rapajic
Department of Electronic, Electrical and Computer Engineering
University of Greenwich, Kent, ME4 4TB, UK

Abstract— Conventional planar bandpass filters are usually formed of coupled-resonators of the same type for the ease of modelling and implementation. Increasingly more sophisticated filters composed of a mixture of different types of resonators are proposed for various purposes. Some are intended to use non-uniform Q-factors across the resonators to better control the passband flatness in lossy filters [1]. Others use specific resonators for dual purpose such as in the case of integrated filter antennas, where the resonant antenna element serves as the radiator as well as one resonant pole in a filter [2, 3]. The antenna element there is usually of a completely different structure and characteristics from the other resonators.

This work explores the combination of single-mode and dual-mode resonators. A mixture of two hairpins and one patch resonator are used to produce a three-pole filter with one transmission zero. The three resonators are in-line coupled without any cascaded quadruplet or triplet structures. The patch is used for its dual modes. One is coupled to the hairpins forming the transmission path, whereas the other orthogonal mode generates the transmission zero. Such a configuration is simple but significantly increases the selectivity of the filter. The metred corner and the size of the patch are the main parameters used to optimise the coupling between the modes and to adjust the position of the transmission zero.

As shown in Figure 1, a 2.5 GHz filter with a bandwidth of 8% and a transmission zero at 2.4 GHz is designed. A return loss of 16 dB is achieved. The substrate has a dielectric constant of 11.2, a loss tangent of 0.0023 and a thickness of 1.27 mm. To minimise the radiation loss and preserve the high Q-factor of the patch, the filter is housed in a metal box. Such a filter configuration with mixed types of resonators has the flexibility and potential in implementing other novel and multiple-functional components and circuits. This will be discussed in more details in the full paper.

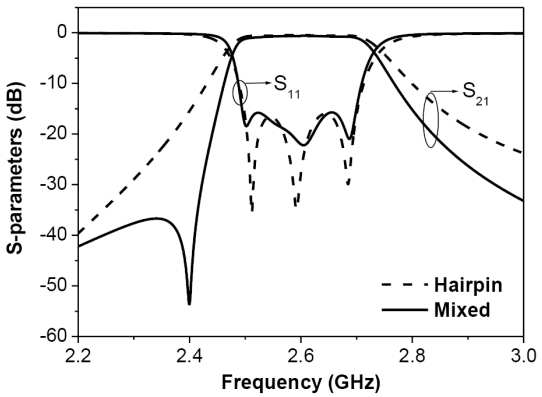

Figure 1: Comparison between a conventional hairpin filter and a mixed hairpin-patch-resonator filter of the same order.

Effect of Complementary Split-ring Resonators on Beam Scanning in the CRLH-leaky Wave Antennas Based on Split-ring Resonators and Slotline

Saeid Mohammadpour Jaghargh, **Pejman Rezaei**, **and Javad Soleiman Meiguni**
Faculty of Electrical and Computer Engineering, Semnan University, Semnan, Iran

Abstract— In this paper, a new leaky wave antenna (LWA) based on complementary split-ring resonators (CSRRs) and slot line are proposed. Effects of CSRRs on beam scanning in a composite right/left handed (CRLH) LWA based on split-ring resonators (SRRs) are investigated. Actually, the effects of these structures on the scan angles have been compared. The commercial Ansoft HFSS software is adopted for the simulations. The proposed LWA is analyzed in S and C band frequency, and the results reveal that the CSRR improves the gain in backward leaky wave radiation. The CSRR-LWA just scans the negative angles. Furthermore, the simulation results demonstrate the potential of the SRR-LWA to radiate from backward to forward scanning angles. As a result this miniaturized CSRR-LWA main beam can scan the space for C-band from -115 to -170 degree in phi $= 0$ (deg) plane. In the other word, the CSRR-LWA only scans in the negative ranges of theta, but SRR-LWA scans the space from $+94^\circ$ to $+156^\circ$ in positive ranges and -133° to -177° in negative ranges of theta.

The Near-field Radiative Heat Transfer for Doped Si-Ge Multi-layered Metamaterials Supporting Surface Plasmon Polaritons

Yang Bai[1] **and Yongyuan Jiang**[1, 2]

[1]Department of Physics, Harbin Institute of Technology, Harbin 150001, China
[2]Key Lab of Micro-Optics and Photonic Technology of Heilongjiang Province, Harbin 150001, China

Abstract— The near-field radiative heat transfer between doped silicon (Si)-germanium (Ge) multi-layered metamaterials is studied by fluctuation electrodynamics. By considering the contribution of surface plasmon polaritons (SPPs) supported by doped Si layer in the infrared, we have investigated the spectral heat transfer coefficient, the energy transmission factor and the total heat transfer coefficient versus separation distance between the doped-Si multilayered metamaterial with a filling factor of 0.4, where the doped Si layer is 40 nm and the Ge layer is 60 nm. Results show that the heat transfer coefficient between doped Si-Ge multi-layered metamaterials is attributed to the surface plasmon polaritons (SPPs) excited at the interface of the doped-Si and vacuum, the Bloch modes supported by the multi-layered structure and the intrinsic loss of the doped-Si. On the other hand, the contribution of SPPs can be obviously suppressed when choosing Ge as the topmost layer, and the energy transmission factor is comparable with the calculated results using the parameter obtained by effective medium theory. Moreover, the total heat transfer coefficient between the multi-layered structures is weaker than that of bulk doped-Si when the separation distance is smaller than 100 nm, but strong in large separation distance. This is due to the fact that the contribution of Bloch mode is restricted at large distance by the strong intrinsic loss of the dope-Si. Whereas the heat transfer coefficient between multi-layered structures composed of material with low loss, such as silicon carbide (SiC), is stronger than that of bulk medium. This study should facilitate the application of nanostructures in more efficient noncontact thermal management, near-field thermophotovoltaics and thermal imaging.

Contribution of Non-local Effects to the Casimir Forces

Y. Francescato and V. Giannini
The Blackett Laboratory, Imperial College London, London SW7 2BZ, UK

Abstract— Dispersion forces, that is Casimir and Van der Waals forces, impregnate our everyday life through physical processes as common as cohesion, friction and attraction. Yet their origin is deeply rooted in quantum mechanics and can be solved for only the most simple geometries. In the late 1940s, Casimir together with Polder predicted the attraction phenomenon taking place between two conducting plates, known as Casimir forces. Since the extension of the theory by Lifshitz in 1956 to the case of dissipative materials, the study of these effects has resulted in a large body of literature arising from both experimental and theoretical investigations [1].

Here we show that in addition to dissipation and dispersion [1, 2], a full description of the Casimir forces must take into account the effect of non-locality, or in other words the dependency of a medium response to the wavevector of the field. Indeed, we demonstrate that the Casimir forces arising from this representation is in stark contrast to the usual-local-optical properties assigned generally to materials. This is illustrated in Fig. 1 where the integrand of the Casimir force [3] is compared between the local and non-local cases. As one can see, the modes contributing to the force are largely unequivalent at high k-vectors. We will discuss typical cases where non-locality plays a crucial role in dispersion forces and draw conclusion on its observation in realistic epxeriments.

Abstract— One of the central open problems in nanoscience is the study of the heat transport in nanoscale devices, which has remained largely unexplored due to experimental challenges. In this context, a key issue is the understanding of the heat transfer via thermal radiation between systems separated by nanometer-size gaps. In this extreme regime, the electromagnetic near-field is expected to give rise to a dramatic enhancement of the radiative heat transfer, something that has only be quantitatively verified for gaps on the order of 20–30 nm [1]. In this work, we present a combined experimental and theoretical study of the radiative heat transfer in the extreme near-field regime (gaps of 1–10 nm). From the experimental side, we performed systematic studies using AFM-based scanning probes with integrated nanoscale thermocouples [2], which were coated with dielectrics (SiO_2 or SiN_x). Our experiments of heat transport between the scanning probes and a flat substrate coated with dielectrics, performed in an ultra-high vacuum environment, confirm that heat transport is dramatically enhanced in the near-field. To understand our experimental results, we investigated these near-field enhancements within the framework of the theory of fluctuational electrodynamics [3]. To be precise, we performed extensive numerical simulations making use of a combination of a fluctuating-surface-current formulation of radiative heat transfer with the boundary element method [4, 5]. Such a combination allows us describing realistic geometries for our tip-sample setups. Our theoretical results are in good agreement with the measured heat flows between both dielectric and metallic surfaces, which establishes the validity of fluctuational electrodynamics in modeling near-field heat transport all the way to nanometer-size separations.

Abstract— In this talk, I plan to show how Casimir interactions can be used as successful tools to probe quantum effects beyond the domain of quantum electrodynamics.

The first part of the talk concerns the field of Casimir forces subject to an external driving, through a model at the interface between quantum optics and general relativity.

The Unruh effect predicts that a single relativistically accelerated detector associates to quantum vacuum fluctuations a thermal power spectrum. Although many single-particle physics studies confirm this scenario, I will explicitly show that, when a couple of uniformly accelerated atoms is considered, also non-thermal effects can manifest and they can be highlighted through the Casimir-Polder interaction among the two particles [1].

The second part of the talk deals with the domain of ultra-cold gases, and I will show how the Casimir force felt by an impurity moving in a Bose-Einstein condensate, can exhibit different scaling behaviours with distance, depending on the velocity of the impurity itself.

I will, in particular, discuss a concrete experimental implementation of this setup, where novel physics of potential impact for optical measurements of Casimir forces can be highlighted [2].

Casimir-Polder Interaction between Rydberg Atoms and a Photonic Crystal Fibre

Wijnand Broer and Stefan Scheel
Institut für Physik, Universität Rostock, Rostock, Germany

Abstract— The Casimir-Polder (CP) force is an electromagnetic dispersion interaction between an atom and a neutral surface without permanent dipoles. This force arises from quantum mechanical (and thermal) fluctuations of the electromagnetic field. The CP interaction can become very strong for a Rydberg atom, which by definition has a large principal quantum number n. As the size of its wavefunction increases as $\propto n^2$, so does its transition dipole moment. The CP interactions thus affect the spectra of the atoms in the presence of macroscopic geometries. Hence, these interactions are of interest for proposals to build atomic lattice clocks in hollow-core fibres. Another example of a potential application is the development of single photon sources using Rydberg atoms in microcells. Both of these applications require a detailed understanding of the atomic structure near macroscopic surfaces.

Here we theoretically study the CP potential between cesium atoms in a Rydberg state and a hollow core photonic crystal fibre made of silica. Our analysis includes the following effects: 1) that of the Rydberg states of the atoms, 2) that of the material properties of the fibre (for example α-, β-quartz or amorphous silica), 3) that of its dimensionality (i.e., its shape and size), and 4) that of temperature. This system is typically out of thermal equilibrium because of the highly excited state of the atoms. This gives rise to an additional narrowband contribution to the Casimir-Polder potential, which can hence become considerably larger than in the case of thermal equilibrium.

Simultaneous Approximation Method of Attenuation and Group Delay Characteristics for Coupled Resonators Filter

Toshiki Matsubara[1], **Toshikazu Sekine**[2], **and Yasuhiro Takahashi**[2]

[1]Graduate School of Engineering, Gifu University, 1-1 Yanagido, Gifu-shi 501-1193, Japan
[2]Department of Electrical and Electronic Engineering, Gifu University
1-1 Yanagido, Gifu-shi 501-1193, Japan

Abstract— In the pulse transmission system, both the attenuation and the group delay characteristic can be given as a specification in the filter. However, synthesis method of simultaneous characteristic approximation for these properties is still unresolved. It is derived by formulating the optimization problem. In this paper, Vector Fitting [1] can be applied to the approximation of characteristics of the minimum phase filter is considered. We have obtained these simultaneous characteristics approximatation by adding the complex transmission zeros to the filter with real transmission zeros. Advantages of our method is that the number of resonators is not increased, since the complex transmission zeros can be obtained by couplings of resonators. Effectiveness of our method is confirmed by numerical examples. As a result, we conclude that the Vector Fitting can be applied to approximation of the filter characteristics.

Using polynomial $f(\omega')$; $g(\omega')$ and $h(\omega')$ of the normarized actual frequency ω', $\mathbf{S}$ matrix of lossless reciprocal circuit is expressed by the following expression.

$$\mathbf{S} = \begin{bmatrix} S_{11}(\omega') & S_{11}(\omega') \\ S_{21}(\omega') & S_{22}(\omega') \end{bmatrix} = \frac{1}{g(\omega')} \begin{bmatrix} h(\omega') & f(\omega') \\ f(\omega') & \frac{f(\omega')}{f^*(\omega')} h^*(\omega') \end{bmatrix}, \tag{1}$$
$$g(\omega')g^*(\omega') = h(\omega')h^*(\omega') + f(\omega')f^*(\omega')$$

where, $g^*(\omega') = \overline{g(\omega')}$ and leading coefficient of $f(\omega')$ is one. When the equivalent circuit of filter include the imaginary resistances (frequency independent reactances), $g(\omega')$ is a Hurwitz polynomial in a broad sense. Following two functions $|S_{21}(\omega')|^2$ and normarized group delay $\tau_n(\omega')$ are applied to the Vecter Fitting.

$$\begin{aligned} |S_{21}(\omega')| &= \sum_{i=1}^{N_g} \left(\frac{c_i' + jc_i''}{\omega' - (a_i' + ja_i'')} + \frac{c_i' - jc_i''}{\omega' - (a_i' - ja_i'')} \right), \\ \tau(\omega') &= \frac{j}{2} \sum_{i=1}^{N_g} \left(\frac{1}{\omega' - (a_i' - ja_i'')} - \frac{1}{\omega' - (a_i' + ja_i'')} \right) \end{aligned} \tag{2}$$

We note that the poles of both expressions are common. First, we derived initial values of S-parameters from filter design methods [2, 3]. Next, improveed poles and residues are obtained by using Vector Fitting. Figure 1 shows that the results of numerical example of rational function approximation. There are good approximations of Chebyshev type both attenuation and group delay.

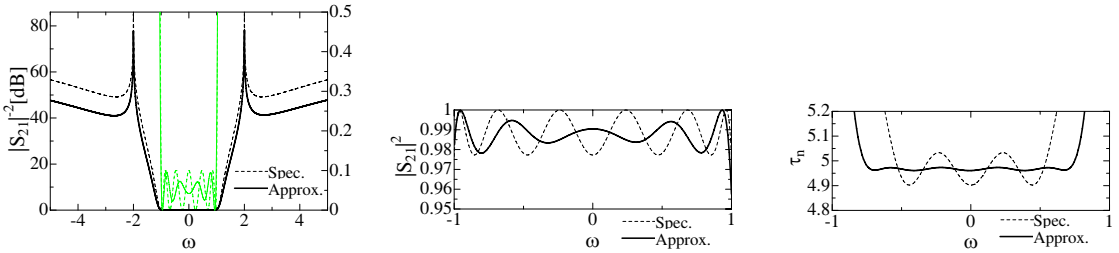

Figure 1: Numerical example, (a) attenuation, (b) attenuation of passband, (c) group delay of passband.

A Compact Band Pass Filter with Wide Stop-band in LGA Package by Low-temperature Co-fired Ceramic

Lisa Li-Ju Chen and Ken-Huang Lin
Department of Electrical Engineering, National Sun Yat-Sen University, Kaohsiung, Taiwan

Abstract— A compact band pass filter with wide stop-band in LGA (Land Gird Array) package was proposed in this paper. The proposed filter was designed to operate at 5.15 GHz–5.85 GHz for 802.11ac applications and implemented in low-temperature co-fired ceramic (LTCC) substrate. The proposed schematic introduces transmission zeros at the lower band to reject the unwanted frequency and provides wide stop-band at high side with 30 dB rejection level. The proposed circuit is composed of three coupled line (TL1 ∼ TL2), three capacitors (C12/C23/C13), two capacitor to ground (C10/C20/C30), four small inductor (L1/L2/L10/L20) and two shunt open stub-lines (TL1/TL2).

This filter was realized in multilayer structure with LGA package which only need smaller footprint on print circuit board. All the components of filter were embedded into the LTCC multilayer substrate with a relative constant of 33, loss tangent of 0.001. The each foil had a thickness of 23 μm and the used conductor was silver with 10 μm thickness at each layer. The minimum line width and space between the lines were 100 μm and 150 μm, respectively. The inductor elements and coupling line can be implemented by via and it can make the filter to have compact size. The 3D design for the proposed filter is to arrange the shielding ground on the top layer and it avoids the performance of filter to be effected by external environment, especially on SiP module application due to height limitation. The 3D structure of proposed filter was shown in Fig. 1.

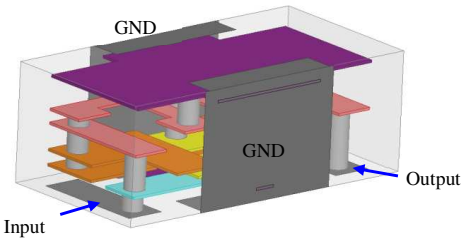

Figure 1: The 3D construction in HFSS.

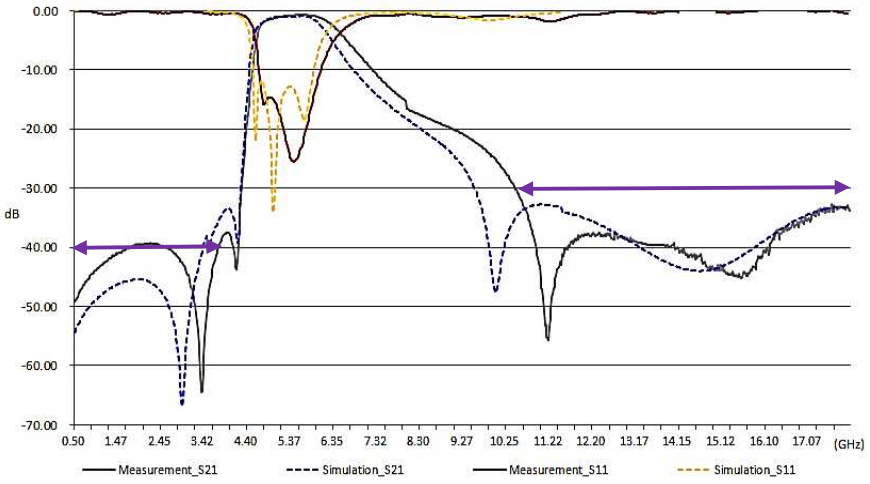

Figure 2: The simulation and measurement result.

The overall size of band pass filter are 1.6 mm (L) × 0.8 mm (W) × 0.6 mm (H) which has small size. The simulated response was shown in Fig. 2. The simulation insertion losses at 5.15 GHz and 5.85 GHz are 1.1 dB and 1.2 dB, respectively. The rejection band with 30 dB attenuation covers from 9.5 GHz to 18 GHz to have good ability to filter out the harmonic noise. The proposed filter also has good attenuation at 500 MHz–4 GHz to reject the unwanted frequency band at low side. Finally, simulated and measured results are presented in Fig. 2 as well.

Heuristic Circuit Transformation Based on Left-handed Filter and Right-handed Filter

Abstract— Passive filters such as bandpass filter (BPF) or bandstop filter (BSF) are fundamental components for wireless communication equipment, and planar filters are preferred since they can easily be fabricated at low cost and suited to the various frequency channels. Meanwhile, composite right/left-handed (CRLH) circuits based on the metamaterial technology have recently been researched [1, 2]. Metamaterials are man-made artificial structures that show unnatural electromagnetic phenomena by negative permeability and permittivity, which means that the phase velocity is negative but the group velocity is positive.

In this study, we firstly present a compact BPF on a printed circuit board (PCB) assuming the use of the microstrip line structure. Duroid 6010 (relative permittivity: $\epsilon_r = 3.6$, loss tangent: $\tan\delta = 0.0023$, thickness of the substrate: $h = 0.635\,\mathrm{mm}$, thickness of the conductor: $t = 18\,\mu\mathrm{m}$) is considered for the dielectric substrate. The BPF is composed of a coupled line and transmission lines with inductive elements, and it produces a dual-mode resonance and transmission zeros. Their conditions are easily solved by using the even-/odd-mode analysis. Since the conditions can be provided as the left-handed (LH) operation, the BSF can also be composed by using the transformation from LH transmission line to right-handed (RH) transmission line. The interdigital coupled line is changed to two open-circuited stubs in order to reduce the series capacitance and the inductive element is eliminated in order to remove the shunt inductance. As a result, the BPF shown in Fig. 1(a) is transformed to the BSF shown in Fig. 1(b).

Both types of filters can be realized in the almost same and very compact size at the same frequency range of 2–3 GHz. Their performances are confirmed by the electromagnetic simulation and measurement.

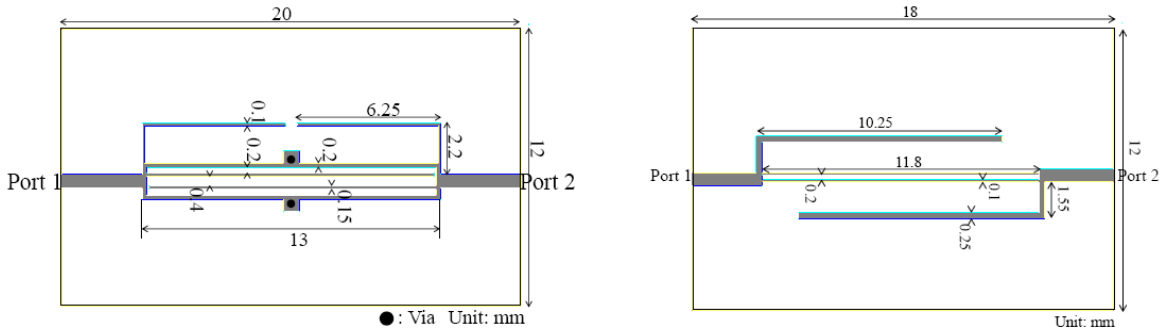

Figure 1: Circuit patterns of the filters: (a) LH-BPF, (b) RH-BSF.

A Compact Tunable Dual-band Bandpass Filter Using Varactor-loaded Step-impedance Resonators

Xiang Zhang, Chang Chen, Mingkang Li, Lingyun Zhou, and Bin Liu
Key Laboratory of Electromagnetic Space Information
Chinese Academy of Sciences, University of Science and Technology of China, Hefei, Anhui 230026, China

Abstract— This paper presents a novel design of a compact tunable dual-band bandpass filter (BPF) using varactor-loaded step-impedance resonators (SIRs). The proposed varactor-loaded SIR is shown in Fig. 1(a). Since the structure is symmetrical, the even- and odd-mode analysis method can be applied to obtain the resonant frequencies. By theoretical analysis, the odd-mode resonant frequency fully depends on the capacitance of the varactor diode connected at the ends of the resonator and the even-mode resonant frequency depends on the capacitances of all the three varactor diodes. This characteristic of the proposed resonator can be utilized to design a tunable dual-band BPF with two controllable passbands. Compared to uniform impedance resonator (UIR), the SIR has more excellent performance such as compact size, and adjustable harmonic resonance frequency etc.. The harmonic resonance frequency of SIR is determined by the length of SIR and the ratio of the two characteristic impedances. By choosing proper ratio of the two characteristic impedances, the length of SIR can be shorter than UIR while keeping the resonance frequency constant. So the proposed filter using varactor-loaded SIRs shown in Fig. 1(b) can be compact.

A tunable dual-band BPF using varactor-loaded SIRs is designed, simulated and measured, as shown in Fig. 1(c). The ratio of the two characteristic impedances of SIR is 0.6. Fig. 2 shows the simulation and measurement results. The designed first tuning passband is from 0.72 GHz

to 1.06 GHz, and the designed second tuning passband is from 1.45 GHz to 2 GHz. The first passband center frequency tunable range measured is from 0.73 GHz to 1.07 GHz and the second passband center frequency tunable range measured is from 1.4 GHz to 1.9 GHz. The designed second passband center frequency is higher than the measured results because of the capacitance error and fabrication error. The whole size of the tunable dual-band filter using SIRs decrease 22% compared to the tunable dual-band filter using UIRs in [1].

Concentric Open End Rings Resonator Filter

Mahmood Karami, **Ramezan Ali Sadeghzadeh**, **and Mahdi Oliaei**
Electrical & Computer Engineering Department, K. N. Toosi University of Technology, Iran

Abstract— In this paper, a single open ring resonator (ORR) filter with three resonants within its equivalent circuit has been investigated. This filter has a good response at ISM band from 3.13 GHz to 5.56 GHz. According to this filter, a concentric double open end ring resonator filter with an ultra wide band (UWB) behavior has been approached. The frequency response of this one is very appropriate up to 15 GHz. The loop of the filter constitutes both periodic self and mutual inductive-capacitive property between two rings which provides many resonants in these frequencies. The interconnections between these tanks are an important factor of its UWB behavior and they have overlap on each other impressively.

Conductor Loss Evaluation of Thin Microstrip Line with Various Copper Roughnesses

Abstract— The surfaces of the copper foils on a dielectric substrate are generally rougnened to obtain a sufficient adhesion strength as depicted in Figure 1, and the lower effective conductivity due to the roughness brings characteristic degradations of microwave and millimeter-wave circuits. This paper presents an experimental study on an impact of conductor surface roughness on thin microstrip line (MSL). Three types of copper foils were used for the fabricated 50 Ohm MSLs using a same dielectric substrate with thickness of 100 µm and the roughness of the foils are listed in Table 1. R_a is a evaluation figure of the surface roughness. The dielectric constants and dielectric loss tangents of the substrates are the same as 2.17 and 1.53×10^{-3} at 17 GHz. Figure 2 shows the measured attenuation constants of the fabricated MSLs with various surface roughness of the copper foils. The loss with the non roughened foil was measured to be less than half the loss of the MSL using the standard roughened foil. The dielectric losses of three MSLs are the same shown as simulated dielecric loss in the figure, and the difference between measured ones are due to the difference of the effective conductivities of the foils. The effective relative conductivities of the foils were estimated from the measured attenuation constants. Figure 3 indicates the estimated relative conductivities. Here, the conductivity is relative to the conductivity of copper (5.8×107 S/m). The non roughened foil has the at effective conductivity around 1 up to 50 GHz. However, the effective conductivity of the other foils decrease drastically with the frequency increase, because their skin depths move toward the surface roughness.

Composite Right-/left-handed Transmission Line Stub Resonator with Improved Out-of-band Rejection Characteristics

K. Saito and S. Tanaka
Shibaura Institute of Technology, Japan

Abstract— Previously, we reported composite right-/left-handed (CRLH) transmission line stub resonators that are compact and can enhance the unloaded-Q beyond the limit of microstrip line resonator [1]. The mechanism of the enhanced unloaded-Q ($Q_u = \omega/2av_g$) can be explained by the near zero group velocity ($v_g \approx 0$) of the CRLH TL used as stub line, which is realized by engineering the dispersion of the CRLH TL in the left-handed (LH) region. The novel BPF type resonator, however, suffered from spurious responses at both sides of the center resonant frequency, limiting the applicability of the resonator. In this work, we present an alternative type of CRLH stub resonator with improved out-of-band rejection characteristics.

Figure 1 compares the circuit schematics and the $|S_{21}|$ frequency responses for the CRLH stub resonators of two different types. The basic idea of the present type of the resonator is to place the shunt inductors in the unit-cells before the series capacitors (looking from the main signal line), whereas they were placed the other way around in the conventional type [1]. This modification affects the order of the transmission zeros (TZs) and reflection zeros (RZs) that appear in the LH frequency region. Figure 2 shows how the out-of-band rejection can be improved using the parameters such as C_2 and L_1. Since the resonant modes in the LH frequency region can be controlled easily by tuning the reactive components of the unit cells, RZ^+ can be pushed away from RZ^- which is the center frequency of the resonator. One design challenge of the proposed resonator is to achieve very low inductance for L_1, which is necessary to increase loaded-Q as well improve overall rejection level. To accomplish this, we used two or more short-ended stubs connected in parallel, as shown in Figure 3.

The proposed CRLH stub resonator, with compact size, enhanced unloaded-Q and good out-of-band rejection characteristics, should prove useful for microwave planar circuit such as low phase-noise oscillators.

Abstract— Ink-jet printing techniques are good alternative to conventional photolithography for the fabrication of electronic devices [1]. This printing technology is mostly applied to flexible electronics devices. The most common substrate for flexible electronics devices is polyimide due to its outstanding electrical properties, good mechanical strength [2]. Effect of bending on RF performance of ink-jet printed device should be investigated because of the flexible electronics devices are operated in the bending state. In this paper, microstrip line was fabricated on 200 µm thick polyimide substrate by ink-jet printing method. Length, height and width of fabricated microstrip line is 14.2 cm, 3 µm and 500 µm, respectively. To measure the RF performance of the fabricated microstrip line with SMA connector (0.8 T) using network analyzer, copper-plated 600 µm thick FR-4 substrates are attached to both ends of the fabricated microstrip line. RF performance of the fabricated microstrip line is simulated using EM simulator and measured at the bending states using VNA (Agilent technology, E5061B). Insertion loss of the fabricated microstrip line is measured according to the varied end-to-end distance from 14.2 cm to 10 cm at intervals of 1 cm. Measured insertion loss is 6.26 dB @ 14.2 cm, 6.23 dB @ 13 cm, 6.20 dB @ 12 cm, 6.13 dB @ 11 cm, 6.10 dB @ 10 cm, respectively at 1 GHz. Return loss is measured to over 10 dB in the frequency range 300 kHz to 3 GHz.

Abstract— The flexible electronics device called next generation electronic devices is actively studied in recent years [1]. The flexible electronics device is fabricated by printed electronics technology such as Roll-to-Roll printing, ink-jet and screen printing. Most of all, ink-jet printing has advantages such as no waste of ink, non-contact patterning and simple fabrication process [2]. In this paper, microstrip line was fabricated on the FC (fluorocarbon) coated PI (polyimide) substrate (thickness 200 μm) by ink-jet printing method. In order to remove solvent in conductive ink, the fabricated microstrip line is sintered by the heated nitrogen gas-beam. Length, height and width of fabricated microstrip line is 30 mm, 3 μm and 500 μm. To measure the RF performance of the fabricated microstrip line with SMA connector (0.8 T) using network analyzer, copper-plated FR-4 substrate (thickness 600 μm) is attached to PI substrate. RF performance of the fabricated microstrip line is simulated using HFSS (High Frequency Structural Simulator) EM simulator and measured using VNA (Agilent technology, E5061B). Transmission loss of the fabricated microstrip line is measured to be −0.55 dB/cm@1 GHz, −0.76 dB/cm@2 GHz, −1 dB/cm@3 GHz, respectively. Return loss is measured to over 15 dB, where the length of the silver signal line is 30 mm.

Coupled Line Power Divider with Multiple-pole Negative Group Delay Characteristics

Girdhari Chaudhary, **Seungho Jeong**, **Phirun Kim**, **and Yongchae Jeong**
Chonbuk National University, Republic of Korea

Abstract— Power dividers are essential blocks in microwave and millimeter systems and have been applied for power combining and splitting in various applications such as antenna feeding networks, high power amplifiers (PAs), linearization of PAs, mixers, test setups, and measurement circuits. The conventional power dividers provide the positive group delay. Moreover, the group delay matching between different paths is essential in various circuits and systems such as supply modulated PAs and feedforward linearization technique. For these circuits and systems, the power divider with negative group delay (NGD) characteristics will be beneficial to compensate positive group delay. Therefore, two-way power NGD divider is proposed in this paper. The schematic of the proposed NGD power divider is shown in Fig. 1, which consists of serial coupled line and shunt connected short-circuited coupled lines with open-circuited isolation port. The center frequencies of shunt coupled lines are slightly different in order to get wideband multiple-pole NGD characteristics. For experimental validation, the NGD power divider with equal-power dividing ratio operating at center frequency of 2.14 GHz was designed, fabricated, and measured. From the measurements, the transmission parameters are determined as $S_{21} = -9.01$ dB and $S_{31} = -8.96$ dB at $f_0 = 2.15$ GHz, which is shown in Fig. 2. Similarly, the measured group delay between different paths are determined as $\tau_{21} = -0.338 \pm 0.07$ ns and $\tau_{31} = -0.341 \pm 0.09$ ns over bandwidth of 170 MHz, which is shown in Fig. 3. The measured amplitude and phase differences between the two output ports are shown in Fig. 4. It can be seen that the maximum amplitude imbalance of ± 0.6 dB and the phase imbalance of $\pm 2.2°$ are observed over the 10 dB return loss bandwidth.

An Estimation Method for 2-port *S*-parameters Using Cable or Jig with Leakage Couplings

Shinji Ohno[1], **Toshikazu Sekine**[2], **and Yasuhiro Takahashi**[2]

[1]Graduate School of Engineering, Gifu University, Japan
[2]Department of Electrical and Electronic Engineering, Gifu University, Japan

Abstract— An estimation method for **S**-parameters of 2-port circuit by using cable or jig with leakage couplings is presented. In our method, two ports of 4-port cable or jig are terminated with 2-port circuit or known loads. And the **S**-parameters between remaining two ports are measured. Advantages of our method is that the **S**-parameters of 2-port circuit are to be estimated only by solving the linear least squares problem. Our method can be applied to determine the **S**-parameters of the circuit with a difficult port to connect the probe of the instrument as the IC package and to determine the **S**-parameters of the circuit ground is not common.

Some estimation methods for the **S**-parameters of the multi port circuit having the port which cannot connect the probe of the measuring instrument to directly are considered [1, 2]. The reason why we cannot connect probes to directly are two mainly. The first reason is in the case of a circuit having the ports which are hard to connect a measuring instrument like IC tips in the package. The other reason is in the case of a circuit having the ports without common ground. In this case, some circuit properties are change if we connect the probes of measuring instrument with common ground.

A models of reciprocal 4-port cable or jig is shown in Figs. 1(a), (b) which has 2 ports that are hard to access with measurement probes. Figs. 1(c), (d) are examples of Figs. 1(a), (b). Port 1 and port 2 can be connected by measuring probes directory, and port 3 and port 4 cannot be connected directory. Using incident wave $\mathbf{a}_a$; $\mathbf{a}_u$ and reflection wave $\mathbf{b}_a$; $\mathbf{b}_u$, **T** matrix **T** of this 4-port is expressed as

$$\begin{bmatrix}\mathbf{a}_a\\ \mathbf{b}_a\end{bmatrix} = \begin{bmatrix}\mathbf{T}_1 & \mathbf{T}_2\\ \mathbf{T}_3 & \mathbf{T}_4\end{bmatrix}\begin{bmatrix}\mathbf{b}_u\\ \mathbf{a}_u\end{bmatrix}, \quad \left(\mathbf{b}_a = \hat{\mathbf{S}}_C\mathbf{a}_a,\ \mathbf{a}_u = \mathbf{S}_C\mathbf{b}_u\right) \text{ or } \left(\mathbf{b}_a = \hat{\mathbf{S}}_L\mathbf{a}_a,\ \mathbf{a}_u = \mathbf{S}_L\mathbf{b}_u\right) \tag{1}$$

$\mathbf{S}_C$ is the estimated **S**-matrix of the unknown 2-port circuit and $\hat{\mathbf{S}}_C$ is the measured **S**-matrix. Here, the known loads $\mathbf{S}_L$ are connected instead of 2-port circuit in Fig. 1(b). So, the following estimation equation is derived from Eq. (1).

$$\mathbf{S}_C = -\left(\mathbf{T}_4 - \hat{\mathbf{S}}_C\mathbf{T}_2\right)^{-1}\left(\mathbf{T}_3 - \hat{\mathbf{S}}_C\mathbf{T}_1\right), \quad \mathbf{T}_3 + \mathbf{T}_4\mathbf{S}_L - \hat{\mathbf{S}}_L\mathbf{T}_1 - \hat{\mathbf{S}}_L\mathbf{T}_2\mathbf{S}_L = 0 \tag{2}$$

Equation (2) is solved by the least squares method. As a result **T**-parameters of the 4-port and unknown **S**-parameters of the 2-port are found. The validity of the method is shown in the numerical and measured examples.

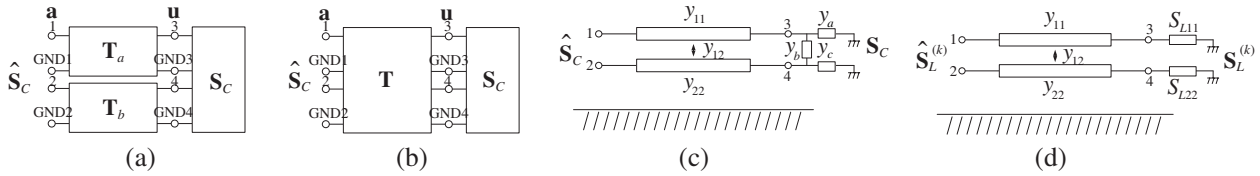

Figure 1: **S**-parameters measurement system with jig. (a) Non-leakage couplings. (b) Leakage couplings. (c) Coupled transmission line with 2-port circuit. (d) Coupled transmission line with known loads.

Spheres and Circles with Radial Anisotropy: Unexpected Scattering Properties

A. Sihvola[1], **H. Kettunen**[2], **and H. Wallén**[1]

[1]Department of Radio Science and Engineering
Aalto University School of Electrical Engineering, Espoo, Finland
[2]Department of Mathematics and Statistics, University of Helsinki, Finland

Abstract— Even if the first studies on radially anisotropic (RA) spheres appeared decades ago [1], it seems that their peculiar properties have only lately attracted the particular attention they deserve. Cloaking properties of scatterers can be substantially boosted by resorting to anisotropy compared with layered isotropic structures [2, 3]. In addition, the astonishing phenomenon of anomalous absorption in spheres with indefinite (hyperbolic) radial anisotropy has been analyzed carefully only very recently [4].

In this presentation, we will focus on certain particular characteristics of scattering efficiencies of radially anisotropic spheres and circular cylinders. There are surprising qualitative differences of the scattering behavior in three and two dimensions, which will be paid special attention, e.g., existence of cloaking and resonating conditions in the hyperbolic regime for 3D case which does not take place for the 2D constellation. This means that for three-dimensional RA spheres, the scatterer can become (in the quasistatic limit) invisible even if there is a strong variation in the internal field pattern. Likewise, there are two types of internal field distributions that appear along with a plasmon resonance behavior.

Furthermore, the non-Rayleigh character of small-particle scattering that has been observed for plasmonic scatterers [5, 6] will be given attention. Ordinary Rayleigh scattering follows the fourth-power (third-power) dependence on the size parameter of the particle for spheres (circles). The deviations of this this quartic (cubic) dependence will be studied systematically and extended into all cloaking and resonant singularity cases for radially anisotropic scatterers in two and three dimensions.

Lavrentiev Ave. 2/1, Novosibirsk 630090, Russia

Abstract— The range of short millimeter waves (SMMW) remains highly attractive for a number of important practical applications, such as security and nondestructive material quality inspection, due to its opportunity to combine the options of relativity high penetrability through atmosphere and different non-metallic objects versus terahertz, infrared and optical radiation, as well as attainability of spatial resolution of the order of several millimeters acceptable for imagining of concealed targets.

Among different methods for detecting SMMW, we may highlight a method of bolometric sensing using ultra thin metamaterial films. Such films, typically configured as a single layer metasurface laying over a grounded dielectric slab, are capable of resonantly absorbing the incoming electromagnetic waves with 100% efficiency and have the thickness d much smaller than the resonant wavelength λ. Minimization of d is essential for decreasing the absorber's heat capacity and, therefore, for achieving high sensitivity and low response time of the bolometric detector.

According to fundamental limitations, the condition $d/\lambda \ll 1$ inevitably leads to narrowing the absorption bandwidth that is used to be considered as a key drawback of the metamaterial absorbers. On the contrary, in our work this condition is turned to the advantage and is exploited to implement high-performance multi-channel SMMW bolometers with high spectral and polarization discrimination. Such detectors are demanded in spectro-polarimetric imaging and measurements schemes with broad-band SMMW sources. Also, such detectors are well suitable for sensing applications with active illumination from a monochromatic SMMW oscillator.

In our contribution we summarize the results of extensive investigations focused on developing metamaterial-based SMMW bolometric detectors operating in the frequency range of 0.09–0.4 THz. In the first part of this work, the multiparametric electromagnetic analysis and optimization of the absorbers' design is presented and the route to maximize the λ/d ratio at the minimal absorption bandwidth and high out-of-band spectral purity is discussed. In the second part, we demonstrate the results of experimental testing for high-performance metamaterial absorbers, whose λ/d ratios reach the value of 200 at the relative bandwidth of around several percent. These absorbers are integrated with bolometric sensors implemented in different schemes, including SMMW-to-IR conversion and pyro-electric detection, and the operational characteristics for each scheme are analyzed.

Left-handed Transmission Lines Equivalent Circuit Model Based on *ABCD* Matrices

U. Martinez-Iranzo, **B. Moradi**, **and J. Garcia-Garcia**
Grupo de Aplicaciones Electromagnéticas Industriales — GAEMI
Engineering Electronic Department, Universidad Autónoma de Barcelona, Cerdanyola del Vallès, Spain

Abstract— Simultaneous negative permittivity and permeability media was first considered by Veselago in the late 1960s. In these media, the sign reversal for both permittivity and permeability results in a negative refractive index, referred to as metamaterial. Since then, these concepts have been used in microwaves for numerous applications due to the unusual properties that exhibit such as inverted Snell's law, Doppler shift, and Cherenkov radiation, in addition to unusual focusing properties. From the theoretical point of view, metamaterials have been described with an equivalent circuit model formed by a capacitor C and a RLC resonator, and in shunt with an inductor L. This description with lumped elements only works in the nearby of resonant frequency. In this work, it is proposed a metamaterial theoretical description using transmission matrices, instead of lumped elements. This study provides two key advantages compared to lumped elements analysis. First, it allows wide frequency range description and establishes clear relations between physical dimensions and the metamaterial transmission characteristics. On the other hand, it provides the possibility to obtain analytically a wide frequency spectrum range provides useful information about the resonances modes and enables the particle studies as can be obtained analytically parameters as group delay or group velocity. In the study and design of metamaterial particles, the direct association of physical dimensions implies the possibility to control design parameters. To verify the theoretical predictions, has been designed a metamaterial structure that has been analytically studied, it has been calculated its $ABCD$ matrix, fabricated and measured, showing a good agreement between measured and analytical results.

Unusual Percolation Threshold of Electromagnetic Waves

Jie Luo, **Zhihong Hang**, **C. T. Chan**, **and Yun Lai**
Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology
College of Physics, Soochow University, Suzhou 215006, China

Abstract— We demonstrate an unusual percolation threshold of electromagnetic waves in index-near-zero media embedded with random inclusions. Such a critical behavior is induced by the long-range connectivity of the "non-conducting" component instead of the "conducting" component. Therefore, such a percolation threshold shows a very different nature from previous percolation like fluids in porous media or conductivity of metal-dielectric composites. It is induced by the vector wave nature of electromagnetic waves.

Chiral Localized Plasmon Resonances Leading to Extreme Optical Chirality

A. V. Kondratov and M. V. Gorkunov
A.V. Shubnikov Institute of Crystallography, Russian Academy of Sciences, 119333, Russia

Abstract— We present an analysis of FDTD simulations of light transmission trough arrays of chiral nanoholes in metal. We report that extreme optical activity and circular dichroism are related with excitation of chiral localized plasmon resonances.

Chirality is a point of great interest in physics, chemistry and biology. Due to the fact that chiral nanostructures can interact with biomolecules and organic objects, chirality on the nanoscale is potentially very useful for biosensing and pharmacy [1]. Subwavelength arrays of chiral holes (Fig. 1(a)) exhibit extremely strong optical activity (OA) and circular dichroism (CD) [2]. Theoretical analysis in terms of the causality principle shows that OA and CD obey generalized Kramers-Kronig relations, but the nature of the phenomenon still remains unrevealed [3]. Another question is why structures with very similar shapes of the nanoholes yield qualitatively different spectral characteristics of OA and CD.

To answer these questions and clarify the effect of the shape of holes we performed simulations for different types of conical and chiral holes. We developed a data processing pipeline consisting of the correction and averaging of the raw atomic force microscopy (AFM) data, creation of the unit cell 3D-model and subsequent FDTD simulations. The results of simulations (Fig. 1(b)) show a good agreement with experimental frequency dependence of OA and CD and strong electric field localization at the output of the chiral nanohole at the peak of CD (Fig. 1(c)). On the other hand, the field distribution far from the peak of CD is significantly different (Fig. 1(d)). Thus, we conclude that the chiral localized plasmon resonance is responsible for the extreme values of OA and CD in such structures.

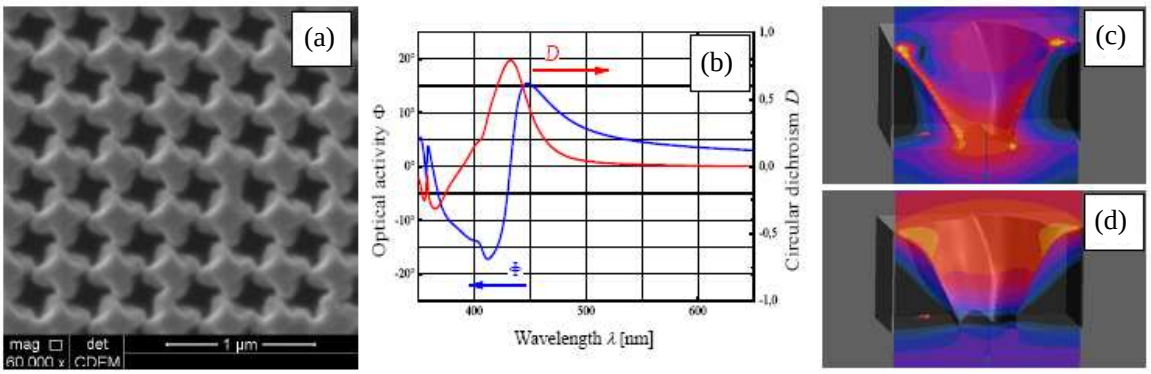

Figure 1: (a) SEM image of a fragment of the chiral nanoholes array milled in a 380 nm thick silver foil; (b) calculated values of OA and CD for a hole shape obtained by reconstructing and averaging AFM scans data; distribution of electric field absolute value inside the chiral nanohole: (c) at the peak of CD and (d) far from the peak of CD.

Abstract— Magneto-optical effects have become the subject of active research due to the possibility of ultrafast and effective control of light properties such as polarization and intensity. Recently it has been demonstrated that these effects can be enhanced in specially tailored nanostructures, in particular, in plasmonic structures [1]. The giant values of magneto-optical effects lead to huge variety of applications such as optical telecommunication devices or highly sensitive magnetic field sensors. With the goal of the latter application here we study those effects that are related to the in-plane magnetization in magneto-plasmonic crystals and find the conditions for achievement of their high values.

The structures under considerations are one-dimensional plasmonic crystals consisting of a noble-metallic grating and a smooth magnetic dielectric film. Four magneto-optical effects take place in such configuration.

Firstly, the transverse Kerr effect (the TMOKE) is present. It allows direct visualization of magnetization component parallel to the grating slits. The light should be TM polarized and the incidence should be oblique. At the excitation of the structure's TM modes the TMOKE is resonantly enhanced. The value of the TMOKE can be several percent that is by three orders higher than for the smooth film without plasmon covering [2].

Secondly, there is the longitudinal Kerr effect (the LMOKE). It is resonantly enhanced at the excitation of modes of any type. The most favorable condition for the LMOKE enhancement is the intersection of dispersion curves for TE and TM modes. The values of the effect are about several degrees that is 10 times higher than for the non-plasmonic structure.

The most important feature of the considered structure is the emergence of the effect of the third kind, that is the longitudinal intensity effect (the LMPIE) [3]. This effect is prohibited in smooth magnetic media. The effect is of resonant nature because it is related to the excitation of the structure's eigenmodes. The LMPIE takes place even at the normal incidence. Usually this effect is quadratic in magnetization. It was found both theoretically and experimentally that this effect can be as high as several tens of percent. The highest value of the LMPIE happens at the simultaneous excitation of both TE and TM modes. This effect is likely to be the most effective way of visualization of longitudinal magnetization.

Finally, the whole class of the phase effects can be considered. Optical resonances that are sensitive to magnetization lead to changes in phases of reflected and transmitted light. These changes can be observed in any magnetization configuration and they are either even or odd in magnetization depending on the light incidence configuration. The magnetization-induced phase change in longitudinal configuration can achieve 7 degrees while for the transversal configuration it is weaker.

The described effects provide efficient modulation of transmitted and reflected light intensity, polarization and phase.

The Role of Mechanisms Responsible for the Extraordinary Transmission through Sub-wavelength Periodic Arrays

J. Fiala and I. Richter
Faculty of Nuclear Sciences and Physical Engineering, Czech Technical University in Prague
Břehová 7, CZ-11519 Prague, Czech Republic

Abstract— This contribution is focused on the investigation of the enhanced optical transmission (EOT) phenomenon through both 1-D and 2-D sub-wavelength periodic arrays perforated in metallic films. In order to gain the basic physical insight into the transmission mechanisms and to reveal the basic resonant processes in interaction of a plane wave with 1-D array of sub-wavelength slits, we have derived two approximate analytical models. Two relevant simplifications were incorporated within the derivation procedure of the first model — (i) surface-impedance boundary conditions were imposed on the metallic boundaries, except on the vertical walls of the slits which are treated as a perfectly conducting metal, and (ii) only the fundamental eigenmode is assumed inside the slits. As for the second model, in order to highlight the surface plasmon-polariton (SPP) excitation based on the scattering of the plane wave or the slit mode into the SPP, a combined model comprising the SPP as an explicit bound mode was further derived.

Using the rigorous numerical modelling, the total transmitted energy maps of various 1-D array of slits are calculated as a function of both the structure geometrical and wave parameters, and, there, the dispersion curves of the existing modes are clearly identified together with the cut-off frequencies of the respective modes and the positions of resonances in these maps [1]. Apart from the cavity resonances of the fundamental slit-guided mode (CM), playing a significant role, the SPP bound modes and CM-SPP hybrid modes are also analysed in the case of 1-D structures.

For the case of 2-D structures, map of modes possessing the lowest attenuation constant inside the hole is calculated, and, furthermore, plasmon-polariton modes of the metallic film are identified. Finally, the prediction capabilities of the approximate models were put under comparison with the rigorously computed data.

Additionally, the attention is also devoted to the much disputed question about the role of SPP and the Rayleigh anomaly (RA) [2, 3]. It is found that the RA does not play such crucial role in contrast to the SPPs that drastically alter the dispersion relations of the Fabry-Perot conditions of the CMs inside the slit, and which mutual interaction subsequently results in the Fano resonances with the pronounced maxima and minima in the spectra — the grating Wood's anomalies. A formalism for describing such Fano resonances is subsequently proposed.

On the Characteristics of Spoof Surface Plasmons (SSP) in the High Frequency Limit

Sayak Bhattacharya and Kushal Shah
Department of Electrical Engineering, Indian Institute of Technology Delhi, India

Abstract— In the low frequency limit (i.e., when operating wavelength is very large compared to the feature-size and periodicity), the field of spoof surface plasmon (SSP) is characterized by a single evanescent order and the corresponding dispersion relation is described by an expression analogous to the dispersion relation of surface plamon polaritons (SPP). However, in the high-frequency limit, the analogy between SSP and SPP breaks down [1, 2]. As the feature-size becomes comparable to the wavelength, the low frequency dispersion relation starts deviating from the dispersion calculated numerically [3].

In this paper, we show that diffraction from the subwavelength features at the surface of a perfect electric conductor (PEC) plays a very important role in determining the near-field characteristics and dispersion of spoof surface plasmon (SSP) in the high-frequency limit. Since the holes on the PEC surface are of subwavelength dimension, the diffracted field from these features would be evanescent in the direction perpendicular to the interface (z-direction). Also, the scattered field will have maximum intensity near to the holes and decay rapidly as the distance along the plane of the interface increases. The decay length (α) and the spatial frequencies (f_x, f_y) of the surface wave are related by: $\alpha^2 + k^2 = 4\pi^2(f_x^2 + f_y^2)$. Here, k is the wavenumber in the dielectric above the interface. This leaves us with two choices: either α would have a unique value (if this is the case, the near-filed would be exactly analogous to SPP and the propagation would be isotropic since, $(f_x^2 + f_y^2)$ would be constant at a fixed frequency) or, α would have multiple values for a fixed frequency (in this case, the near field would be described by multiple evanescent orders in contrast to a single evanescent order for SPP and low-frequency SSP. Also, the propagation would be anisotropic). However, the boundary conditions suggest that the transition of the field across the interface should be smooth if there is no change in the dielectric constant below and above the interface. For single exponential decay, the transition of the field profile across the interface would not be smooth. However, superposition of multiple evanescent orders can make the transition smooth (for example, this phenomenon is found in fluorescence from a bulk material, where stretched exponential decay is used to describe the emission decay curves). In addition, the aperture of the hole occupies most part of the unit cell and constitutes a considerable fraction of the operating wavelength. So, in the high frequency limit, one expects the field profile of SSP to be described by superposition of multiple evanescent orders. We have determined the decay constants of these evanescent orders using angular spectrum representation and have verified the multi-exponential nature of the field profile against data obtained from full vectorial 3-D finite difference time domain (FDTD) simulation. In essence, we have shown that enforcement of the boundary conditions makes the propagation of SSP inherently anisotropic. Anisotropy of SSP propagation is very important in realization of several applications like self-collimation, beam-splitting etc..

In order to further understand the properties of SSP in the high frequency limit, we note that the scattered field from each of the holes can interact with its neighboring holes in a manner analogous to the electron orbitals of different atoms in a crystal. We show that a tight binding model which takes into account next nearest neighbor interactions leads to a closed form expression for the SSP dispersion relation and an analytic prediction for the self-collimation frequency with reasonable accuracy. We also give numerical results in support of our theoretical expressions.

Design of a Low Loss Silicon Based Hybrid Dielectric-loaded Plasmonic Waveguide and a Compact, High Performance Optical Resonator

Cheng-Hung Hsieh, **Chien-Ming Kuo**, **Min-Jyun Huang**, **Yu-Ting Chu**, **and Keh-Chyang Leou**
Department of Engineering and System Science, National Tsing Hua University, Hsinchu 300, Taiwan

Abstract— Here we report the design of a top metal silicon (Si) hybrid dielectric-loaded plasmonic waveguide (TM-SiHDLW) and a compact, high performance TM-SiHDLW-based optical disk resonator. For the TM-SiHDLW, a propagation length of 0.35 mm and a mode area of $\sim$ 0.029 μm^2 were demonstrated by numerical simulation analysis based on finite element method. The waveguide adopted a top metal stripe structure for easier process integration with conventional micro fabrications and a thick (200 nm) metal stripe was found to yield optimal performance due to reduced Ohmic loss in conductor around the stripe edge/corner. Moreover, a relatively thick (150 nm) dielectric spacer between the Si ridge and the metal stripe was employed to achieve both long propagation length and good field confinement. Based on the same consideration, a waveguide width of 200 nm was chosen so that the mode area could be still less than 0.030 μm^2. The effect of a thin silicon nitride (SiN_x) layer covering the waveguide for minimizing uncertainties on optical properties of TM-SiHDLW resulting from high density of dangling bonds on Si surface, has also been investigated. For a SiNx layer thickness less than 10 nm, no significant degradation on the performance of the TM-SiHDLW was found, as revealed by simulation analysis.The disk resonator based on TM-SiHDLW employs a metal enclosure to significantly reduce the radiation loss while minimizing the overall size of the resonator. From the simulation results, a quality factor up to 2000, more than twice the results in previous studies, can be obtained with an acceptable resonator dimension. Therefore, the TM-SiHDLW is a particularly promising candidate for compact plasmonic devices in photonic integrated circuits.

Plasmonic Optical Tweezers Based on Random Metallic Nano-islands

Zhiwen Kang, **Jiajie Chen**, **Haixi Zhang**, **and Ho-Pui Ho**
Department of Electronic Engineering
The Chinese University of Hong Kong, Shatin, N.T., Hong Kong SAR, China

Abstract— We report a highly versatile optical trapping device substrate based on random metallic nano-islands deposited on glass surface. The plasmonic absorption peak of the nano-islands, which is within the visible and near-infrared region, can be tuned by controlling their size and separation using a low temperature anneal process. Optical trapping of polystyrene beads suspended in an aqueous medium at low power density of $\sim 10^2$ W/cm^2 has been recorded. This value is at least 3 orders of magnitudes lower than the threshold power density required by conventional optical tweezers. We have analyzed the force components acting on the beads, which are associated with optical gradient under plasmonic enhancement, convection of fluid above the laser-heated spot and thermophoretic effects caused by the temperature gradient in the hot zone. Our results suggest that thermophoresis plays a significant role in the observed trapping phenomenon. Its dependence on the ion concentration of the aqueous medium is discussed. Optical trapping on the cleaved end of a single-mode optical fiber that has been coated with nano-islands is also possible. The device can be used for trapping life cells such as *E. Coli*. Further incorporation of the nano-island substrate to a microfluidic system readily leads to the demonstration of practical optofluidic applications including guided flow control, light-activated valves and fluidic mixing based on plasmonic local heating in the nano-islands. The reported work provides a simple platform for on-chip optical manipulation of nano- and micro-sized objects, and may offer a wide range of application possibilities in physical and life sciences.

UV Plasmonic Performance of Ga, Mg and Al. Influence of Growing Oxide Shell

D. Ortiz, J. M. Sanz, J. M. Saiz, F. Gonzalez, and F. Moreno
Group of Optics, Department of Applied Physics, University of Cantabria, Spain

Abstract— Resonant response of nanoparticles as a reaction to external electromagnetic fields make them attractive for a wide range of applications, such as real-time sensors, surface enhanced Raman spectroscopy (SERS), light energy guiding, nanosensing or electromagnetically induced transparency, among others [1]. The demands to detect, recognize, and/or destroy biological toxins, to enhance biological imaging, and to characterize semiconductor devices at the nanometer scale has increased the interest in UV plasmonics [2–4]. Previous studies have shown the good plasmonic performance of various metals as Aluminum, Gallium and Magnesium in the UV part of the spectrum [5]. However, taking into account that oxides naturally form on most of the metals, it is important to understand the effect of oxidation on their plasmonic response [6, 7].

In this research, the effect of the growing oxide shell on the plasmonic performance is numerically analyzed using the Discrete Dipole Approximation (DDA) method [8]. To perform the calculations, a hemispherical nanoparticle, radius of 40 nm, located on a dielectric substrate (sapphire, $n = 1.78$), is considered to mimic typical experimental conditions [9]. The nanoparticle consists of a core/shell metal/native oxide structure, in which the core radius changes from 20 to 38 nm. The system has been excited by a monochromatic, linearly polarized plane wave at normal incidence. For each of the metals considered, the spectral dependence of the following two parameters has been calculated and analyzed: 1) the absorption efficiency of the particle system, and 2) the intensity of the electric field enhancement averaged over the surface.

From the results, it can be concluded that the addition of an oxide shell on the nanoparticle surface produces a decrease of both the amplitude of the electric field and the absorption efficiency for all cases. Besides, the resonance could be either red or blue shifted depending on the material and the thickness of the shell. These results may help explaining the behavior of metals nanoparticles. They also show the importance of controlling the oxide contamination and open a way to tune resonances in nano-antenna design.

Effective Medium Theory for Metamaterials beyond the Long-wavelength Limit

Shiwei Tang, Baocheng Zhu, Qiong He, Shulin Sun, Yongfeng Mei, and Lei Zhou
State Key Laboratory of Surface Physics
Key Laboratory of Micro and Nano Photonic Structures (Ministry of Education)
Physics Department, Fudan University, Shanghai 200433, China

Abstract— Metamaterials are electromagnetic composites constructed by subwavelength-sized microstructures, and thus can exhibit tailored *effective* permittivity ε and permeability μ. Metamaterials have attracted much attention recently due to their strong abilities to manipulate electromagnetic waves, leading to many fascinating physical effects unattainable in naturally existing materials. In this research field, effective-medium theory (EMT) plays a crucial role since it serves as a bridge to link theories, which are frequently conducted on model hypothetical systems, and experiments which are always performed on realistic metamaterial systems with complex microstructures. Therefore, a good EMT, which can better guide people to design appropriate metamaterials to realize the predicted phenomena, is always highly desired. In the past years, many versions of EMTs were successfully developed, but many of them suffer different limitations in different aspects [1].

Here, we proposed a new version of EMT, which is particularly suitable for determining the effective parameters of a periodic structure involving *dispersive* metallic structures. Based on the mode-expansion theory under a single-mode approximation, we can derive the analytical expressions for the reflection/transmission coefficients at the interface between air and the target metamaterial. Mapping such a complex structure to a homogeneous system, we then obtain the effective-medium parameters of the metamaterial by requesting the two systems to exhibit the same reflection/transmission coefficients. We first employ our EMT to study the effective-medium properties a multilayered structure (Fig. 1(a)) composed by two different slabs with arbitrary constitutional and geometrical parameters [2]. Our EMT not only recovers those previously derived formulas valid only at certain limiting conditions [3, 4], but works well far beyond these limitations to nearly cover the whole parameter spaces as long as the subwavelength condition is satisfied. Finite-difference-time-domain (FDTD) simulations and microwave experiments are performed on realistic structures to justify our theory. We next generalize our theory to a more complex situation which consists of a two-dimensional periodic array of metallic structures with arbitrary cross sections (Fig. 1(b)). More applications of our theory will be described in the conference [5, 6].

Ultrathin Metasurfaces with Ultrahigh Cross-polarization Conversion Efficiency

Cheng-Wei Qiu[1], **Xumin Ding**[1, 2], **Kuang Zhang**[2], **Lei Zhang**[1], **Qun Wu**[2], **and Fei Qin**[1]

[1]Department of Electrical and Computer Engineering, National University of Singapore, 117583, Singapore
[2]Department of Microwave Engineering, Harbin Institute of Technology, Harbin 150001, China

Abstract— Recent years have witnessed a great surge of interest in metasurfaces providing phase-discontinuities, which find novel applications in flat lenses, spin-orbit manipulation, wavefront engineering, holography, etc.. Compared to conventional lenses or imaging devices, metasurfaces provide an alternative approach to wave manipulation, thickness reduction, pixel refinement, and transverse resolution. However, ultrathin metasurfaces operating in transmission face the challenge of extremely low efficiency, as only a few percent of the total power of incident light gets processed by the metasurface, preventing the widespread use of these devices. Here, we experimentally demonstrate two types of ultrathin metasurface with manipulation efficiency one order higher than previous works in visible and microwave frequencies.

On one hand, without sacrificing the ultrathin flatness (with finite — yet small — thickness), we proposed a complementary bilayer metasurface operating at visible range by incorporating stacking a V-shaped metasurface atop its Babinet inverted version with a gap of 70 nm in between, which demonstrated a remarkably high conversion efficiency of 29% and extinction ratio of 12.7 dB simultaneously within a broadband. For the first time, positive extinction ratio is achieved, indicating an anomalous light dominated transmission.

On the other hand, based on Pancharatnam-Berry phase elements, we design and verify a planar ultrathin metalens ($\sim \lambda/1000$ in thickness) demonstrating anomalous cross-polarization transmission efficiency reaching $\sim 24.7\%$ in our proof-of-concept experiment, which is almost at the theoretically predicted upper limit 25% for ultrathin metasurfaces. By controlling the handedness of the incident wave, in fact, converging and diverging functions are interchangeable using the same flat lens. Our finding presents a significant leap for the transmission type metasurface, beneficial to put metasurface into practical application.

New Applications for Zero-index Metamaterials

Yangyang Fu, Aichen Chen, Yadong Xu, and Huanyang Chen
College of Physics, Optoelectronics and Energy, Soochow University, Suzhou 215006, China

Abstract— In this talk, we will firstly introduce an interesting property of epsilon-near-zero (ENZ) metamaterials — The Goos-Hanchen effect. After that we will show that electromagnetic wave transmission could be manipulated in a zero-index-metamaterials (ZIM) waveguide structure which consists of a narrow dielectric slit. Finally, we will design a light emitter based on another interesting property of ZIM.

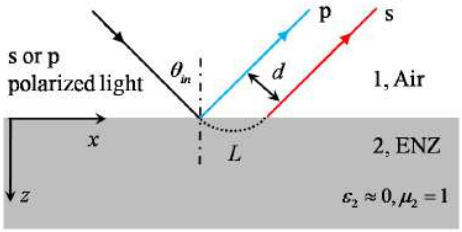

Figure 1: The schematic plot for the Goos-Hanchen effect in ENZ metamaterials.

Effective Surface Conductivity and Absorption Enhancement of Graphene Meta-surface

Yuancheng Fan and Fuli Zhang
Key Laboratory of Space Applied Physics and Chemistry
Ministry of Education, Department of Applied Physics, School of Science
Northwestern Polytechnical University, Xi'an 710072, China

Abstract— A kind of single-layer metamaterials, namely meta-surface [1, 2], has drawn enormous attention in recent years for various possibilities to manipulate light with ultra-thin structured surfaces. Plasmonic resonance of graphene micro/nano-structure is promising for atomically thin and tunable meta-surface [3–5]. We employed a recently proposed sheet retrieval method [6], which is quite suitable for the two-dimensional materials, to get the effective surface conductivity of graphene meta-surface [5]. The effective surface conductivity is helpful in understanding the optical response of graphene meta-surface, we will present our recent studies on graphene meta-surface based tunable absorption enhancements [7–9].

Nonclassical Light Propagation through Atmospheric Turbulence

Jeffrey H. Shapiro
Research Laboratory of Electronics, Massachusetts Institute of Technology
Cambridge, MA 02139-4307, USA

Abstract— Free-space optical (FSO) communication, by which is meant line-of-sight laser communication of classical information through the earth's atmosphere, has received enormous attention, starting from soon after the invention of the laser. It is long been understood that reliable, high data-rate (say Gbps) FSO communications will be precluded by the presence of clouds or fog in the line of sight, limiting such links to operation in clear weather conditions, in which the principal propagation impairments — at wavelengths outside of atmospheric absorption lines — are those due to refractive-index turbulence. The extended Huygens-Fresnel principle — augmented to include atmospheric extinction loss — provides a powerful tool for analyzing and optimizing FSO optical communication in clear-weather conditions. Because turbulence is non-depolarizing, and has sub-psec multipath spread plus msec or longer coherence times, the extended Huygens-Fresnel principle takes the following form

$$E_L(\rho', t) = \int_{\mathscr{A}_0} d\rho E_0(\rho, t - L/c) h(\rho', \rho), \quad \text{for} \quad \rho' \in \mathscr{A}_L. \tag{1}$$

Here, $E_0(\rho, t)$ and $E_L(\rho', t)$ are the scalar complex envelopes of the $\sqrt{\text{W/m}^2}$sec-units laser fields for the transmitted and received light, respectively, as functions of the transverse coordinate vectors $\rho = (x, y)$ and $\rho' = (x', y')$ in the transmitter's exit pupil ($\mathscr{A}_0$ in the $z = 0$ plane) and the receiver's entrance pupil ($\mathscr{A}_L$ in the $z = L$ plane) and time t. Equation (1) assumes that the transmitted field's bandwidth is less than the atmosphere's coherence bandwidth (reciprocal of its multipath spread), and that this field's time duration is shorter than the atmosphere's coherence time. As a result, the temporal behavior of the extended Huygens-Fresnel principle is reduced to the line-of-sight time delay, L/c, where c is light speed. More importantly, Equation (1) is a spatial-superposition integral — a consequence of propagation through turbulence being a linear, albeit stochastic, process — whose Green's function is often written as

$$h(\rho', \rho) = e^{-\alpha L/2} \frac{e^{ikL + ik|\rho' - \rho|^2/2L}}{i\lambda L} e^{\chi(\rho', \rho) + i\phi(\rho', \rho)}. \tag{2}$$

From left to right, the terms on the right-hand side represent: atmospheric extinction loss with path-average extinction coefficient α; paraxial propagation through vacuum at the laser's center wavelength λ (center wave-number $k = 2\pi/\lambda$); and the turbulence-induced logamplitude $[\chi(\rho', \rho)]$ and phase $[\phi(\rho', \rho)]$ fluctuations imposed on the field received at $\rho' \in \mathscr{A}_L$ from a point-source emission from $\rho \in \mathscr{A}_0$ during the coherence time in question. Within the weak-perturbation regime, complete statistics for the turbulence fluctuations have been developed from the Rytov approximation. For many purposes, however, the mutual coherence function of the $\exp[\chi(\rho', \rho) + i\phi(\rho', \rho)]$ suffices, and this function is known — from the local method of smooth perturbations or the small-angle approximation to the linear transport equation — well into the regime of saturated scintillation.

With the rise of interest in quantum information processing, the use of nonclassical light beams, e.g., photonnumber states, squeezed states, and entangled states, for transmission of classical and/or quantum information over atmospheric paths has likewise garnered increasing attention. In this paper we will start from the quantum form of the Huygens-Fresnel principle for propagation through vacuum [1, 2] and develop the corresponding quantum form of the extended Huygens-Fresnel principle. We will also present some illustrative results obtained therefrom.

High Harmonic Generation in the Undulators for Free Electron Lasers

K. Zhukovsky
Department of Theoretical Physics, Physical Faculty
M. V. Lomonosov Moscow State University, Moscow 119992, Russia

Abstract— Undulator radiation (UR) was discovered by Motz in the middle of the 20th century. It represents a form of a synchrotron radiation (SR) and is due to the photon emission by accelerated relativistic electrons, executing oscillatory trajectories in a periodic magnetic field. Free electron lasers (FEL) require UR sources with special properties, calibrated for the user's needs. In particular, high UR harmonics are used to advance towards X-ray range. Modern UR designs include precision made many period undulators with, sometimes, double period magnetic field. High quality of the UR harmonic is of paramount importance. UR line is unavoidably subjected to broadening, originated from various sources, such as the electron energy spread, the beam divergency, the transport losses and the non-periodic magnetic components. Analytical expressions for the UR spectrum and for the intensity are obtained in the case of high-energy electrons with account for major sources of the spectral line broadening. The compensation of the divergency by the constant magnetic component is demonstrated in the analytical form. High harmonic generation is studied with account for all relevant sources of homogeneous and inhomogeneous broadening. In long undulators with $N > 150$ and $k > 1$, instead of the expected gain for the high harmonics a significant line broadening may occur, being a negative factor for high gain SASE FEL. The X-FEL source electron beam with $E = 17.5\,\mathrm{GeV}$ ($\gamma = 35000$), the energy spread $\sqrt{\sigma_e} = 10^{-4}$ and the initial deflection $\theta_0 = 2 \cdot 10^{-3}\,\mathrm{mrad}$ is considered. The shapes and the normalized intensities of the generated UR harmonics are shown. Good usability of wide range of the harmonics with the small deviation $|\Delta\nu_{n=9}| \approx 3$ of the frequencies from the ideal spectrum is confirmed. The radiation of a FEL with a double frequency undulator is evaluated with account for losses. Even for a highly monoenergetic beam with $\sqrt{\sigma_e} = 10^{-4}$ and with the divergency $\gamma\psi_{\max} = 0.1$ we obtain for a SASE FEL a significant reduction of the high harmonic saturated power, almost down to the level of the FEL performance with a common planar undulator. When the third harmonic is suppressed by the field H_2 of the proper sign, the fifth harmonic dominates, but its intensity decreases by one order due to the homogeneous and the inhomogeneous losses, as compared with the evaluations for an ideal undulator.

Coherent Synchrotron Radiation and Self Amplified Spontaneous Emission Free Electron Lasers (SASE-FEL)

K. Zhukovsky
Department of Theoretical Physics, Physical Faculty
M. V. Lomonosov Moscow State University, Moscow 119992, Russia

Abstract— New type of X-ray radiation source — X-ray free-electron laser (XFEL) should give the potential of providing the sub-picosecond pulse length of a conventional laser at the X-ray wavelength of a synchrotron radiation source.

In FEL electrons enter the undulator with initially random phases, so that mostly incoherent undulator radiation (UR) is emitted at the resonant UR wavelength. Because the electrons interact collectively with the radiation they emit, small coherent fluctuations in the radiation field grow and simultaneously begin to bunch the electrons at the resonant wavelength. This collective process continues until the electrons are strongly bunched at the end of the undulator, where the process saturates and the electrons begin to de-bunch.

In between undulators and SASE FEL oscillators are positioned. They employ mirrors, which limit the high frequency range — common mirrors do not reflect well $< 100\,\mu$m but allow easy mode locking mechanism. Inside the gain bandwidth, longitudinal modes of the laser will constructively periodically interfere with each other when in phase, producing an intense burst of light. Only phase-matched wavelengths will constructively interfere and form the modes of the radiation field to create a comb of equally spaced modes in the output frequency spectrum. Mode locking modifies the temporal envelope of the output field from a continuous wave to a series of short, periodically spaced pulses.

Laser macropulse of microsecond duration consist of a train of short micropulses, which are picoseconds in length. Used for ultrafast spectroscopy and femto-chemistry. The macropulses repeat at a repetition ratio limited by the accelerator usually 10–100 of Hz. The micropulse repetition rate can be from several MHz to even THz. Electrons move some slower than photons and as the wave in the undulator travels over a distance $\lambda/2$ in a time $\lambda/(2c)$, the electron travels over a smaller distance $\lambda_u/(2c)$, so that wave slip on half undulator period becomes $\lambda_u/2$.

Why is it more difficult to build free-electron lasers for X-rays than for larger wavelengths? For small wavelengths we need high-energy electrons, but high electron energy also increases the gain length LG $\sim \gamma$. We must keep the gain length short, as required for an X-FEL. The undulator field H_0 and period λ_u must be maximized, but λ_u must remain short for short wavelength $\lambda{\sim}\lambda_u/\gamma^2$. The electron beam current i must be high and its transverse cross section σ small. However, the γ-factor cannot be freely decreased if we want to obtain X-ray wavelengths. In the X-ray there are almost no good mirrors to form an oscillator cavity. The FEL functions as a single-pass amplifier, generating peak powers of the order of 10^{10} W in pulses, lasting tens of femtoseconds.

The high-gain FEL interaction is a positive feedback process — the electrons emit radiation, which affects their position (phase) and thus causes them to emit with greater coherence. SASE FEL process arises from noise. First waves emitted by the electrons trigger formation of microbunches. Contrary to non-micro-bunched electrons (c), the emission in micro-bunches of electrons (d), separated from each other by one wavelength, is correlated! This causes an exponential intensity increase with the distance that continues until saturation is reached. If an initial coherent laser seed wave is superimposed over the random electron phase, this seed is amplified along the undulator and yields bunching at seed wavelength until saturation. In this regime, the energy oscillates between the wave and the electrons rather than continuing to increase exponentially for the wave.

High gain harmonic generation (HGHG) schemes exploit Seed laser + harmonic generation section + amplifier. The first, short undulator is tuned to the frequency of the coherent seed laser whose interaction with the electron beam introduces a small longitudinal energy modulation. The magnetic dispersion section converts this energy modulation into a density modulation. The second undulator, called the radiator, is tuned to the n-th harmonic of the seed frequency. When the modulated electron beam passes the radiator, the radiation produced by the n-th harmonic component is amplified to saturation pulses with < 20 fs duration.

To make pulses shorter a SASE FEL design with chicane mode-locking is introduced. The magnetic chicanes give an extra slippage of the radiation with respect to the electron bunch.

Only those radiation wavelengths that have an integer number fit into the relative — radiation to electron bunch — slippage in one module will remain phase-matched to constructively interfere over many modules. Such constructively interfering wavelengths form the modes of the radiation field to create a comb of equally spaced modes in the output frequency spectrum.

Alternatively, self-seed FEL scheme forms short pulses. Its advantage: independent of any external radiation source (which must be very stable, precisely matched to the electron beam in space and time). Same frequency in two undulators! First undulator, a short SASE FEL, operates in the linear gain regime, produces radiation pulses with the characteristic features of SASE at a power level approximately three orders of magnitude below saturation. The electron beam is then sent through a magnetic chicane, which destroys the density modulation introduced in the first undulator and delays the electron beam by the same amount as the radiation pulse. The radiation pulse is spectrally filtered by a narrow-band grating monochromator, which stretches the pulse and provides a coherence length longer than the electron bunch length. This radiation is the seed for the second undulator, which amplifies it to saturation. The output radiation exhibits a narrow spectral line with only a small background of spontaneous radiation. Spectral brightness increases in this way by almost two orders of magnitude!

Main factors degrading the FEL emission are electron energy spread, angular divergence, transverse electron beam size, diffraction of the wave. As the electrons transfer energy to the wave, their own energy decreases. The wave emission is not the same from all electrons, so that different electrons have different energies, with an increasing energy spread. At a certain point, the energy spread is so large that there is no gain anymore.

Much before the electrons loose a substantial portion of their energy they slow down by emitting electro-magnetic energy, change their phase with respect to the wave and start taking energy rather than giving it!

Future developments of X-FELs include improved temporal coherence of X-ray SASE and the development of relatively high-reflectivity diamond crystal mirrors in the X-ray regime makes them feasible. Reducing X-ray pulse durations to the attosecond regime will provide spatiotemporal resolution of atomic processes below 100 as.

Investigation the Possibility of Obtaining Spiral Light Beams with Adjustable Parameters

Abstract— Light beams with controllable parameters are widely used in science and industry. Beams with non-uniform distribution of intensity, phase and polarization are used in laser tweezers, for microscopic objects manipulation, objects non-destructive testing, surface treatment, laser welding and drilling, studying the surface properties and the new materials creation.

Here we show how it is possible to generate a light beam in a form of spiral with the controllable pitch, length and radius. Beams with wavefront dislocations have a spiral phase distribution in the direction of propagation. The maximum intensity of the interference pattern of a Gauss beam and a co-propagating beam with a wavefront dislocation forms a spiral curve in the space. Selecting the appropriate parameters of the light beams it is possible to obtain the desired intensity distribution in the direction of propagation.

In order to calculate the intensity distribution of the interference pattern the scalar wave equation was solved using MATLAB software. The beam waists of the beams under consideration were supposed to be coincident.

The numerical simulations have shown that the spiral pitch decreases with the Bessel beam of the first order divergence increasing, the stable length of the spiral decreases with the Gauss beam divergence decreasing.

We present a method of generation of beams with the spiral intensity distribution in the direction of propagation. The pitch of spiral distribution is determined by the numerical aperture of the Bessel beam and the stable length of the spiral distribution is determined by the numerical aperture of the Gauss beam. The proposed method was tested experimentally.

Structured Laser Radiation in Optical Inhomogeneous Media Refractography

B. S. Rinkevichyus, I. L. Raskovskaya, A. V. Tolkachev, and A. V. Vedyashkina
V. A. Fabrikant Physics Department, National Research University "Moscow Power Engineering Institute"
Moscow 11250, Russia

Abstract— The report devoted to analysis of the properties of structured laser radiation (SLR) produced from Gaussian beam passing through a refractive (ROE) or diffraction (DOE) optical elements and its applications in the modern method of optically inhomogeneous media investigation — laser refractography [1]. Fig. 1 shows example of schematic diagram of laser refractographic setup. SLR passes through transparent optically inhomogeneous medium with temperature stratification (4), recorded by digital camera 6, processed by personal computer 7 and then we can obtain characterization of optically inhomogeneous medium (temperature graph 8).

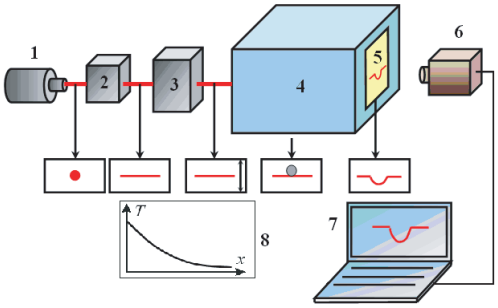

Figure 1: Schematic diagram of the experimental setup: 1 — laser, 2 — DOE, 3 — scanning system, 4 — medium under study, 5 — diffuse screen, 6 — CCD camera, 7 — PC, 8 — refractogram processing.

The setup uses semiconductor laser 1 emitting radiation in the red or the green wavelength region. The radiation power amounts to 5–25 mW. The laser beam passes through DOE 2 that transforms the initial narrow laser beam into a structured laser radiation differing in shape, for example, plane, conical, or cross-shaped laser beams. To position these beams with respect to the object under study, use is made of scanning system 3 that allows these beams to be moved in two orthogonal planes. Temperature and concentration boundary layers in the vicinity of heated or cooled bodies, as well as diffusion layers, are investigated in glass cell 4. Two-dimensional refractograms are observed on diffuse screen 5 from the cell and recorded with digital camera 6 whose output is entered into personal computer 7. The computer processing of the refractograms by means of a special program yields information 8 about the parameters of the near-wall and boundary layers. The bottom row of images in the above Figure 1 illustrates the stages of transformation of the narrow laser beam into structured radiation and then into a 2D refractogram.

The experimental technique for studying various boundary temperature layers near heated or cooled bodies was described in detail in the monograph [1].

Controlling the Lasing Threshold in Two-dimensional Photonic Crystals with Gain

Sotiris Droulias[1], **Peng Zhang**[2], **Thomas Koschny**[2], **and Costas M. Soukoulis**[1, 2]

[1]Institute of Electronic Structure and Laser, FORTH, Heraklion 71110, Crete, Greece

Ames, Iowa 50011, USA

Abstract— The need for lasers with dimensions as small as possible leaves little space for the gain material, which can push the lasing threshold to extremely high levels. In order to overcome this, light must interact with the gain material as long as possible. This can be achieved when the group velocity is very low and the fact that photonic crystals offer this feature at their band edges makes them an excellent candidate.

Based on this idea, we investigate the lasing threshold in microstructured systems containing a four level gain medium and show how it can be modified as a result of the interplay between the group velocity and interface reflectivity of the lasing mode. To this end, we establish a simple theoretical model that decomposes the contributions of these features to the Q factor. In order to demonstrate them in realistic structures we choose a 2D PC of a finite amount of layers. The Maxwell equations are coupled with the semi-classical 4-level rate equations and are self-consistently solved under a finite-difference time-domain (FDTD) scheme [1]. Our simulations show that operation near the band edge can lead to strong reduction of the lasing threshold with respect to a uniform gain slab of the same dimensions, in spite of the lower gain density, even for as few as 10 layers [2]. Moreover, with a slight structural modification, the PC is surprisingly demonstrated to exhibit lower lasing threshold at steeper band edges. Our self-consistent FDTD calculations are explained in a straightforward manner by the theoretical model, which may also predict other counter-intuitive behaviors, such as lower lasing threshold inside a band, rather than the band edge.

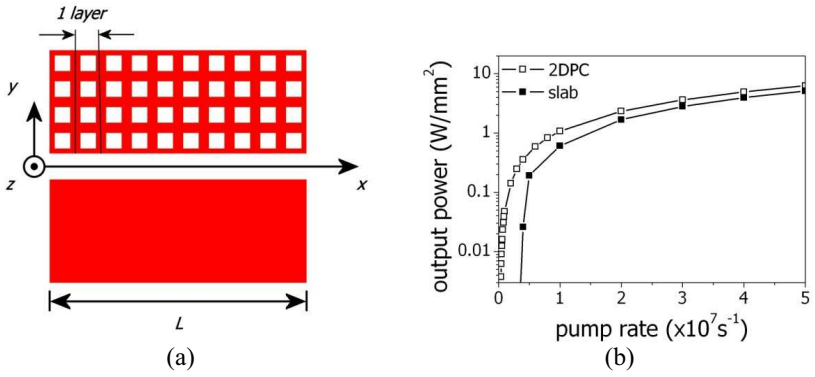

Figure 1: (a) Schematic of the 2DPC consisting of 10 layers (top) and the respective slab of uniform gain and same length (bottom). The red areas denote the host dielectric which is homogeneously embedded with the four-level gain material. Both systems are infinite in the yz plane and confined in the x direction, along which the emitted wave propagates. (b) Lasing power in log scale of the 2DPC (open squares) and gain slab (filled squares) as depicted in Figure 1(a) for different pump rates. Both systems operate at the frequency which corresponds to the bottom of the 2nd band of the 2DPC. The lasing threshold of the photonic crystal is 1 order of magnitude lower than that of the gain slab.

Investigation of Kinetic Processes of a Diode-pumped Alkali Laser

Guofei An, You Wang, Juhong Han, He Cai, Wei Zhang, Liangping Xue, Hongyuan Wang, Zhigang Jiang, Jie Zhou, and Ming Gao
Southwest Institute of Technical Physics, Chengdu, Sichuan 610041, China

Abstract— A diode-pumped alkali laser (DPAL) provides the significant promise for high-powered performances. For a high-powered DPAL, both the absorption and the lasing distribution crucially affect the output physical features. In this report, a mathematical model is introduced for examining the kinetic processes of the gas-state media by using a segmental approach. The energy transmission inside the oscillator has been theoretically analyzed for construction of a reciprocating regime which is based on the self-consistency principle. Basically, the conclusion can be extended to any end-pumped laser configurations.

Abstract— Frequency conversion efficiency of IR laser radiation in nonlinear-optical crystals extremely depends on both absorption and scattering properties of the crystal. Recently, piezoelectric resonance laser calorimetry was introduced for the precise measurement of optical absorption coefficients of crystals [1].

In present paper novel method is proposed for measurement of scattered radiation power of nonlinear-optical crystals. Like piezoelectric resonance laser calorimetry it is based on the concept of equivalent temperature of crystal heated by laser radiation [2]. Equivalent temperature of nonlinear-optical crystal is determined directly by measuring frequency shift of the temperature calibrated piezoelectric resonance. Piezoelectric resonance can be observed when the external electric field frequency corresponds to one of the crystal internal vibration mode frequencies. At first approximation piezoelectric resonances frequencies linearly dependent on temperature during uniform heating of the crystal $Rf_i(T) = Rf_i(T_0) + K_i^{\mathrm{prt}}(T - T_0)$. It was demonstrated that thermodynamic temperature of the crystal, nonuniformly heated by laser radiation of P power, can be replaced by its equivalent temperature: $\Theta_{\mathrm{eq}}(P) = T_0 + (Rf_i(P) - Rf_i(T_0))/K_i^{\mathrm{prt}}$, where T_0 is crystal temperature at zero power. Power of radiation scattered by nonlinear-optical crystal, can be determined by measuring equivalent temperatures of two additional resonators that are made of the identical crystal material and are placed at fixed equal distances from the main nonlinear-optical crystal that interacts with laser radiation. Difference between two additional resonators is that first one is transparent to the scattered radiation and the second one is absolutely opaque ("black body") and completely absorbs radiation in wide spectral range. Temperature change of additional resonators is primarily conditioned by the ambient air heating. Still additional heating of the second resonator is caused by absorption of both scattered radiation and thermal radiation of the main crystal. In the experiment $KTiOPO_4$ (KTP) crystal with dimensions $3 \times 3 \times 30\,\mathrm{mm}^3$ was used as the main crystal and additional resonators were made of thin ($0,\ 2 \times 3 \times 30\,\mathrm{mm}^3$) $LiNbO_3$ crystals. Transmission of 7 W laser radiation at 1064 nm wavelength through KTP of resulted in 1 K difference between equivalent temperatures of non-transparent and transparent $LiNbO_3$ crystals. Theoretical estimation gives several mW of total power scattered in KTP that corresponds to the 0.1% scattering coefficient. It should be noted that KTP optical absorption coefficient has the same order.

The Effect of Iron Nano-inclusions in Multilayered Integrated Optical Waveguides

Isabelle G. de Moraes[1], **Anderson O. Silva**[1],
Maria Aparecida G. Martinez[1], **and Maria Thereza M. R. Giraldi**[2]

[1]Photonics Laboratory, Centro Federal de Educação Tecnológica Celso Suckow da Fonseca, Brazil

Abstract— In the last years, research on new materials and technologies together with established modal coupling theories has featured the construction of directional couplers, power dividers, polarizers and isolators [1]. Most of these devices are based on the control of the electrical field properties, as the propagation modes, polarization and others. In this work, we investigate the impact of ferromagnetic composite nano-inclusion in the coupling of multilayered optical waveguides structure based on alternating InGaAsP and InP layers, operating at 1550 nm. The complex refractive index of the mixture (the host and inclusion materials) is obtained from iron experimental optical properties data and Maxwell Garnett models [2]. The beating length and power transfer within the multilayer structure are determined by the use of the nonorthogonal Coupled Mode Theory [3, 4] for an identical and a non-identical cases. In the identical case, the guiding layers are incrusted identically with the same filling factors in the structure and otherwise in the non-identical case. The motivation is to use nano-inclusions to improve the coupler efficiency increasing the modal confinement, and decreasing the beating length. This effect occurs because increasing the concentration of these nano-inclusions enhances the difference between the refractive index in the waveguide layers. On the other hand, ferromagnetic composite adds loss to the system, creating a trade-off between decreasing beating length and output power. Overall, for the identical case, the beating length decreases with the increase of the nano-particles filling factor, for the cladding thickness ranging from 0.3 µm up to 1 µm. The reduction rate is more sensitive to the filling factor for a cladding thickness greater than 0.6 µm. For a filling factor of 0.2%, the beating length reduces from 107.2 µm to 34.5 µm, a 70% reduction with respect to the lossless case, for a cladding thickness of about 0.8 µm. The total power decreases with the enhancement of the filling factor values and cladding thickness. For a 0.2% filling factor, losses in the structure vary from 3 dB up to 8dB for the cladding thickness ranging from 0.3 µm up to 1 µm. For the non-identical case, the structure beating length reduces with the nano-inclusion filling factor. For a 0.2% filling factor, the beating length reduces from 107.2 µm to 60 µm, about 56% of reduction with respect to the lossless case for a cladding thickness of 0.8 µm. The structure total losses reduce substantially when compared to the identical case, reaching a maximum of 2 dB loss for a 0.2% filling factor. The total loss reduction in the non-identical case strongly depends on cladding thickness. As the cladding thickness increases, the coupling waveguide slightly decouples, and light remains mainly in the lossless waveguide, reducing the overall loss. We demonstrate that suitably controlling the nano-inclusion filling factor and cladding thickness, particularly for the fundamental TE modes, a more efficient multilayer coupling structure, with reduced beating length and reasonably losses can be designed.

Abstract— Temperature sensor based on the FBG inscribed radiation-resistant specialty optical fiber under γ-ray irradiation was demonstrated. The measured temperature sensitivity at dose-rate of 35.33 Gy/min from 30°C to 100°C was about 7.2 pm/°C.

Recently, we have developed a radiation-resistant germano-silicate fiber with two inner cladding layers of a pure silica buffer and a boron-doped silica, to enhance photosensitivity for inscribing FBG in the fiber core without decreasing the radiation resistance [1]. We demonstrate a novel temperature sensor based on the FBG inscribed radiation-resistant fiber within a temperature range from 30°C to 100°C under γ-ray irradiation with a ^{60}Co γ-ray (MSD Nordion, pencil type/C-188 sealed) at dose-rate of 35.33 Gy/min (total dose of 10,458 Gy). A 10 mm length of FBG was inscribed onto the 200 mm fiber by using a phase mask (QPS Photronics Inc.) with a KrF excimer laser at 248 nm. The temperature dependent Bragg reflection wavelength of the FBG was measured under γ-ray irradiation by using the optical spectrum analyzer (OSA, Ando AQ 6317B) together with the white light source (WLS, Ando AQ 4305) operating around 1310 nm as an input light source.

The peak power of the Bragg reflection band at 1310.09 nm and the full width at half maximum (FWHM) bandwidth of the fabricated FBG were about 15.62 dB and 0.24 nm, respectively. With the increase of temperature from 30°C to 100 °C under the γ-ray irradiation from 0 to 6,642 Gy for 188 minutes, the power and the wavelength of the Bragg reflection peak were found to decrease to 15.28 dB and shift toward longer wavelength of 1310.81 nm, respectively. But the FWHM bandwidth remained practically unchanged during the γ-ray irradiation, regardless temperature. The measured temperature sensitivity of the fabricated FBG at dose-rate of 35.33 Gy/min was about 7.2 pm/°C.

Abstract— Formation of point defects in optical fibers by intense ionizing radiation causes radiation-induced attenuation (RIA) that can seriously degrade the capabilities of most fiber-based devices such as fiber lasers, high-speed communication systems, nonlinear optical devices, and fiber sensors, etc.. Radiation-hardening against the RIA is therefore indispensable for the fiber-based applications in radiation-harsh environments.

By modifying the fiber geometry or glass composition, one can simply obtain desirable optical properties. Photonic crystal fiber (PCF) has a cladding region comprised of arrays of air holes that run along the fiber length surrounding the central core. Investigations concerning the radiation response of the PCF have been performed to evaluate the feasibility of the PCF based applications in radiation-harsh environments, which seems to be promising due their radiation resistance [1].

In this study, we have fabricated a PCF with fluorine (F) doped silica glass core which is known to be the most radiation resistant composition under steady-state gamma-ray irradiation conditions [2]. The PCF was fabricated by the stack-and-draw technique using fused silica capillary tubes and a F-doped silica glass rod with F concentration of $\sim 1,000$ ppm (Shin-Etsu Quartz Products Co., Ltd.). The core size, the hole diameter, and the pitch of the PCF were around 1.9 μm, 1.2 μm, and 2.4 μm, respectively. A 1 meter length of the PCF was intermittently pre-irradiated by gamma-ray from ^{60}Co source. The RIA characteristics of the PCF was investigated under different irradiation conditions (dose rates, accumulated dose, and irradiation interval). After the pre-irradiation, the RIA level at 1310 nm of the fiber was found to greatly decrease and became rapidly saturated. The measured rapid and large extent recovery of the RIA after the end of the irradiation was thought to be worthy of notice.

Abstract— Microbubble has stimulated broad attention for the highly-efficient contrast agents in biomedicine and drug delivery, and microfluidic control. There is still a challenge to generate different kinds of microbubbles by numerous techniques including flow-focusing devices and ultrasound-induced cavitation. The complex focused laser controlled systems can produce for microbubbles based on photothermal effect, but has large loss. In view of cost and operability, assembling photothermal materials onto microwire exhibiting strong evanescent field should be more desirable to produce microbubbles. Herein, we present a representative photothermal device by depositing graphene oxide (GO) onto a microwire. Excited by the near-infrared light, GO-deposition can act as a heater for creating a variety of microbubbles. Three kinds of microbubble were successfully generated by the GO-heater. Firstly, when the GO-microheater was immersed in N,N-dimethylformamide (DMF) and superheat limit of the liquid was reached, a lot of spherical microbubbles with diameters from tens to hundreds of micrometers were generated directly on the microheater based on nucleate boiling. Secondly, when the GO-microheater was located at the DMF/air interface and its neighboring microwire was immersed in GO-DMF suspension, ellipsoid microbubbles were indirectly generated on the smooth microwire based on heterogeneous nucleation and continuously grew in the thermal gradient field governed by GO-microheater. Finally, massive cavitating microbubbles can be generated near a GO microcavity and ejected away at the high excitation power. This technique has prospective applications in microfluidics, optofluidic control, and other biochip techniques.

A High Survivability Mesh Topology FBG Based Optical Sensing System with SDN Controlling

Jhih-Heng Yan[1], **Wei-Cheng Chen**[2], **You-Wei Chen**[1], **Kai-Ming Feng**[1, 2], **and Chung-Yu Wu**[3]

Abstract— Optical sensing technique has been studied and developed for decades, where fiber Bragg grating (FBG) based optical sensing systems are one of the most attractive research topics. Due to the light weight, electromagnetic interference immunity, and high sensing accuracy properties, optical sensing system with FBG sensors have been applied to various sensing environments, not only large-scale infrastructures but also industrial equipment and personal wearing devices. However, due to the weak structure nature of fibers, FBG as well as their connection fibers usually suffer from environmental and human damages. Many conventional optical sensing systems will be partially or totally out of work even one link/node failure occurs.

To enhance the system survivability, we have proposed a FBG sensing system with a novel mesh network topology in our previous works. In the design of our proposed FBG based optical sensing system, each sensor set integrates multiple FBG segments referred to different Bragg wavelengths. The wavelength arrangement not only follows an interleaved manner among the designed four sensor sets, but also corresponds to the applied arrayed waveguide grating (AWG) channels. With such design, the sensing resolution can be optimized based on different sensing environments by manipulating the FBG segment combination in each sensor set. Furthermore, almost all sensor sets can act as the light-paths while they are not the sensing target during the sensing procedure period, which greatly enhances the sensing network survivability.

Based on our previous achievement, in this paper ready for PIERS submission, we introduce *software-defined network* (SDN) technique to our sensing system. Also, although SDN technique is recently popular in wireless sensing networks, to authors' best knowledge, this is the first time that SDN technique is employed in an optical sensing system. The manual operation is basically out of the network control procedure, which is exactly one of the design principles of SDN technique. To further reduce the system controlling complexity, we design a multiple-region sensing network with multiple SDN controllers. With the interconnection specification of SDN controllers, this multiple sensing-region can be effectively realized, where the most noteworthy features are listed below.

- *The power and the round-trip time of sensing signal are reduced.* The whole sensing network is reorganized as multiple smaller regions, where each of them is supervised by a SDN controller. Since the distance between central office and every FBG sensor set decreases, the power and the round-trip time of sensing signal are thus largely reduced.
- *The complexity of the remote node controlling is relieved.* The remote node controlling has been used to be a complicated issue. With the employment of multiple-region sensing network as well as SDN controlling, the quantity of supervising remote node is reduced, and therefore the controlling complexity is relieved.
- *The survivability of sensing network is further strengthened.* While a link/node failure occurs, its SDN controller will inform this network state to other controllers. Therefore, all the SDN controllers in the sensing network may take over the alternative sensing paths recalculated by *Dijkstra's algorithm*. The network survivability is consequently increased.
- *The flexibility of sensing network configuration is enlarged.* To upscale the sensing network has become an easy work with the design of sensing network building blocks. Moreover, when the sensing network is upscaling, the controlling complexity can be remained at the same level as that of a small sensing region.

In this paper, the demonstrations are arranged for two steps, the experimental step and the simulation step. In experimental step, we build a 2-by-2 single SDN-controlled central office including a fiber ring laser based transmitter and an AWG based receiver. The link failures can be easily located with the analysis of received sensing signal power by the SDN controller. Two alternative light-paths are then calculated by SDN controller after failures are reported. In the simulation step, we build the multiple central office sensing systems with various network scales. The relationship between link failures and system survivability is verified. As a result, in the

sensing system with a 6-by-6 network scale, the results indicate that the sensing system is still survived for up to seven link failures.

Direct Writing of Fiber Bragg Gratings through Polyimide Coating by Femtosecond Laser Pulses at the Wavelength of 1026 nm

A. V. Dostovalov[1], **A. A. Wolf**[1], **and S. A. Babin**[1, 2]

[1]Institute of Automation and Electroetry, SB, RAS, Russia
[2]Novosibirsk State University, Russia

Abstract— Experimental results are presented on direct point-by-point writing of the first- and the second-order fiber Bragg gratings through polyimide protective coating by femtosecond laser pulses at the wavelength of 1026 nm. Writing was carried out in specialty optical fibers: high-temperature tolerant Fibercore SM1500(9/125)P and pure-silica core hydrogen tolerant SM1500SC(9/125)P.

Introduction: Fiber Bragg gratings (FBG) are widely used optical components in different areas: from spectral filtering in lasers to sensing applications. The main advantages of femtosecond laser writing in comparison with conventional UV modification of refractive index consist in possibility to modify non-photosensitive fibers through plastic coating and to obtain gratings with higher resistance to thermal decay. We present the results of direct point-by-point FBGs writing in specialty polyimidecoated fibers by high-energy femtosecond laser pulses.

Experiment: The first- and the second-order FBGs were inscribed using direct point-by-point writing technique in high-temperature tolerant Fibercore SM1500(9/125)P fiber (Fig. 1) and pure-silica core hydrogen tolerant SM1500SC(9/125)P fiber, through 10 µm polyimide protective coating in both cases. The results of the FBGs testing at high temperatures (up to 350°C) showed that for a given exposure time (6 hours) there is no degradation of grating strength which is typical for FBGs written by the UV radiation. At the same time, after temperature exposure, the protective polyimide coating of the fibers remained undamaged, which gives an advantage over acrylate coating which is resistant only for temperatures up to 150°C.

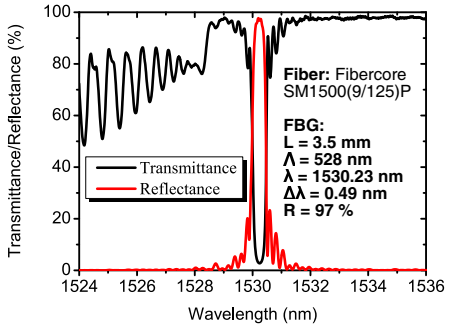

Figure 1: Transmittance and re ectance spectra of the first-order FBG written in polyimide coated fiber using point-by-point technique.

Conclusion: The FBGs written in specialty fibers by point-by-point direct writing technique through protective polyimide coating may serve as robust in-fiber laser mirrors and temperature/strain sensors.

A Novel Demodulation Scheme for Fiber Sensor Based on Chaotic Fiber Laser

Lingzhen Yang[1, 2] **and Jun Zhang**[1, 2]

Abstract— Fiber Bragg grating (FBG) is attracting considerable interest in sensing elements. A novel demodulation system for a concatenation of identical FBGs based on tunable fiber chaotic laser is proposed. The chaotic fiber laser is the ultra-long ring cavity structure. The tunable fiber grating (TFBG) in the cavity as a narrow-band filter has the tuning range from 1540.26 nm to 1571.86 nm. A sensor network consists of five identical weak fiber gratings separated by a short length of single mode fiber. The chaotic correlation that can allow every Bragg grating of the sensor addressed simultaneously. The correlation peaks of the cross-correlation between the reflected light from FBG sensor and reference light from chaotic fiber laser has been studied for the demodulation of FBG sensors network in strain measurement. Simulation and experimental results on the capability of strain measurement are presented and discussed. The cross-correlation peaks depend on the voltage strength between the reference chaos and reflected signals from the identical weak fiber Bragg grating sensor. The experimental observations confirm that the demodulation results are in excellent agreement with the acquired by the theoretical analysis. This method is not only simple and low cost, but also achieves the multi-point synchronous measurement.

A Relativistic Self-consistent Model for Studying Enhancement of Child-Langmuir Limit Due to Counter-streaming Ions

M. C. Lin[1] and J. P. Verboncoeur[2]

[1]Department of Electrical and Biomedical Engineering
Hanyang University, Seoul 133-791, Korea
[2]Department of Electrical and Computer Engineering
Michigan State University, East Lansing, Michigan 48824, USA

Abstract— A maximum electron current transmitted through a planar diode gap is limited by space charge of electrons dwelling across the gap region, the so called Child-Langmuir (CL) law. By introducing a counter-streaming ion flow to neutralize the electron charge density, the CL limit can be dramatically raised, so electron current transmission gets enhanced. In this work, we have developed a relativistic self-consistent model for studying the enhancement of maximum transmission by a counter-streaming ion current. The maximum enhancement is found when the ion effect is saturated, as shown analytically. The solutions in non-relativistic, intermediate, and ultra-relativistic regimes are obtained and verified with 1-D particle-in-cell simulations. This self-consistent model is general and can also serve as a comparison for verification of simulation codes, as well as extension to higher dimensions.

Octuplet of Direction Indicators with Distinct Spatio-temporal Symmetries

Jiri Hlinka
Department of Dielectrics, Institute of Physics, Czech Academy of Scinces, Prague, Czech Republic

Abstract— Physical quantities defined by a magnitude and an oriented axis in 3D space are often represented by three-component Euclidean vectors. Frequently, axial and polar vectors are distinguished, depending on whether they do flip their sense or not, respectively, upon the action of the spatial inversion (parity symmetry operator). For classification of temporal processes or the properties of magnetically ordered materials, the action of the time-inversion operator ($1'$) can be used. For example, magnetization M and magnetic field vector H are "time-odd axial" vectors, the electric polarization P or electric field E are "time-even polar" vectors. At the same time, other quantities like velocity or toroidal moment are "time-odd polar" vectors. The two inversion operations generate an Abelian (commutative) group of 4 elements with 4 one-dimensional irreducible representations; the symmetry operations this group allow to classify these vectors into 4 categories [1–4].

We emphasize [1] that there are another four types of directional quantities, which are also defined by a magnitude, an axis and a geometrical sign, and which are also often associated with the three-component Euclidean vectors, but which show a different spatiotemporal symmetry than the above mentioned examples. These extra families can be exemplified as follows: two kinds of chiral "bidirectors" (associated with the so-called true and false chirality, resp.) and two achiral "bidirectors", transforming as the nematic liquid crystal order parameter and as the antiferromagnetic order parameter of the hematite crystal α-Fe_2O_3, respectively [1].

The aim of this contribution is to discuss applications of this concept and the notation proposal to the properties of magnetoelectric crystals and to the electromagnetic phenomena related to them.

Full Graphitization of Amorphous Carbon by Microwave Heating with Catalyst

Taewon Kim, Jaegeun Lee, and Kun-Hong Lee
Department of Chemical Engineering
Pohang University of Science and Technology (POSTECH), South Korea

Abstract— Metallic properties (high electric and thermal conductivities) and nonmetallic properties (high thermal resistance, inertness, and lubricity) of graphite make it as an essential material for refractories, automobiles, lithium-ion batteries, fuel cells, solar cells, nuclear reactors, and graphene production. Owing to the limited reserve of natural graphite and the ever-increasing demand in energy applications, graphite has been designated as a "supply risk material" by the British Geological Survey. (Graphite is ranked 9th in terms of supply risk, higher than the platinum group elements). Synthetic graphite can fill the gap between supply and demand, but there has been not much research on the process of making synthetic graphite. The common manufacturing process used to synthesize graphite, known as Acheson process, relies on thermal heating of amorphous carbon to 3000°C. (Typical processing time is 2 weeks). Although the energy requirements are enormous, the Acheson process remains the major industrial process since its invention in the 1960s. Therefore, a novel and energy-efficient graphitization process is highly desirable.

Here, we report a novel method of graphitization using microwave heating with catalyst. Although microwave heating has been reported previously, full graphitization of amorphous carbon powders is achieved for the first time by adding catalyst precursors to the amorphous carbon powders. Interlayer spacing and I_G/I_D ratio of amorphous carbon powders became almost identical to those of the reference graphite powders after microwave heating in 5 minutes.

Present work implies that microwave graphitization can be an alternative process for synthetic graphite production. Furthermore, it can also be applied to the production of other graphitic materials like highly crystalline graphene or carbon nanotubes and their derivatives.

Determination of the Parameters of Composites with Magnetic Particles from the Study of the Spectra of Ferromagnetic Resonance in the Microwave Frequency Range

V. A. Zhuravlev, **V. A. Meshcheryakov**, **and E. P. Lilenko**
Tomsk State University, Tomsk 634050, Russian Federation

Abstract— Active exploration of the microwave frequency range sharpened the need for magnetic materials absorbing electromagnetic radiation. Such materials are required to reduce harmful influence on biological objects, to provide electromagnetic compatibility of units and blocks of high-frequency devices, to build anechoic chambers and to protect information. Composite radar absorbing coating (RAC) which consists of a matrix of high-molecular polymer compounds and filler particles of ferromagnetic or ferrimagnetic materials are widely used. Such materials are most effectively used as electromagnetic waves absorbers located on the metal surfaces.

It is necessary to know the material parameters of the filler particles of the composite material for targeted development and production of RAC in a given frequency range and level of reflectance in the operating band. These parameters are the values of the magnetocrystalline anisotropy fields (H_{ai}), the gyromagnetic ratio (γ) and saturation magnetization (M_0).

The study of the spectra of ferromagnetic resonance (FMR) in the microwave frequency range is one of the few methods to determine the required material parameters such inhomogeneous and macroscopically isotropic materials, including materials with nanosized and nanostructured particles.

The development and testing based on the study of FMR methods of determining the characteristics of the anisotropic powder and composite materials is the aim of this work.

To do this, we calculated the permeability tensor of the composite material containing randomly oriented particles uniaxial magnetic material. We proposed based on the analysis of FMR spectra in the microwave frequency range two-stage method of determining the anisotropic characteristics of such composite materials.

In the first stage the frequency dependences of the maxima and the derivatives of the resonance curves are analyzed. It gives us the estimation for the gyromagnetic ratio γ and anisotropy fields H_{ai}. In the second stage by a detailed comparison the shape of experimental and theoretical resonance curves we obtain more accurate values of the anisotropy field.

The paper presents the results of applying this method to determine the anisotropic characteristics of polycrystalline samples of hexaferrites and composite materials containing nano-sized ferrimagnetic particles.

Microwave Absorption Properties of Foam Glass Material Modified by Adding Ilmenite Concentrate

O. V. Kazmina[1], **V. I. Suslyaev**[2], **M. A. Dushkina**[1], **V. A. Zhuravlev**[2], **and K. V. Dorozhkin**[2]

[1]Tomsk Polytechnic University, Tomsk 634050, Russian Federation
[2]Tomsk State University, Tomsk 634050, Russian Federation

Abstract— Currently, due to the increasing background microwaves the development of radar absorbing materials (RAM) for various purposes are particularly relevant. RAM are used to solve problems of electromagnetic compatibility of radio electronic devices, protection of biological objects from electromagnetic radiation, as well as to reduce the radar signature objects of military and civil purposes. The materials that combine several useful consumer properties are of particular interest.

The unique combination of properties that do not have any of the known heat insulator has foam glass material. This material is environmentally safe and has a low thermal conductivity and density with relatively high strength. The purpose of this work — study microwave transmission and reflection coefficients in the frequency range 26–260 GHz of foam glass, modified by titanium concentrates and the establishment of the possibility of its use as a radar absorbing material.

We studied the radar absorption and mechanical properties of foamed glass, made from industrial cullet glass tube with the addition of ilmenite concentrate. Concentrate composition in wt.% was follow: TiO_2 — 61.85; Fe_20_3 — 27.90; $Si0_2$ — 2.00; $A1_20_3$ — 2.00; Cao — 0.15; MgO — 0.40. Additive concentration was varied from 0.5 to 1.5 wt.%. Previously, we have found that with small additions of ilmenite concentrate the foam glass becomes more durable. Adding to of the foaming mixture the ilmenite concentrate in an amount of 0.5 wt.% increases the compressive strength of the foam glass twice.

Measuring the transmission and reflection coefficients produced by the "free space methods" on the vector network analyzer Agilent Technologies E8363B in the frequency range of 26–36 GHz and terahertz spectrometer type STD-21 in the frequency range 60–260 GHz.

For study of the electromagnetic response we used flat samples $30 \times 30\,\mathrm{mm}^2$. Thickness of the samples was 2.2–2.4 cm. The measurements showed that the microwave reflection coefficients for all of the samples are small. This is due to the microwave properties of material and diffuse scattering from surface of foamed glass.

The experiments showed that small additions of ilmenite concentrate to foam glass can not only improve the mechanical properties of material, but also to expand the scope of its application. Material is actively cooperating with electromagnetic radiation and can be used as an absorber to create: protective shields that reduce the harmful effects of microwaves on biological objects, anechoic chambers and rooms with low levels of electromagnetic fields.

Maximum radar-absorbing properties have a foam glass samples with addition of ilmenite concentrate with a particle size of 3 microns and amount of 0.5 wt.%. The value of the transmission coefficient at a frequency 26 GHz was about -10.5 dB/cm and -15.2 dB/cm at a frequency 260 GHz.

Significantly Improved Absorption Properties at Microwave Bands for Multi-layer Hexaferrite Thick Film Composites

Z. W. Li and Z. H. Yang
Temasek Laboratories, National University of Singapore, 5A Engineering Drive 1, 117411, Singapore

Abstract— With the developments of electronic, telecommunication and radar technologies, the absorption and shielding of electromagnetic (EM) radiation has attracted much attention. When EM waves are irradiated into magnetic materials, a natural resonance (ferromagnetic resonance without an applied magnetic field) occurs, thus achieving the attenuation of EM waves.

The absorption EM materials generally consist of magnetic fillers and silicone, as known the EM composites. The fillers play an important role in determining the absorption properties of composites. In this work, three hexaferrite fillers, namely often used particles, flakes and thick films, are prepared and their absorption properties are compared. It is found that composites filled with the thick films have excellent high-frequency magnetic properties and absorption properties, as compared to other two fillers.

First, for often used magnetic fillers, such as hexaferrite or carbonyl iron particles, the permeability is rather small; real and imaginary permeability are only about 3–4 and 1–2, respectively, for composites with volume concentration of 50%. For the hexaferrite film composites, the real and imaginary permeability significantly increase to 7 and 4.3, respectively. The increase is attributed to an in-plane arrangement of the films in composites.

More important, due to significantly enhanced permeability and almost the same permittivity, the hexaferrite film composites show excellent EM absorption properties: the thickness is only 3 mm, absorption bands cover from 2.1 to 14.5 GHz for return loss $RL < -10$ dB, and the percentage bandwidth is 150%, which achieves 3/4 of theoretically maximum bandwidth 200%.

Final, the mechanism of enhanced broad bandwidth is discussed. EM absorption comes from two different mechanisms: quarter-wavelength resonator and magnetic resonance. The former is determined by the ratio of permeability to permittivity and the latter is associated with the magnetic loss. For the film composites, two absorptions with $RL < -10$ dB can exist on the same thickness, thus significantly expanding the absorption bandwidth.

In conclusion, the hexaferrite film composites are potential candidates for use as EM absorption materials with small thickness, low return loss and broad bandwidth at microwave S, C, X and Ku bands.

Low-frequency Electromagnetic Bands in Metallic Lattices

K. Wang
Laboratoire de Physique des Solides
UMR CNRS/Université Paris-Sud, Orsay 91405, France

Abstract— We present a complete study on the low-frequency electromagnetic band structures in various metallic lattices in air background, using both numerical and tight-binding approaches. The band structures and evolutions are comparatively investigated with respect to local resonances and their variations following the sizes, shapes and the symmetries of the structure unities. We show that the lowest-frequency bands are formed by s-like resonance modes sustained by the local structure unities, of which the contributions vary following structure modulations, and, under certain conditions, the second bands (above the first band gaps) are formed by p-like modes sustained by the same structure unities. The s and p bands can both be described in the frame work of a tight-binding model, allowing band structure analyses in terms of relations between local resonance modes and their mutual correlations. This work demonstrates that the origin of the low-frequency electromagnetic bands and gaps in general metallic structures can be explicitly analyzed from the perspective of local structure arrangements, that determine both the local resonance conditions and their mutual coupling. The plasma gaps and the first band gaps arise naturally from specific local structure patterns.

Heat Transfer between Anisotropic Nanoparticles

Abstract— We study radiative (near field) heat transfer between objects in vacuum at different temperatures. By use of classical scattering theory [1], we derive closed expressions for this transfer for objects of arbitrary shape and material, from which general properties of the transfer can be analyzed. We present several examples including spheres, cylinders and ellipsoidal particles [2], thereby demonstrating the size and shape dependence of radiative heat transfer.

Abstract— The report is concerned with optical properties of magnetic nanocolloids (ferrofluids), i.e., materials of a special type which are solutions of magnetic particles suspended in a carrier fluid. These materials exhibit specific physical properties [1]. Ferrofluids have been studied since the 1960s but still remain an important research object because new physical phenomena are constantly revealed in them. Ferrofluids find different applications, for example, they are considered to be promising for biomedical purposes [2]. Of considerable interest are also optical devices in which ferrofluids are used as active elements. Their operation is based on the magneto-optic effects which have pronounced specific features in nanocolloidal solutions of magnetic particles. There are optoelectronic devices in which the interaction of light with the material occurs at large lengths. These are fiber-optic systems with a ferrofluid-filled microstructure [3–5]. It can be expected that under certain conditions nonlinear properties of ferrofluids will manifest themselves in them, which is important from not only practical but also fundamental point of view.

We studied optical nonlinearity in kerosene and water solutions of magnetite (Fe_3O_4) prepared by using the technology which gives nanoparticles with an average size of about 10 nm. To provide an optical transparency, the samples were diluted from the initial concentration (several percent) to 0.2 Vol. % of the solid phase content.

The experimental technique was chosen to be z-scanning [6] involving displacement of the material studied along a focused laser beam. The setup included a compact electromagnet which produced a magnetic field of 0–500 Oe applied to the sample. It was perpendicular to the light beam. The light polarization could be either parallel or perpendicular to the field. The electromagnet could move together with the sample along the beam, thus passing through the region with the maximum optical energy concentration. As a radiation source, a Nd:YAG-laser was used (the second harmonic, $\lambda = 532$ nm).

As the experiment showed, at high optical power levels the ferrofluids exhibited a strong nonlinearity detected from the dependences typical of the z-scanning technique [6]. It was found that the magnetic field exerted a strong influence on the nonlinear characteristics, which can be attributed to formation of agglomerates of nanoparticles in the fluid. The effects related to the light scattering which depended on the field and radiation power were also observed.

Possible mechanisms of the observed phenomena one of which is thermal diffusion of nanoparticles in the field gradient created by the focused laser radiation are discussed.

Abstract— The development of laser ranging technology benefits remote sensing, machine vision and three-dimensional (3D) imaging. Accuracy of these systems strongly relies on the characteristics of laser and detector response. In this paper, reected laser pulse profile is investigated and analysed based on different target reflectivity. Results show that reflected laser pulse appears to deviate from ideal Gaussian model that is commonly assumed. The reflected laser pulse demonstrates asymmetric Gaussian-shape temporal associates with a time delay. It is observed that target reflectivity that is influenced by the material types and roughness has direct impact to the sensitivity of detection and intensity variations but does not change the distribution characteristic. These show direct connection to deviation in range estimation and should be further evaluated for correction to improve the accuracy in a range gated system.

From Markovian Jump Processes to Ionospheric Waves Disturbances

R. Talhi
CNRS/LPC2E and University of Tours
3A, Avenue de la Recherche Scientifique, 45071 Orleans Cedex 2, France

Abstract— The objective of this paper is to provide an overview of Markovian Jump Processes (with continuous time and discrete state space) applied to the modelling of some ionospheric wave disturbances. Markovian Jump Processes (MJPs) are fundamental stochastic processes that are used to model some unpredictable observable phenomena related to disordered and inhomogeneous environments, and can be readily implemented in numerical algorithms. Hence, these stochastic processes play an important role in many fields of science and technology, ranging from computational finance (in credit risk modelling [1]), and wireless communication networks (in random traffic performance [2]), to physics (in electron transport inside disordered organic semiconductors [3]), chemistry and biology (in stochastic kinetic models [4]), among others. MJPs aim to aid our understanding of the previous unpredictable phenomena by providing a consistent probabilistic framework to predict their future behaviour.

More precisely, the main purpose of this work is to focus on this probabilistic technique applied to study the asymptotic behaviour of some wave disturbances propagating in a typical random medium such as the ionosphere which is characterized by spatial and temporal chaotic fluctuations, and therefore unknown in detail, ill-defined, and poorly understood. In this context, the basic methodology is as follows: the radiative transfer theory, which governs the propagation and scattering of electromagnetic waves in the general case of random media, is used. More specifically, the radiative transfer equation, which describes the electromagnetic wave-energy propagation, under its vector (or matrix) form including energies and polarization parameters (in Stokes representation), is considered. This equation which has no analytical solution, is solved by means of numerical methods or simulation based techniques. One has to consider the energy propagation at a certain time (t), at a certain position (X), in a certain angular direction (K), and with a certain polarization (P), where $K(t)$ and $P(t)$ jump at scattering times, while $X(t)$ is continuous in space. Hence, the previous equation admits a probabilistic interpretation represented by a Markovian Jump Process (or stochastic process with minimal memory, i.e., given the present state of the process, the future is independent of the past states) for the position $X(t)$, direction $K(t)$, and polarization $P(t)$ of each photon (in quantum representation) undergoing scattering by random ionospheric inhomogeneities. In the simulation of MJPs trajectories, it is important to notice that steps are considered independent and identically distributed; moreover, the computation of any next scattering time is done according to the Poisson (or exponential) distribution. Then, we consider the forward Kolmogorov equation associated with the previous MJP (i.e., equation of the time-evolution of the MJP probability density function), that we solve numerically by a Monte-Carlo estimation procedure (based on the large numbers law, and on the central limit theorem). Finally, we get an approximate solution of the vector RTE, by averaging over the first order moments of the previous discrete probability densities with respect to the polarization parameters matrix.

Our methodology is illustrated with some applications to attempt to analyse the impact of turbulence strength and electron density fluctuations on radio-waves scattering in HF-frequency band (∼5 to 20 MHz). To this end, we assumed a typical ionospheric parameters, turbulence spectrum (power law form), and electron density profile (Chapman profile). Then, we focused firstly on the prediction of the 3D-angular power distribution and the rate of polarization of HF-waves altered by multiple scattering, and secondly on the important role of the 3D-anisotropic irregularities encountered in many scattering problems. Obtained results, which seem rather good when compared to published ones, will be presented and discussed.

As concerns the above mentioned methodology, we have to point out some open questions or subjects of controversy [5, 6]. Since we use the wave-particle duality, are stochastic processes related to quantum mechanics? Furthermore, is a Markov process equivalent to a quantum process? In other words, how to formulate a Markov process (with its crucial Markov property) into the framework of quantum mechanics?

Abstract— In this paper we address the problem of performing adaptive weather sensing with a phased array radar by exploiting information-theory-based methods with the goal of adaptively defining scanning strategies for weather observations. Through their unique beam agility, phased array radars can instantaneously change the pointing direction and acquisition parameters of the scanning beam. This capability can be exploited to dynamically and adaptively define scanning strategies that achieve an optimum compromise between update time, spatial sampling and sampling, and data quality, which can potentially lead to improved warnings and forecasts. Using information theoretic methods, scanning strategies can be tailored so that the information extracted from the atmosphere is maximized. The distinguishing attribute of the information measures is that they provide a single metric able to automatically capture the complex tradeoffs involved in the design of scanning strategies for weather observation. In this paper we present an algorithm that tailors the scanning strategies for different regions based on their information content. We demonstrate the advantages of this algorithm over conventional scanning by mimicking phased array observations using high temporal and spatial resolution data collected with the University of Oklahoma Advanced Radar Research Center's PX-1000 radar.

Impacts of a Gap-filling Radar in a Mountainous Area: Case of Lobo Overlook, Colorado

B. L. Cheong[1, 2], **P. E. Kirstetter**[1, 3], **T.-Y. Yu**[1, 2], **J. Busto**[4], **T. Speeze**[4], **and J. Dennis**[5]

Abstract— The Weather Surveillance Radar — 1988 Doppler (WSR-88D) of the United States is presently the operational radar system for forecasters to monitor the weather. While the radar network has been upgraded to provide polarimetric and Super-Resolution (0.5 degree) coverage out to 300 km, there are many regions, particularly in the Rocky Mountains, that the WSR-88D radars do not provide sufficient coverage due to the complexity of terrain and planetary curvature of the Earth. Forecasters often rely on the scans from high elevations to infer what is happening near the surface. Under circumstances where no other means are available, the upper scans are the only source of measurements. In order to produce qualitative precipitation estimate (QPE), however, these upper scans do not provide the critical measurements needed for numerical models to produce accurate predictions. The Mineral County of the State of Colorado is one of the many regions within the Rocky Mountains that suffers poor radar coverage due to the surrounding mountain ridges, which are in the line-of-sight of the closest three WSR-88D radars, blocking radar beams from reaching this area. The limitations impede the ability of forecasters and local emergency managers to make accurate predictions and issuing weather warnings. In Fall 2014, a transportable polarimetric X-band radar was deployed at the Lobo Overlook of the Mineral County for a 45-day experimental campaign to assess the value of a permanent radar setup in this area. Large systems like the WSR-88D radars are costly, a compact radar, such as the PX-1000, however, costs tremendously less and could be sufficient for short-range (60 km) weather surveillance. This was the case for the Mineral County and several counties adjacent to it. The experiment was successfully conducted and several case studies have shown added values of deploying a polarimetric radar in this area, supplementing the current radar coverage of the WSR-88D network. Three selected cases are provided in this presentation for illustration.

A Novel Approach to Counter the Low Observable Characteristic of Stealthy Targets by Analyzing the Radar Cross Section

Faran Awais Butt[1], **Ijaz Haider Naqvi**[2], **and Ali Imram Najam**[3]

[1]University of Management and Technology (UMT), Lahore, Pakistan
[2]Lahore University of Management Sciences (LUMS), Lahore, Pakistan
[3]National Engineering and Scientific Commission (NESCOM), Islamabad, Pakistan

Abstract— Stealth technology has brought up a revolution in the field of electronic counter measure and has exposed the ineffectiveness of the mono-static radars. The stealth aircrafts diffract and/or scatter very low power electromagnetic radiations owning to its special geometry and highly absorbent material. However, if an electromagnetic wave is incident at 'good' angles, stealth aircraft though low observable cannot be called as invisible. In this paper, the results of the extensive simulations on a model stealth aircraft have been presented. Simulations are performed on an aircraft model to prove the effectiveness of the proposed model. By energizing the aircraft at 'good' angle(s) of incidence, significant scattering can be observed over a range of aspect angles. Thereafter, a multi-static approach is proposed making a polygon arrangement of radar transceivers in order to guarantee the detection of a stealth aircraft.

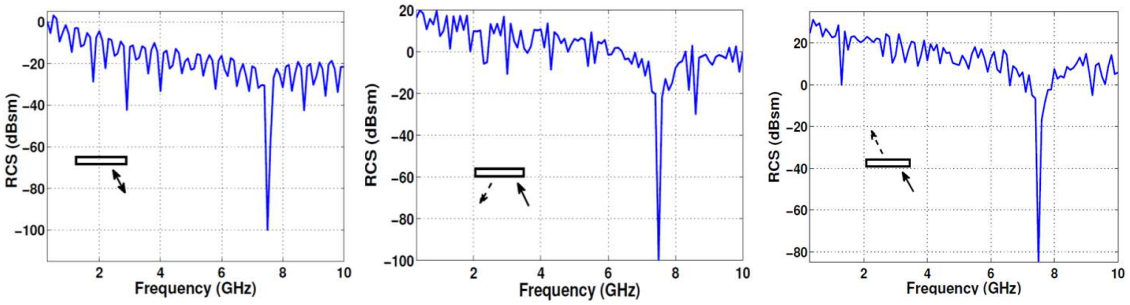

Figure 1: RCS vs. frequency for various angle of incidence and reflection.

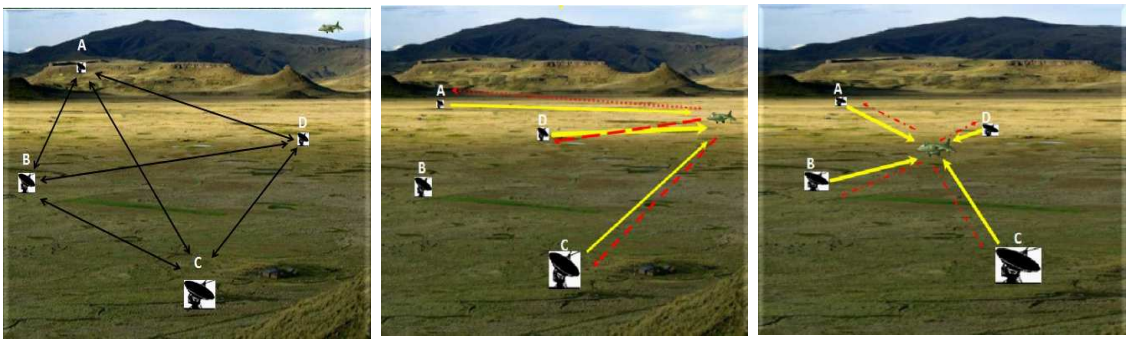

Figure 2: Our proposed solution of using 4 radar transceivers arranged in a polygon.

The bi-static and multi-static radar must use data in fusion in the process of information collection. The concealment feature of bi-static radar is not complete as the transmitter station is still electromagnetically exposed and can be easily attacked. Our configuration overcomes the negative effects of such a situation since there are four radars working with each other. Our proposed configuration can be used for low frequency radar since the radars are acting as transceivers for each other and by using correlation and proper filtering, clutters can be avoided and at the same time our proposed system can easily be upgraded with any desirable feature like changing of polarity, operating frequency or miscellaneous features.

From the observations we saw that there was a maximum positive RCS for greater range of frequencies at the shadowed side of stealth aircraft, so if there is a receiver there, it can make use of these scatterings to detect the target threat.

Ultra Short and High Voltage Pulse Shaping for Atom Probe Tomography Improvement

Abstract— Improvement of atom probe tomography technique requires the use of high voltage rectangular pulses on a sample inside an ultra-high vacuum chamber. In this paper, a design for ultra-short (∼ps) rise time and less than one nanosecond rectangular pulses, based on a photo-conductive switch, is described. The performances of the device are compared to theoretical predictions.

An Amplitude Based on Vital Sign Monitoring Using Impulse-radio UWB Radar

J. Yu[1], **J. Matuzas**[2], **T.-Y. Lee**[1], **and M.-H. Ka**[1]

[1]School of Integrated Technology, Yonsei Institute of Convergence Technology
Yonsei University, Republic of Korea
[2]Center for Physical Science and Technology at Vilnius, Geozondas JSC, Lithuania

Abstract— In this paper, a method for vital signs which are breathing rate and heart beat rate using impulse radio UWB radar is proposed. The method of calculating breathing and heart beat based on an amplitude variation of received short pulse signal. When an impulse UWB radar is measure the vital signs, rates are usually measured by a movement of peak position of received signal. To obtain high accuracy frequency, a receiver requires a high speed sampling rate. The fast sampling rate has problems of cost and a large size of H/W. The suggested method is unnecessary the high speed sampling rate receiver. It is used a variation of an amplitude of cross correlation of each received signal. The fourier transform of the variation is represented vital signs. In addition, an uneven sampling rate is used. The rates are estimated by least square spectral method instead of the fourier transform. In spite of low sampling rate, these methods have a better signal to noise ratio than method for detecting movement of peaks.

Analysis of Micro-Doppler Characteristics of Human Activity Using Hilbert-Huang Transform Analysis

Ram M. Narayanan
Department of Electrical Engineering, 202 Electrical Engineering East
The Pennsylvania State University, University Park, PA 16802, USA

Abstract— Various parts of the human body have different movements when a person is performing different physical activities, thereby resulting in unique micro-Doppler signatures. The conventional time-frequency analyses of human activity (usually including the short time Fourier transform (STFT), Wigner-Ville distribution (WVD), and wavelet analysis) are not adaptive to nonlinear and nonstationary signals. If one can decompose the noisy human Doppler information and extract only the human-induced Doppler from it, the identification of various human activities becomes easier. We have applied the Hilbert-Huang transform (HHT) technique to analyze micro-Doppler signals arising from human activities, since this approach is adaptive to such nonlinear and nonstationary signals. The Hilbert-Huang Transform (HHT) is a novel signal analysis technique based on the combination of the empirical mode decomposition (EMD) and the Hilbert spectral analysis approaches. This method implements the 'empirical mode decomposition' using which a dataset can be decomposed into a finite and often small number of 'intrinsic mode functions' that possess well-behaved Hilbert transforms. Since this decomposition is adaptive, it is very efficient. The decomposition is based on the local characteristic time scale of the data and is applicable to both nonlinear and nonstationary processes. The EMD identifies intrinsic oscillatory modes by their characteristic time scales in the data empirically. It separates the intrinsic mode functions (IMFs) from the original signal one by one, until the residue is monotonic. The original signal is thus decomposed into a finite and a small number of IMFs, where an IMF is any function with the same number of extrema and zero crossings, with symmetric envelopes. This method was applied to radar data resulting from human activities. The HHT based signal processing can effectively improve pattern recognition and reject unwanted uncorrelated noise. The Hilbert Transform presents results in the form of an energy-frequency-time distribution, designated as the Hilbert spectrum, which can provide sharp identifications of embedded structures. In the HHT approach, the IMFs based on local signal properties define an instantaneous frequency. The introduction of the instantaneous frequencies for complicated datasets eliminates the need for spurious harmonics to represent nonlinear and nonstationary signals. This method when applied to radar data resulting from human activities shows significant differences in the IMF spectrum for various human activities, which can be used for activity classification and recognition using radar micro-Doppler.

Measurements and Analysis of the Doppler Signatures of Rotating Targets by the Hilbert Huang Transform

Mickael Bruno[1], **Alessio Balleri**[1], **and Clayton Stewart**[2]

[1]Centre for Electronic Warfare, Cranfield University, Defence Academy of the UK, UK
[2]Department of Electronic and Electrical Engineering, University College London, London, UK

Abstract— Radar echoes from moving targets present a shift in frequency due to the well-known Doppler effect. Typical radar targets are often composed of several moving components which, with their own micro motions, induce a frequency modulation around the principal Doppler shift. These modulations are called the target micro-Doppler signature and contain specific information on the target that can be used for target classification.

In recent years, micro-Doppler signatures for target classification have attracted considerable research interest and they have been used to classify many different types of targets, including cars, tracked vehicles, humans and animals. Considerable research efforts have been dedicated to characterising the micro-Doppler signatures of rotating target components in order to allow and improve classification of aircraft, helicopters, UAVs and to study the clutter returns from wind turbines.

A significant proportion of the previous work on classification of rotating targets by micro-Doppler is based on the use of time-frequency methods, such as the Short Time Fourier Transform (STFT), which impose a trade-off between time and frequency resolution; the longer the dwell time the better the frequency resolution and the poorer the time resolution and vice versa.

The Empirical Mode Decomposition (EMD) is a recent method which has been developed to decompose signals into a series of functions, called Intrinsic Mode Functions (IMFs), which admit a regular Hilbert transform. The EMD, together with the Hilbert Huang Transform (HUT) is a method for the analysis of nonlinear and non-stationary time series and may potentially offer significant advantages for the task of target classification as it does not suffer from the trade-off between frequency and time resolution.

Very little work has been published in the literature on the EMD and the HUT for target classification by micro-Doppler. Most of the previous work on micro-Doppler of rotating targets based on the EMD has been carried out on simulated data and there is very little in the literature presenting experimental results. Previous algorithms have largely been tested on noise-free simulations and often, when experimental data was used, very little information on the radar parameters and the target echo signal characteristics was provided. This has made it difficult to draw conclusions on the performance of this technique and its robustness against the radar carrier frequency and the data Signal to Noise Ratio. To the best of our knowledge, in the existing literature, there have been very little attempts, if any, to carry out a thorough analysis of the information contained in the IMFs of real rotating targets.

In this paper we measure the signature of a rotating propeller at X-band and we study the properties of the IMFs of the target and their corresponding HUTs. Results are analysed as a function of the target aspect angle, the target rotation speed and the target number of blades. Results show that the it is possible to extract the information on the rotating speed of the propeller and on the number of blades over a large number of IMFs and at all aspect angles, including those where the Doppler shift induced by the blades is low.

Waveform Diversity for Ultra-wideband Ground Penetrating Radar Imaging

Delphine H. N. Marpaung and Yilong Lu
School of Electrical and Electronic Engineering, Nanyang Technological University
50 Nanyang Avenue, Singapore 639798, Singapore

Abstract— Waveform diversity has been one of the intensive research areas in ultra-wideband (UWB) wireless systems, including wireless communication systems and radar systems. For radar applications, waveform diversity may enhance the performance of the narrow-band radar. In this paper, we explore the potential benefits of waveform diversity for 3-dimensional (3D) UWB ground penetrating radar (GPR) imaging. One of the important issues in the 3D GPR imaging is the interpretation of objects that present in the GPR data/images. Therefore, our focus is on utilizing the waveform diversity for better detection and characterization of an object in GPR imaging.

We propose a novel waveform diversity approach for 3D UWB GPR imaging, where a set of a few UWB waveforms are used for transmitting and collecting respective echo data/images, sequentially. In this paper, we use the first 4 orders of Hermitian waveforms, which are widely used in the waveform diversity in UWB communications. We perform simulation to generate GPR echo data on the following target shape: sphere, plate, and corner re ector, and the following target electromagnetic properties: dielectric, normal conductor, and good conductor.

We then process the simulation data from each waveform independently and extract several features that can be used to distinguish the shape and the material of the target. These features are then utilized to derive the colour assignment of the target. Such colour provides better representation on the shape and the electromagnetic properties of the target.

The result shows that the waveform diversity can be used for distinguishing the shape and the material of the target. These properties are very useful for better detection and interpretation of objects in 3-dimensional ultra-wideband ground penetrating radar imaging.

On the Coneigenvalue Decomposition of Sinclair Matrices

T. Dallmann and D. Heberling
Institute of High Frequency Technology, RWTH Aachen University, Germany

Abstract— The Sinclair matrix is a 2×2 matrix which can be used to describe the polarimetric backscattering of radar targets. By decomposing this matrix into the so-called Huynen-Euler parameters various scattering mechanisms occuring at the target can be identified [1]. One of these mechanisms is the single reflection, which is typically caused by flat or slightly bended surfaces. A second mechanism is the double reflection which usually occurs between two surfaces which are oriented orthogonal to each other. A third mechanism is dipole scattering, which can be caused by wire-like structures. The Huynen-Euler parameters allow to distinguish between these scattering events and provide even more information like the orientation of the target. Since the aforementioned mechanisms not only influence the polarization of the scattered wave but also indicate at which angles and frequencies the radar cross-section (RCS) of a target increases, this set of parameters is of special interest for radar cross-section analysis. Therefore this decomposition is used in some recent publications about the measurement and analysis of RCS signatures and radar images [2, 3].

Unfortunately one of the Huynen-Euler parameters causes problems: There are conflicting opinions regarding the question if the skip angle ν which allows the distinction between single and double reflections can be determined from the Sinclair matrix. The extraction of the Huynen-Euler parameters requires a coneigenvalue decomposition of the Sinclair matrix S which can be described with [5]

$$Sx^* = \lambda x. \tag{1}$$

For coneigenvalues it can be shown that if λ is a valid coneigenvalue of a matrix S, then all $\lambda e^{j\theta}$, $\theta \in \mathbb{R}$ are also valid coneigenvalues [5]. On the first sight this indeterminacy prevents that the skip angle can be determined properly and led Lüneburg to the following conclusion:

> "The phase indeterminacy of the coneigenvalue is an essential feature of the anti-linear time-reversal operation in backscattering. Its interpretation and significance for target characterization and classification purposes (Huynen's skip angle) is at present not fully understood." [4].

In contrast to this a technique was developed by Baird which allows to extract Huynen's skip angle from the Sinclair matrix [3]. To the knowledge of the authors this discrepancy is still an unresolved problem.

To resolve the aforementioned contradiction a physical interpretation of the coneigenvalues of the Sinclair matrix will be given in this paper. Moreover, the connection between coneigenvalues and coneigenvectors will be explained. Finally an alternative approach for the calculation of the Huynen-Euler parameters from a Sinclair matrix will be presented. The explanations and approaches discussed in this paper therefore contribute to the effort of placing radar polarimetry on a solid mathematical foundation.

3D Polarimetric Imaging of Complicated Surfaces

Alex J. Yuffa, Kristan P. Gurton, and Gorden Videen
Computational & Information Science Directorate
Army Research Laboratory, Adelphi, MD 20783, USA

Abstract— Approximately ninety percent of all radiation naturally emitted by humans lies in the long-wavelength infrared (LWIR) part of the electromagnetic spectrum. This emitted radiation is partially polarized by the human skin [1] and thus, it contains information about the surface normal. In this presentation, we will demonstrate how the polarization state of the emitted radiation can be used to obtain a three-dimensional (3D) image reconstruction of a human face [2]. This technique only requires a single view of the subject and is completely passive. This is an important advantage as it is usually difficult to have precise control over illumination sources.

To construct the 3D image, we first record the Stokes parameters of the emitted radiation with a polarimetric camera equipped with a Stirling-cooled mercury cadmium telluride focal-plane array of 640×480 pixels. The camera uses a Fourier modulation technique to obtain the Stokes parameters on a pixel-by-pixel basis. By combining these pixel-by-pixel Stokes parameters with Fresnel relations, we obtain the orientation of the surface normal at each pixel. These surface normals are not unique as the Stokes parameters are invariant under a rotation of π radians. This ambiguity is resolved by introducing an additional constraint that requires surface normals on the occluding boundary to point away from the subject's head. This constraint is enough to resolve the surface normal ambiguity for almost all pixels in the image and thus, we finally obtain unambiguous surface normal for each pixel. Lastly, by integrating these surface normals we obtain a 3D facial image as shown in figure below.

Current Control of the Matrix Converter Fed Induction Motor Drive

J. Lettl, **J. Bauer**, **and S. Fligl**
Faculty of Electrical Engineering, Department of Electric Drives and Traction
Czech Technical University in Prague, Czech Republic

Abstract— The area of the controlled AC drives is very wide and most of them are based on the induction motors (IM) fed by frequency converters. Compared to the indirect frequency converter consisting of input rectifier, DC link and output inverter, matrix converter lacks need of bulky passive accumulation element and that is why it shows several advantages. Because the output voltage is produced by the means of direct switching of the proper input voltage to the output terminals the dynamics of the output voltage control is higher and also the output frequency can be changed very fast. Concurrently the main disadvantage of the converter is the limitation of the output voltage amplitude, provided that the sinusoidal currents on the input are demanded.

Advantages of the induction machine as the electro-mechanical converter in modern drive can't be questioned, however its control is more complicated and requires control algorithms based on separate control of the flux and torque. Field oriented control strategies are well known for this purpose. The input voltage is used as a controlled quantity. However, current feeding of the IM is also possible.

Problem of current source inverters (CSI) is that compared to voltage source inverters (VSI), CSI has to be designed for exact motor. That is why also methods how to replace CSI by VSI with current control were developed. The inverter then requires closed loop control with feedback directly from output AC currents. The currents have to have therefore wide bandwidth from nearly zero frequency up to carrier frequency. Usually two current sensors are enough, because without connected neutral point the third IM current has to add to zero. Moreover, this solution avoids zero sequence component errors. The output of the converter then differs from the CSI output. Its waveform follows a shape of the reference current with a superimposed PWM ripple. Form this point of view such current controller has several differences:

- it requires reference signals in actual time domain,
- the harmonic content can be reduced with PWM frequencyincrease,
- current controllers have to operate with AC signals instead of DC ones,
- the precision is higher because the controllers havenot to work in dynamic operation,
- the higher accuracy of the field orientation is reached.

In this paper a method of realization of rotor flux oriented control of the induction machine fed by matrix converter with current control is described. Simulation results are compared with results of measurement on the realised prototype of the matrix converter drive.

Physical Meaning of an Induction Machine Dynamic Model

S. Fligl, **J. Bauer**, **and J. Lettl**
Czech Technical University in Prague, Czech Republic

Abstract— The presented paper summarizes the approaches to dynamic description of an induction machine and presents them from the view point of the modern theory of dynamic systems. Great impact has the selection of the particular state variables. It decides about the mutual dependency of calculated values. Despite of the fact that it is still a correct description of the same system, it influences the design of control structures. Only the matrix form underlines clearly the particular differences.

The dynamic model of an induction machine is well known, but still it covers its secrets. Depending on the author, a different decision are made, what state variables will be used. However, this happens often without any justification, just according the trained technical experience or feeling. Thus, let us investigate here, how the set of equation changes in accordance with the selected particular set of variables.

Since the T-shaped model as well as the Gamma–shaped model is designed to describe the same physical object, we can find many similarities. However, the gamma shaped two phase model simplifies significantly the description and thus will be used throughout this article. The selection of the state variables can be defined as a combination, i.e., in particular selecting two members from a grouping of four (stator and rotor current, stator and rotor flux), such that the order of selection does not matter. The number of $4!/(2! \times (4\text{-}2)!)$ combinations is existing. From these six combinations, only three enable to decouple one half of the model from the supplying system and thus realize a truly hierarchical control system. This results also into significantly different time constants. This paper presents all necessary derivations for any particular equitation and provides guidance what variable set to use based on the target application.

Control Strategy of Grid Connected Converter under Unbalanced Conditions

Jiří Lettl[1], **Martin Bejvl**[2], **and Viktor Valouch**[1]

[1]Department of Electric Drives and Traction, Faculty of Electrical Engineering
CTU, Prague, Czech Republic
[2]Institute of Thermomechanics, Academy of Sciences of the Czech Republic
Prague, Czech Republic

Abstract— In ideal situation, the three-phase grid voltage is harmonic, phase to phase shifted by 120°; voltage and current are in phase. The track of the space vector of the three-phase voltage transformed to $\alpha\beta$ coordinates has a form of the circle.

In real situation, the three-phase grid voltage is distorted by high-order harmonics and by a negative sequence component, producing ripples in the voltage on the capacitors in the intermediate circuit and in active and reactive power, too. The three-phase AC current is disturbed as well.

Thus, there is a demand to develop such a control strategy of the converter that can cope with grid voltage disturbances, among them high-order harmonics and the negative sequence component mainly belong.

The object of the work is an analysis of the control of the positive and negative sequence of the AC current of the converter in order to eliminate reactive power, high-order harmonics of the grid current and ripples of the voltage in the DC intermediate circuit.

Both sequences of the grid current are controlled separately and simultaneously. The positive sequence of the current is controlled in the positive coordinates, which looks like DC control. The negative sequence of the current is controlled in the negative coordinates, which looks like DC control, too. Both the controls are realized by separate PI controllers working simultaneously.

A lot of effort has been made to analyse and compare many published control schemes that aspire to compensate the input voltage unbalance reliably. A new simple dual current control algorithm was developed and tested in the MatLab/Simulink environment and verified by measurement in laboratory with good results.

The developed method of the reference converter current calculation for the dual current controller is based on the measured and control variables and does need neither the solution of the set of nonlinear equations nor using previous patterns of the calculated reference current. To avoid a solution of a system of non-linear equations we can respect the losses produced in the line inductor by modifying the value that is produced as the output of the DC voltage controller. The losses calculated iteratively from the currents in the previous instant provide us with such a correcting term that may be added to the output of the voltage controller.

Different grid voltage conditions were considered, including the positive symmetrical component, negative symmetrical component, harmonic as well as the subharmonic signals with low frequencies.

Windowing Effect on Electromagnetic Interference and Efficiency at Using Pulse Width Modulation Techniques

T. Lelek, V. Lenoch, J. Lettl, O. Sadilek, V. Schejbal, and P. Sykora
Department of Electrical and Electronic Engineering and Signaling in Transport
Jan Perner Transport Faculty, University of Pardubice, Czech Republic

Abstract— In power semiconductor voltage converters, semiconductor elements are used mainly in switching mode because of decreasing power losses. Pulse-frequency and pulse-width modulation are two basic operation modes mainly used today. In both of them switching voltage with very sharp edges causes higher harmonic frequencies as a result. Traction drives of high power nowadays typically contain induction motors or permanent magnet synchronous motors fed by voltage inverters nowadays. Because it is not possible to use another operation mode of semiconductor elements it is necessary to be engaged in research of those devices in terms of electromagnetic compatibility and from the point of view of decreasing electronic distortion.

It is well known that windowing is one of the earliest techniques for designing the finite-impulse response (FIR) filters. The filter coefficients can be obtained in closed form without the need to solve complex optimization problems as in some other sophisticated FIR design techniques. Therefore, the design time is very short and the technique remains to be an attractive tool for FIR filter design.

For a rectangular window, the maximum sidelobe amplitude is equal to approximately $-13\,\mathrm{dB}$ relative to the maximum value, i.e., the sharp transition in the ideal response is converted into a gradual transition. To reduce the oscillations, i.e., higher harmonics, other window functions having spectra exhibiting smaller sidelobes should be used. The sidelobes of the rectangular window represent the high-frequency components and due to the sharp transitions from one to zero are placed at the edges of the window. Therefore, the amplitudes of these sidelobes can be reduced by replacing the sharp transitions by more gradual ones.

The design of various low-pass FIR filters has been done using several windows. The rectangular (with $-13\,\mathrm{dB}$ sidelobes), Bartlett (with $-25\,\mathrm{dB}$), Hanning (with $-31\,\mathrm{dB}$), Hamming (with $-41\,\mathrm{dB}$) and Blackman (with $-57\,\mathrm{dB}$) windows have been used. This allows decreasing the electromagnetic interference substantially.

In the paper, the pulse-width modulation (PWM) techniques are analysed and electromagnetic interferences and efficiencies are examined using numerical simulation.

Analysis of Multi-resonant Circuitin Overloading States

J. Koscelnik, B. Dobrucky, M. Frivaldsky, and M. Prazenica
Faculty of Electrical Engineering, Department of Mechatronics and Electronics
University of Zilina, Univerzitna 1, Zilina 010 26, Slovakia

Abstract— The paper deals with the analysis of multi-resonant circuit during overload states. Investigated topology is multi-resonant non-isolated LCL2C2 converter. The main focus is given on its transient properties and ability to withstand short circuit. Simulation analysis was verified by experimental measurements.

Standard categorization of resonant tanks is series or parallel combinations. The proposed LC2L2C2 belongs to the category of non-isolated multi-resonant converters. Resonant circuit is composed of two serial LC branches between which, two parallel LC filters are connected.

The shape of output voltage has to be pure sinusoidal waveform, due to fact, that L-C filters at the output are tuned on first order harmonic. Switching frequency is equal to resonant frequency of R-L components. Regulation of magnitudes can be done using pulse frequency modulation (PFM) or asymmetric pulse width modulation control (APWM). Simple modification of main circuit with the implementation of high frequency transformer forms the isolated version of LCL2C2 converter. In this way, due to transformer ratio, a higher regulation range of output voltage can be achieved.

Nevertheless, the determination of proper operation area is necessary in order to investigate how to achieve suitable operation regions. Based on input impedance frequency characteristic, it is possible to choose two load-invariant input impedance operational points for determination of switching frequency. At this point of input impedance characteristic, its value is not dependent on the load of the converter.

Based on the computed values of LCL2C2 elements, the gain characteristic of proposed converter was made using Matlab simulation tool. Dependency of the gain curves on the load change will be graphically presented. Based on this characteristic it would be possible to determine the proper operation regions of converter. It is generally know that the optimal value of switching frequency for nominal operation equals to resonant frequency of LC element. Anyway, it is more suitable to set the switching frequency in the range from $f_{\min}$ up to $f_{\max}$ under overload (e.g., 200–800%), or short-circuit operation. In this way it won't be able to overcome nominal value of the input current and/or output voltage, respectively. Of course, it can be combined with the asymmetrical control of input voltage of the inverter.

The short circuit occurs hen the value of output current rises. It causes the saturation of magnetic elements and changes the induktance values. Therefore, it changes the ratio between switching and resonant frequency. These has also effect on the output voltage gain. These phenomena can be considered by the method of self-regulation due to own internal feedback. In case of short circuit the output current is limited by the converter self-regulation. Also, the regulation causes the current shape distortion and its THD increases by approximately 3–5%. THD final values are about 6–9%. All these "negatives" are the tax on self-regulating feedback. Under these conditions, it is necessary to consider the regulation by asymmetric change of duty-cycle or changing the ratio of f_{sw} and f_{res}. Also, it is possible to consider over-dimensioned the accumulation elements. Theoretical aspects, simulation experiments and experimental verification will be given in full paper.

Mutual Inductance of Two Helical Coils — Theory, Calculation, Verification

Michal Frivaldsky, **Pavol Spanik**, **Marek Piri**, **and Viliam Jaros**
Department of Mechatronics and Electronics, Faculty of Electrical Engineering
University of Zilina, Slovak Republic

Abstract— One of the important parameter for wireless power transmission is the mutual inductance that tells us about how much is the electromagnetic coupling between two cylindrical coils strong, when an air is positioned between them, and when are without coaxial and angular deflection.

Proposed paper will deal about the verification of calculation processes of a mutual inductance between two helical coils. Nowadays, there are many procedures how to compute mutual inductance between two coils. The main approach of proposed paper is exact specification of the formula, which may be used for the determination of the mutual inductance.

The first step before mathematical calculation is verified, the development of source code in Matlab was done. This code shall serve for computation of self-inductance, and mutual inductances. The code is divided into three parts. First part is part, where we define main parameters of both coils, e.g., radius or height of coil. Main parameters of coils can be taken over from existing system for wireless energy transfer. Second part is calculation of self-inductance. At first, the program calculates module the elliptic integrals and then next subsystem calculates self-inductance. Third part is similar as second, but this part is for calculation of the mutual inductance of two wire coils.

As was already mentioned, the main parameters of the coils can be taken over from existing system for wireless energy transfer. The transmitting and receiving coils were designed with helical geometry. For the investigation of mutual inductance between transmitter and receiver, it was necessary to measure input current of transmitting coil I_{Lp} and voltage on the load U_Z. This is due to fact, that mutual inductance cannot be measured directly.

Next figure shows final comparison between computation and measurement of mutual inductance. Proposed paper will also describe the theoretical procedure that is necessary for computation of mutual inductances as well as for design of computation algorithm. The extension of this algorithm will be further done in order to investigate voltages and currents of transmitting and receiving coil. For this purpose, determination of parasitic components of wireless power transfer system is very important.

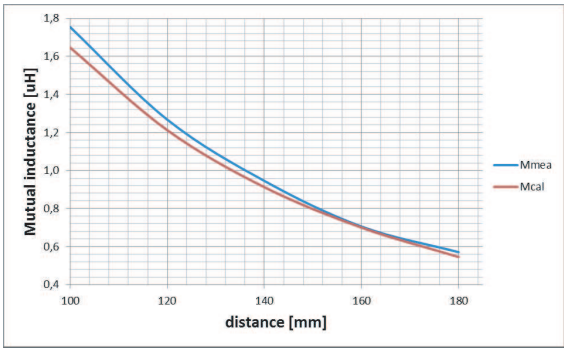

Figure 1: Graphical interpretation of the measured and calculated mutual inductance in dependency on distance between transmitter and reciever.

EM Field Based Industrial Technologies

Application of Meta-materials in the Ports of Conveyor Belt Microwave Heating Systems

A. V. Brovko
Yuri Gagarin State Technical University of Saratov, Russia

Abstract— Meta-materials can be considered as a promising resource of improvement of the existing technologies, as well as a key element of novel technologies due to unusual interaction with electromagnetic waves. In particular, negative values of effective permittivity and/or permeability of these materials allow obtaining such technically interesting electromagnetic effects as negative refraction, band gaps, magneto-electric coupling, etc..

In this paper meta-materials are investigated with the purpose of improvement of existing conveyor-belt microwave heating systems. One of the actual tasks for these systems is construction of input/output ports for the conveyor belt, which do not allow electromagnetic energy to escape from the microwave processing volume. Existing methods do not provide attenuation of microwave energy in the case of large aperture of the ports, or suffers from arcing effect due to high power of microwaves. To this end the idea of application of meta-materials at the ports arises.

Results of numerical analysis show possibility of construction of meta-material walls of waveguide ports with cross section up to 200×500 mm, which significantly reduce leakage of microwave energy from conveyor-belt heating chamber. Meta-material considered in this paper consists of printed circuit boards with metallization as a set of split-ring resonators. Estimation of effective permittivity and permeability of the meta-material was performed by FDTD analysis of the microstructure following Nicolson-Ross-Wier approach. Numerical results show that both effective permittivity and permeability may have negative values at the frequency 2.45 GHz, and these values provide negative (left-handed) refraction, which can be used for preventing escape of microwave energy from processing chamber through conveyor belt port.

Reflection of the eigenmodes in meta-material wall waveguide was estimated by FDTD analysis on macro-level. In this approach the meta-material is considered as continuous media, which permittivity and permeability are governed by Drude dispersion model. Parameters of the model provide negative values of the permittivity and permeability on the frequency 2.45 GHz.

Numerical estimation of the performance is presents in this paper, and aspects of practical implementation are discussed.

Detection of Wood Decay by Microwaves

H. Dobšíček Trefná, **Y. Yu**, **T. McKelvey**, **and M. Persson**
Chalmers University of Technology, Sweden

Abstract—

Introduction: In Sweden, approximately 20% of harvestable trees are affected by rot. Furthermore, there are many trees with hidden damage caused by eg. mooses or machines. During harvesting, this leads to the downgrading of wood from sawlog to pulpwood. Today, the first three meters of damaged log are directly graded as pulpwood, while the rest is subjected to a new inspection. This leads to unnecessary waste, which is roughly valued at 600 million/year. In this paper we present a microwave system which can quickly differentiate the rotten timber from the healthy.

Methods and Results: Our method is based on analysis of the differences in behaviour of electromagnetic signals propagating through healthy and damaged wood. We developed a measurement system consists of a circular antenna array and two-port vector network analyser integrated with computer controlled switch matrix module. The whole system can be mounted on the harvester head in the way the log is placed approximately in the center of antenna array. The signals that are transmitted through the cross-section of the log are then analysed by a so-called subspace distance based classification algorithm. We have performed proof of concept testing the prototype system on freshly-cut healthy and decayed trees. In total 16 wooden logs were measured of which 10 were healthy and 6 contained white rot fungi.

The detector identifed 82% of rotten and healthy samples. The success rate increased above 90% for subgroup of samples with smaller diameter which contained clearly defined rot.

Conclusion: We demonstrated the capability of the designed system to detect decayed wood. Due to the relative simplicity and size of microwave based system accompained with the high acquisition speed make them a potent candidates to be transfered to industrial environment.

ACKNOWLEDGMENT

Abstract— A proposed inductive gas discharge tube (IGDT) including two electrodes and one hollow insulator ring is studied. The insulating ring of a GDT has spinal metal outside with inductive characteristics. In comparison to the conventional design, the proposed IGDT can provide early triggering capability during fast IEMI introduced and results a smaller residual surge current.

Numerical Simulation of Droplet Motion Induced by High Power Electromagnetic Field: Estimation of Errors Induced by Using Phase Field and Level Set Methods

J. Vrba, Jr. and D. Vrba
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— Phase Field and Level Set methods are often used for tracking interface between two immiscible liquids in Computational Fluid Dynamics (CFD). There were several works dealing with simulations of emulsion coalescence using electric field (electrocoalescence) of Water in Oil emulsions using coupled electric and fluid dynamic simulations employing these two methods. The methods use a transition region of the Phase Field and Level Set function on the interface between the two phases (Level Set function is depicted in Fig. 2). In this region all material properties change smoothly between the values of material properties of the two phases. This artificial layer of the smoothly changing dielectric properties changes electric field distribution and correspondingly the dielectrophoretic force density which governs the droplet motions. Since the thickness of this transition region decreases with increasing mesh density the problem is dependent on the mesh density used in the simulation. In this paper, influence of the mesh density as well as of the distance between droplets on accuracy of the dielectrophoretic force density is investigated. For this purpose two 2D axial symmetric models (depicted in Fig. 1) which track the both phases of the emulsion in time domain was done using in COMSOL Multiphysics implemented Phase Field and Level Set methods. Parallel to this model a simple electrostatic (single-physic) 2D axial symmetric model, without considering the LS and PF methods was created and the dielectrophoretic forces are computed with it. The results of the three models are compared and the error is evaluated and discussed.

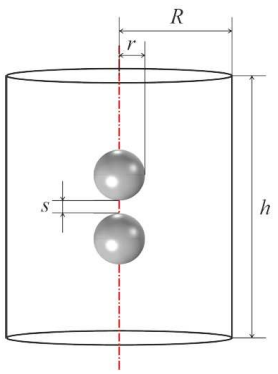

Figure 1: Two droplets placed in a homogeneous time-harmonic electric foeld $\vec{E}_0$. Parameters s, r, R and h stands for the distance between the droplets, radus of the droplets, radius and height of the computational domain, respectively. The oscillation direction of the electric field $\vec{E}_0$ is parallel to the connection line between the droplet centers.

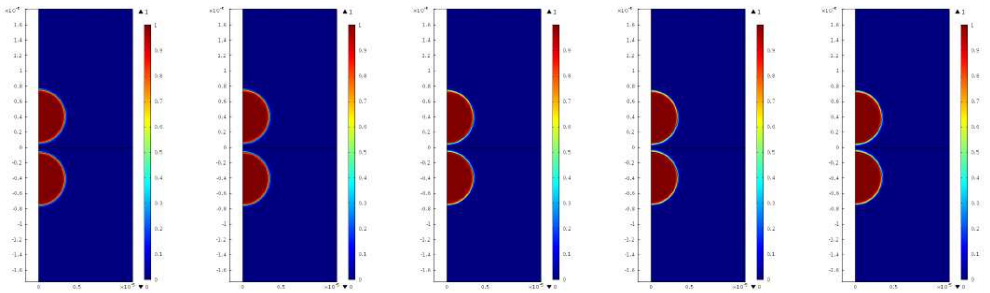

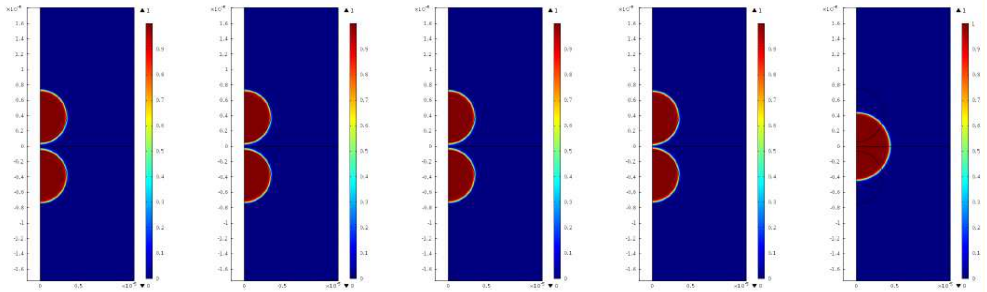

Figure 2: Droplets' positions at different time instances for the case of W/O emulsions predicted with the 2D axially symmetric numerical model.

Visualization of Exposure in Industrial and Medical Applications

Jan Vrba[1], **Ladislav Oppl**[1], **Jan Vrba, Jr.**[2], **and David Vrba**[2]

[1]Department of EM Field, Czech Technical University, Technicka 2, Prague 6, Czech Republic
[2]Department of Biomedical Technique, Czech Technical University, Nám. Sítná, Kladno, Czech Republic

Abstract—

Background: As the importance of usage of microwave technologies in many applications (e.g., industrial, medical, biological, scientific etc.) is rising it is necessary to develop simple to use, reproducible and exact methods of evaluation of microwave primary (i.e., thermal) effects on various materials. In medical application we aim not to hurt the patient and we try to enhance efficiency of the treatment to minimize the adverse impact on the healthy tissue. On the other hand in industrial use we need the processing to be economical and energy efficient.

It is very difficult to monitor effects of electromagnetic field on exposed material in real time but it can be crucial for deeper understanding of processes that take place during procedures using microwave energy (i.e., microwave processing of various materials, microwave thermotherapy, microwave heating and drying etc.). Using conventional methods of evaluation of temperature, volume and other properties usually effects the distribution of electromagnetic field and interferes with it. It is possible to stop the process at any time and evaluate effects of this partial exposure but it is not very sophisticated approach and for example temperature measurements will be affected by this methodology as well. In this paper we are aiming to put contactless and noninvasive methods of measurement of temperature and volume into practical use and we propose methodology and present design of microwave system for visualization.

Methods: Design of the applicator used in the visualization system had to be altered from standard design approach used in conventional applications (i.e., microwave drying, hyperthermia applications etc.). We aimed to design open resonator type applicator which could be used safely and would allow sufficient insight for the visualization equipment.

In this paper we chose to visualize microwave processing of cornstarch beads and evaluate obtained results by processing several separate frames of produced film. Standard camera (i.e., recording in visible part of spectrum) and infrared camera served as the visualization equipment.

For processing of obtained images (from the film) we used Matlab and we were able to determine how volume of layer of cornstarch beads and its average surface temperature are changing. We propose that this method is suitable for many other applications (i.e., evaluation of applicators for medical procedures etc.).

Results: Results of the visualization of the microwave processing and results of evaluation of various single frames in Matlab are presented. We propose that we developed suitable and simple to use method for evaluation of processes in microwave applications. In this paper we also designed microwave system for visualization which enables homogenous exposure of various materials to electromagnetic field.

Shenzhen Key Laboratory of Micro-nano Photonic Information Technology
Key Laboratory of Optoelectronic Device and Systems of Ministry of Education and Guangdong Province
College of Electronic Science and Technology
Shenzhen University, Shenzhen 518060, China

Abstract— Multi-beam microwave heating based on the wave confinement of hexagonal photonic crystal multilayered cavity is reported. The proposed hexagonal cavity is formed by alternative layers of alumina (Al_2O_3) and air with the thickness of $0.3a$ and $0.7a$ respectively, where 'a' is the lattice constant. The 17 layer cavity is normally excited with six microwave beams with the peak strength of 1000 V/m. The center of the cavity is loaded with a low loss dielectric and electromagnetic thermal co-simulations are carried out to study the heat transfer due to multi-beam confinement. It is found that characteristic modes of the proposed cavity show the temperature raising rate of 0.77°C/s, 190.26°C/s and 29.52°C/s at 13.855 GHz, 14.54164 GHz, and 14.78175 GHz respectively. This feature is highly useful for arriving the higher temperatures and the creation of plasmas. Particularly, it is anticipated that the proper scaling of the proposed cavity at laser length-scales provide an excellent source of laser beam heating in industrial welding and green photonic solutions.

Abstract— Recently, man's work and life are increasingly tight with the rapid growth in communications and information technology. The informationized society has changed human being's way of life as well as challenged the traditional residence. Followed by the rapid economic expansion, living standard keeps raising up day by day that people have a higher requirement for dwelling functions. The intellectualized society brings diversified information where safe, economic, comfortable and convenient life has become the ideal for every modern family.

This paper presents design and implementation concepts for a wireless real-time home automation system based on Arduino microcontroller as central controllers. The proposed system has two operational modes. The first one is denoted as a cellular telephone mode in which the user can monitor and control the home appliances from anywhere over the world using the cellular phone through Wi-Fi communication technology. The second one is referred to a self-automated mode that makes the controllers to be capable of monitoring and controlling different appliances in the home automatically in response to the signals comes from the related sensors. To support the usefulness of the proposed technique, a hardware implementation with Matlab-GUI for the proposed system is carried out and the reliability of the system is introduced. The proposed system is shown to be a simple, cost effective and flexible that making it a suitable and a good candidate for the smart home future.

Correlation Characteristics for an Event/Sports Center at 3.2 GHz

Alejandro Aragón-Zavala[1], **Vladan Jevremovic**[2], **and Ali Jemmali**[3]

[1]Electronics Department, Tecnológico de Monterrey, Campus Querétaro, Querétaro, Mexico

[3]R&D Department, iBwave Solutions Inc., Montreal, Canada

Abstract— The key to reliable and fast mobile digital data connections is signal to noise + interference ratio (SINR). The degree of signal cross-correlation between the serving and interfering signal(s) has a significant impact on SINR. Shadowing (slow fading) cross-correlation must be quantified in order to properly calculate SINR. For significant shadowing cross-correlation to occur, the LOS requirement is essential, and as macro mobile networks have almost exclusively Non-Line of Sight (NLOS) coverage, the impact of signal cross-correlation is low. However, as distances between small cells in indoor networks are much smaller, the LOS requirement is mostly satisfied in those types of networks. While many authors have investigated shadow fading for indoor networks, very few have reported results for sports venues, such as stadiums, in which sector handover can become critical and where handover mismanagement could lead to excessive network resource usage.

In systems that relay in a tight power control like CDMA2000 and WCDMA, shadowing autocorrelation and de-correlation distance are important as they allow a good estimate of mobile transmit power fluctuation around its mean value. While there are numerous studies that measure shadowing autocorrelation and calculate shadowing correlation distance in macro networks, there are very few such studies done for in-building networks.

As mobile data consumption has been dramatically increased, various national spectrum governing bodies started to look into ways to allocate more spectrum bands to mobile networks outside those frequencies. An example is the Federal Communications Commission (FCC), the US Spectrum governing body, which proposed a new Citizen Broadband Radio Service in the 3.5 GHz band, specifically to allow small cells deployment on shared basis with incumbent federal and non-federal users of the band. While the rulemaking has not been made yet, the proposal is a part of greater strategy to free up 500 MHz of spectrum for commercial use by 2020. Therefore, it is of interest to investigate cross correlation and auto-correlation properties of stadium networks at frequencies near 3.5 GHz. Likewise, 3.5 GHz spectrum is authorized for mobile use in European countries, and Japan plans to make the 3400–3600 MHz band available for mobile broadband.

This paper presents radio measurement results that were conducted at a university sports/event center at 3.2 GHz. Radio measurements undertaken at this frequency show that signals from two base stations have correlation in the 0.04–0.43 range for small angles (below 30°), showing a positive correlation coefficient, in agreement with our previous work. De-correlation distances are in the range of 1.2 to 14.4 meters, which are strongly dependent on the presence of metallic structures in the vicinity of the tested antennas as well as on the antenna height. Autocorrelation shows an exponentially decay behavior, as previously reported. These measurements were used to establish suitable auto and cross correlation models and de-correlation distances at the venue at the frequency that is reasonably close to the proposed Citizen Broadband Radio Service band. From these findings, recommendations for modelling auto-correlation and cross-correlation in sporting venues at these frequencies could be made, which then can be used to extend out study to similar venues at higher and lower frequencies.

Hidden Markov Models Based Channel Status Prediction for Cognitive Radio Networks

Wojciech Bednarczyk and Piotr Gajewski
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 Str., Warsaw 00-908, Poland

Abstract— Cognitive radio (CR) networks can be designed to manage the radio spectrum more efficiently by utilizing of temporarily not used channels in primary users' licensed frequency bands. Here, the spectrum utilization can be improved significantly by spectrum sharing between primary and secondary users (who are not being served by the primary system). In this paper, we propose to use so called Hidden Markov Models (HMM) to predict the spectrum occupancy of sharing radio bands.

The proposed technique can dynamically select different licensed bands for secondary user with significantly less interference from and to the licensed users. This can be solved by predicting of the time duration of primary users non-active state in selected band. Using the HMM to build the channel prediction algorithm, for dynamic spectrum allocation in cognitive radio networks, the CR can utilize them more efficiently because it should leaving the currently occupied band, before the primary user starts of his transmission in that band.

In this paper, we discuss the theoretical aspects of statistical modeling by HMM and show how HMM can be applied to dynamic spectrum management. At the beginning, we will shortly describe the theory of HMM using simple examples. Then we will focus our attention on the three fundamental problems for HMM design. Firstly we show the evaluation of the probability of an observations sequence by using a specific HMM. The second question will be discussed is how to determine a best sequence of model states. And finally the adjustment of model parameters so as to best account for the observed signal will be discussed. We will show that once these three fundamental problems are solved, the HMM can be applied to dynamic spectrum management in cognitive radio networks. The details of simulation will be described. The results obtained using HMM are very promising and they show that HMM offer a new paradigm for predicting channel behavior in cognitive radio.

Modified Lowest ID Algorithm for Practical Wireless Clustered Network

Wojciech Bednarczyk, **Jerzy Dołowski**, **and Jarosław Michalak**
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 Str., Warsaw 00-908, Poland

Abstract— Clustering is a promising approach for building hierarchies and simplifying the routing process in mobile Ad-hoc network environments. The main objective of clustering is to identify suitable node representatives, i.e., Cluster Heads (CHs), to store routing and topology information and maximize clusters stability. Traditional clustering algorithms suggest CH election exclusively based on node IDs or location information and involve frequent broadcasting of control packets, even when network topology remains unchanged.

Several heuristics have been proposed to address Ad-hoc networks clustering problem. One of the most popular ones is Lowest-ID (LID), wherein each node is assigned a unique ID. Periodically, nodes broadcast their IDs through a *Hello* control message, within a period time *Hello* period. The lowest-ID node in a neighborhood is then elected as the CH; nodes which can hear two or more CHs become gateways.

The main asset of LID method is its implementation simplicity. It is also quick clustering method, as it only takes two *Hello* periods to decide upon cluster structure and also provides a more stable cluster formation.

We proposed a modified clustering algorithm, the Lowest Node ID (LNID). This algorithm has the following crucial features:

- a state machine with semi-stable states,
- ability to change the state during work,
- additional control messages (as development of original OMNET messages),
- MAC address as ID of nodes,
- stabilizing procedures

It is well known that energy used by a system has a special importance not only from energy consumption point of view (especially in battery supplied devices) but from interference level introduced by the system which has essential impact on a capacity of system and its ability to simultaneous working among others wireless links.

Efficiency of LNID algorithm in practical constraints were assessed in dependence on special network stabilizing algorithms from point of view:

- Time of clusterization process,
- Energy used by the network in clusterization process,
- Clusterization correctness,
- Structure stability of clusterized network.

Simulations will be done for static network assuming Free Space Path Loss propagation model with chosen reliability of information delivery in a radio link.

Application of DRTM to Aircraft Landing System

Junichi Honda
Surveillance and Communications Department, Electronic Navigation Research Institute
Chofu, Tokyo 182-0012 Japan

Abstract— This paper describes a numerical simulation of multipath interferences caused by buildings for aircraft landing system. Focusing on the LOC (Localizer) among ILS (Instrument Landing System), we discuss on the effect of multipath interferences. The LOC consists of carrier and sideband signals. The landing aircraft move along the ILS course whose signal phase variable becomes almost zero. However, the reflected and diffracted waves from buildings cannot be ignored because unexpected waves result in disturbances of the normal landing course. Therefore, we need to simulate electromagnetic field in advance in order to prevent the signal errors, especially for the relocation of building and LOC. In this paper, we numerically compute multipath interferences caused by buildings. In the numerical simulation, we use the DRTM (Discrete Ray Tracing Method) which were proposed by Prof. Uchida. The DRTM based on the ray tracing method is able to reduce ray searching time. We compute ray distribution between a source and a receiver by using a simple airport model, and we analyze electromagnetic field and the current of electricity at the receiver side. We discuss the multipath interferences in airport. We show that the DRTM is one of suitable numerical technique for aircraft landing system.

Using Antenna Diversity to Improve Wake-up Range and Probability

T. Kumberg, R. Tannhaeuser, and L. M. Reindl
IMTEK Laboratory for Electrical Instrumentation, Department of Microsystems Engineering
University of Freiburg, Georges-Koehler-Allee 106, Freiburg 79110, Germany

Abstract— Wireless sensor networks (WSN) can be used to monitor critical infrastructure such as bridges. WSNs often consist of small sensor nodes which have only limited power supply and are installed at places that are hard to reach [1]. But, due to the goal of long term monitoring, which usually is in the range of more than ten years, long lifetimes of WSNs should be realized [2]. Therefore, energy consumption of WSNs needs to be minimized for example by using low-power wake-up receivers. They reside in a low-power stand-by state until they receive a wake-up signal. After receiving this signal, or a trigger from a sensor, they wake-up to full functionality [2, 3].

With the development of wake-up receivers, a paradigm shift can be observed in wireless sensor networks communication protocols [4]. Now, communication and as such, sending of messages is only necessary if a sensor node has data available that needs to be sent or if the sensor node was asked to send data. In other words, idle listening and sending of synchronization messages is no longer required.

But low-power wake-up receivers introduce also new challenges as their sensitivity is much lower than the sensitivity of communication radios, as depicted in Figure 1 where nodes A and B are in wake-up range of the Sender and nodes C, D and E are also in communication range. Due to this, several wake-up messages may be necessary to reach a sensor node that is in communication range but not in wake-up range. Another challenge is that sending of a wake-up message may be as expensive as sending of a communication message [4].

The low-power wake-up sensor node presented by [3] uses the AS3932 low-power wake-up receiver that listens permanently to a 125 kHz signal that is modulated on an 868 MHz carrier frequency and demodulated by the use of a rectifier and a low-pass filter. Changing between communication and low-power wake-up listening is realized with the antenna switch (ADG918).

In this paper we present a wake-up node, which is based on the node presented by [3]. Figure 2 shows the modified design that uses antenna diversity in the wake-up path. Due to this, the node shows an improved wake-up range in free-space propagation and improved wake-up probability in a multipath propagation environment. We show that no additional active parts are needed, which would increase power consumption. The general design and its performance are tested by using simulations. A test setup is used to verify the simulation results and to show the behavior of the new design.

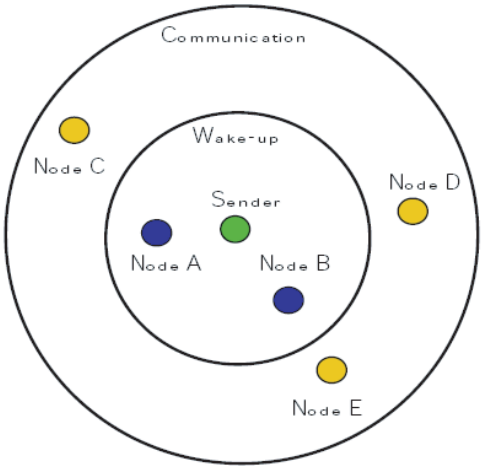

Figure 1: The nodes A and B which are in wake-up range of the Sender. Nodes C, D and E are also in communication range of the Sender.

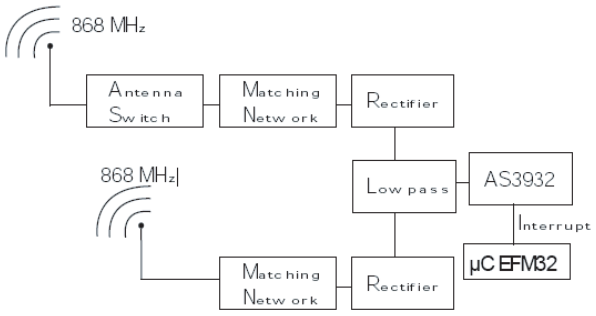

Figure 2: Schematic of a sensor node using antenna diversity in the wake-up path to improve wake-up range or wake-up probability.

Interference Aware Iterative Receiver Performance for the Uplink of LTE-A

Carlos Reis, **Nuno Souto**, **Américo Correia**, **and Mário M. da Silva**
ISCTE-University Institute of Lisbon and Instituto de Telecomunicações, Portugal

Abstract— In this paper we study the performance of an interference aware iterative block decision feedback equalizer (IBDFE) for the uplink of LTE-Advanced with single carrier (SC) transmissions. The receiver makes use of the correlation between the interference in the receiving antennas and minimizes the mean squared error (MMSE) of the detected symbols. Link level simulation results show that the proposed receiver clearly outperforms the conventional IBDFE and the linear interference rejection combining (IRC) detector. System level simulation results show that the use of the new iterative receiver achieves additional throughput gains. However, the gains obtained depend on the schedulers employed and on the number of receiving antennas.

Abstract— Mobile communication systems must support multiple users achieving at same time privacy of users contents. Security common solutions are based on encrypted algorithms from higher layers, such as private and public encrypted keys. Other possibility is to implement physical layer security schemes. One advantage of physical layer security relies on their ability to be combined with other security schemes from higher layers.

MIMO (Multiple-input multiple-output) systems can increase throughput in modern wireless networks and reduce interference. Other advantage of MIMO systems is the reduction of the transmitted power. On the other hand, to achieve high spectral efficiency multilevel modulations with high peak-to-average power ratios should be used, which may affect efficiency of power amplification. This problem can be avoided with a transmission scheme, where the constellations are decomposed on several uncorrelated BPSK (Bi Phase Shift Keying), QPSK (Quadri Phase Shift Keying) or OQPSK (Offset QPSK) components, being each component amplified and transmitted independently by an antenna. Combination losses are also avoided since the several signal components are combined at channel level. On the other hand due to the broadcast nature of MIMO systems, security is another critical issue in such systems. However, the constellation shaping on the desired direction introduced by these new transmitters means that we have directivity at the transmitted constellation that can be employed to assure security at physical layer. Privacy is achieved since each user must know the set of coefficients associated to each BPSK component as well as the array configuration, otherwise receives useless data. Therefore, the inherent security lies on the constellation directivity, i.e., the direction in which the constellation is optimized, which can be improved by changes on coefficients' phases or using constellations that are decomposed with a higher number of BPSK components. The several cases analyzed here show effectiveness of the proposed approach to implement a security scheme at physical layer level.

Experimental Characterization of In Vivo Radio Channel at MICS and ISM Bands

Abstract— Wireless communication and channel modeling for implantable biomedical devices have received more attention in recent years for diagnosis and therapy. Mutual communication between the implantable medical devices and the ex-vivo devices is commonly performed in the medical implant communications service (MICS) band (402–405 MHz) as it represents reasonable signal propagation characteristics in human body [1]. MICS has wide range of applications such as stimulatory devices including pacemakers and implantable cardioverter/defibrillator. It is crucial to analyze the signal attenuation in the lossy human tissues and the propagation around the human body. Experimental measurements used to confirm the validity of the simulation results done using human body models are usually performed inside phantoms. Phantoms are relatively easy to be analyzed and implemented; however, real time in vivo measurements of implantable devices are essential to verify the performance in a real environment that has many and different tissue layers. These multitissues have different electrical properties such as conductivity and signal attenuation depending on the used frequency as well as age, size, sex, etc.. A comparison between a single equivalent layer of a body model and a three layer structure was presented showing the advantages and limitations of each one [2]. Numerical electromagnetic analysis was applied to model in/on body radio propagation channels which clarified the importance of digital phantom accuracy [3].

In this study, numerical versus experimental analysis of implantable antennas for biomedical telemetry in the MICS is presented. In addition to simulation studies, measurements are performed on adult cadaver. For both simulation and measurement studies, an antenna is placed at different organs inside the body (keeping in view the most promising implantable applications) i.e., heart, stomach and intestine. The ex-vivo antenna is initially placed on the surface of body and then at 5 different locations outside the body with spacing of 20 mm upto 100 mm with steps of 20 mm from the surface of body. In addition different depths of implant antenna is considered as well. Path loss is calculated for all scenarios and compared with the simulation results. A reasonably good agreement is obtained among the simulation and measurement results. The study enables better understanding of losses inside the body for different organs, which will help in developing better implantable devices.

Performance of Ultra-wideband Body-centric Wireless Networks

Zied Bouida[1], **Marwa Qaraqe**[2], **Qammer Abbasi**[1],
Mohamed Abdallah[1], **and Erchin Serpedin**[2]

[1]Department of Electrical and Computer Engineering, Texas A&M University at Qatar, Doha, Qatar

Abstract— The main idea behind body-centric wireless communications is to connect multiple devices that are located on the human body. In this context, several research topics have covered the study of body-centric communications especially with the scope of personal area networks and body-area networks. Indeed, the urgent need for wireless personal communication systems (PCS) is a normal result of the highly-increasing demand for technological advances required to satisfy humans' rapid-paced life-style changes. Many innovative PCS have been proposed, particularly in the area of body-worn devices. These body-worn devices initiated the concept of body-centric communication systems (BCCS) offering a huge number of applications in healthcare systems.

Both narrow-band and wide-band frequencies can be used for body centric wireless communications. However, ultra-wideband (UWB) is a promising wireless communications technology that is characterized by low energy and large bandwidth and can be used for short-range, high-data-rate communications. UWBs low-power requirements makes it an ideal candidate for BCCS [1]. Moreover, the use of such higher frequencies reduces the propagation of waves into the human body. As the demand for higher data rate increases, new techniques that aim at achieving these data rates are evolving. Among the most popular is the combination of the UWB technology with multiple-input-multiple-output (MIMO) systems, i.e., multiple-antennas-based transceivers [2].

In this submission, we study the performance of ultra-wideband body-centric wireless networks (BCWN). In this context, we evaluate the capacity of UWB MIMO on-body channels. In order to study the effect of on-body antenna positions, we consider four different transmit-receive antenna location scenarios where the transmit antenna is fixed on the Waist and the receive antenna is placed in different positions. More specifically, the four considered scenarios are the Chest-Waist, Wrist-Waist, Ankle-Waist, and the Back-Waist settings as shown in Figure 1. Based on field-measurements, the obtained results reflect the impact of different antenna positions on the performance of on-body networks. For each of these scenarios, we evaluate the channel capacities depending on the amount of channel state information (CSI) available to the transmitter. More specifically, we evaluate the equal-power capacity and the water-filling capacity for the cases where no CSI and full CSI is available to the transmitter. We also provide a mathematical framework for the computation of the capacity of UWB MIMO systems.

Measurements and Simulations of Electric Fields Emitted from LTE Femtocells inside a Building Office

Hsing-Yi Chen and Shu-Huan Wen
Department of Communications Engineering, Yuan Ze University
135, Yuan-Tung Road, Nei-Li, Chung-Li, Taoyuan Shian 32003, Taiwan

Abstract— In the near future, long term evolution (LTE) femtocells will play a key role in enterprise and metro deployment areas for indoor wireless communications. With the increasing use of indoor wireless networks, there is a challenge to provide a better coverage, higher cell capacity, and higher data rates for mobile applications in the initial design and planning. Therefore, EM field distribution and variability of LTE femtocells in indoor-environments should be well studied in order to ensure an adequate coverage and good performance for indoor wireless communications. In this study, the FDTD method was used to calculate electric fields emitted from a LTE femtocell placed at the left-hand-side of an empty office at frequencies of 700, 860, 1990, and 2600 MHz. The validity of the simulation results of the electric fields is further checked by measurement data. After validating the accuracy of the FDTD method, the FDTD method was used to calculate electric field distributions inside the office, with and without the presence of 20 people and furniture for the LTE femtocell placed near the center of a horizontal plane with a distance of 1.0 m from the upper slab and transmitting a power of 10 dBm. Simulated electric fields at most of the locations on the horizontal plane with a height of 1.0 m above the bottom slab for the office with and without the presence of 20 people and furniture are found in the range of -10 to -30 dBV/m which means a good signal will be picked up in the office. The maximum power density emitted from the LTE femtocell is 1.326×10^{-4} W/m^2 which is far below the ANSI/IEEE safety standard of 4.6–17.3 W/m^2 for public exposure at frequencies of 700–2600 MHz.

Meshing Noise in Parametric Analysis of Passive Components with 3D FEM

A. Lamecki, L. Balewski, and M. Mrozowski
Faculty of Electronics, Telecommunications and Informatics
Gdansk University of Technology, Poland

Abstract— Design of passive components for modern RF and microwave systems requires the application of high accuracy software for electromagnetic simulation. Amongst a variety of numerical techniques that can be utilized to compute device's response, the finite element method (FEM) has emerged as an industry standard due to flexibility to handle complex, arbitrary shaped 3D devices.

A typical design cycle uses some kind of an iterative tuning method (based on optimization) which requires a device to be simulated multiple times in order to fit the response to required design specifications. During the tuning procedure, the design parameters are modified at each step and the simulation of the updated design is performed. This procedure is repeated until the specification is met. In the case of a FEM solver, the geometry of a modelled structure is represented in a discretized form as a mesh (usually tetrahedral or quadrilateral). At each tuning iteration the mesh is generated and built from scratch. As it will be shown in this submission, the major difficulty with such design procedure is the lack of continuity of design response vs. the change of design parameters (geometric variables). This effect can be observed in the simulated device's response as a meshing noise and it is most disadvantageous when optimization is performed and may ultimately prevent convergence.

In order to reduce the influence of the meshing noise on the convergence of the tuning procedure, a different strategy has to be applied in order to eliminate remeshing at every tuning step. This can be achieved by the application of mesh deformation techniques, as proposed in in [1]. It can be proven that such strategy allows for the elimination of the remeshing noise from the parametric sweep. Preliminary results of application of mesh deformation techniques obtained within InventSim — a novel 3D FEM Simulation and Optimization Framework [2, 3] confirm the advantages of the proposed approach.

280 GHz Signal Sensor Design Using Subharmoinc Mixing in 40 nm CMOS Technology

Tzu-Chao Yan[1], **Chun-Hsing Li**[2], **and Chien-Nan Kuo**[1]

[1]National Chiao-Tung University, Hsinchu 30010, Taiwan
[2]Natioanl Central University, Jhongli, Taiwan

Abstract— THz imaging sensing has become an emerging wireless application beyond communications in the past few years, especially for CMOS technology [1]. An imaging detector makes use of the plasma wave theory and operates in the frequency range higher than the cutoff frequency in FET devices [2]. The construction of an image relies on raster scanning of the received power from each pixel. Consequently, power detection is a fast method to obtain a 2D image. It would be more valuable to construct a 3D image, which requires phase detection. To carry out phase detection, frequency mixing turns out to be a simple way. The detected signal phase is determined and referred to a local reference signal (LO).

In this summary, we present the circuit design forsignal phase detection at 280 GHz, using subharmoinc frequency mixing based on the plasma wave theory [2]. Previous works of frequency mixing typically apply a Schottky mixer as in [3]. In [4], the theory and circuit configuration using FETs are discussed in details. Nevertheless the LO signal is combined with the RF signal in the free space as one single input before the antenna. In this work, an on-chip LO is generated. The LO signal frequency is chosen in a half of the RF signal frequency around 140 GHz. An external signal at 23.3 GHz is input to generate the LO signal through an on-chip frequency multiplier chain. The single-ended input passes through bonding wires with careful design to minimize the insertion loss. The multiplier chain includes a frequency tripler, an amplifier, and a frequency doubler. It still requires some other passive components, such as March and balun and Wilkison divider circuits designed using transmission lines, to obtain quadrature RF signals. MOSFETs perform frequency down conversion with LO and RF at the gate and source port, respectively. The output IF signal frequency is set around 10 MHz. It is necessary to add an IF amplifier of 57 dB gain to boost up the level for measurement. The simulated result shows that the output voltage of 117 mV is obtained, given the received RF power of −60 dBm. The gain level of the IF amplifier is so high that dc offset cancellation is required. A feedback network with low-pass filtering works for the cancellation purpose. According to the IF output of quadrature phases, we can make post processing to retrieve the RF signal phase.

On-Wafer Calibration Technique with Fixed Probe Positions for Production Tests of Radio Frequency Integrated Circuits

Chien-Chang Huang and Wei-Che Lin
Department of Communication Engineering, Yuan Ze University
135, Yuan-Tung Rd., Chung-Li, Taoyuan 32003, Taiwan

Abstract— Scattering parameter (S-parameter) calibration of vector network analyzer is essential and important for device/circuit measurements in high frequency applications. For production tests of radio frequency integrated circuits (RFICs), the on-wafer probes in fixed positions to fit the dimension of the device-under-test (DUT) is usually preferred, and the associated calibration standards in the same dimension can further save the testing time since the probes need not to be moved during calibrations and measurements. Though some commercial impedance-standard substrates (ISSs) have the same probing position for their calibration standards, the probing position may not meet the DUT dimensions. In this paper, a calibration technique with three on-chip standards including a transmission line, a series resistor with offset line segment, and a shunt resistor with offset line segment, in the fixed probing constraint suited for RFIC production test is presented, where the on-chip standards need not to be characterized in advance. The self-calibration feature of the proposed technique relaxes the accuracy requirements of the on-chip standards, and becomes attractive for production test applications. To show the robustness of the proposed calibration technique, some simulation studies with noise effects are conducted in GaAs substrates with the on-wafer measurement verifications up to 110 GHz.

A High-Q Linear CMOS Digitally Controlled Accumulation-mode Varactor Array for Multiband RF Circuits

Sanggil Kim and Donggu Im
Division of Electronics Engineering
Chonbuk National University, Jollabuk-do 561-756, Korea

Abstract— Electronically tunable capacitors are key elements for tunable and reconfigurable RF circuits. The most popular tunable capacitor topologies in CMOS are the analog varactor and digitally controlled switched capacitor array (SCA). The conventional analog varactor shows a high quality factor (Q-factor) in both the minimum capacitance ($C_{\min}$) and the maximum capacitance ($C_{\max}$) states with a wide tuning range, but it has a poor linearity performance due to the voltage dependent nonlinear capacitance. In case of the digitally controlled SCA, while it shows a very good linearity, its Q-factor in $C_{\min}$ state is strongly dependent on the substrate loss by the parasitic junction capacitances between P-well, deep N-well, and P-substrate and the parasitic junction resistance. Especially, if the SCA is implemented in a standard digital CMOS process without deep N-well, it suffers from severe Q-factor degradation in $C_{\min}$ state at higher frequencies. In order to overcome the aforementioned drawbacks of the analog varactor and the digitally controlled SCA, the digitally controlled binary-weighted accumulation-mode varactor array (AVA) is proposed. Contrast to the conventional analog varactor tuned by continuous analog voltage, the proposed AVA uses only two states of $C_{\min}$ and $C_{\max}$ of the analog varactor by digitally on/off control. Instead of a zero voltage reference, the negative voltage ($-VDD$) is applied to the gate of the analog varactor in $C_{\min}$ state in order to maximize the tuning range, power handling capability, and linearity. The total capacitance varies by turning on ($+VDD$) or off ($-VDD$) each branch of the proposed AVA The proposed AVA keeps a high Q-factor in all states even if it is implemented in a standard digital CMOS process without deep N-well, while showing comparable linearity performance in comparison with the conventional SCA. In simulation, the Q-factor at 2.4 GHz is greater than 70 over all states and the tuning range is about 3.1. The simulated third-order input-referred intercept point (IIP3) at the same frequency is greater than +35 dBm over all states.

A V-band Balanced MMIC Power Amplifier

S. Ismail, S. Karimian, and R. Sloan
School of Electrical and Electronic Engineering
The University of Manchester, Manchester, M60 1QD, UK

Abstract— A highly stable V-band balanced power amplifier has been proposed based on MMIC using the pseudomorphic High Electron Mobility Transistor (pHEMT). The amplifier consists of two stages with device length of $8 \times 25\,\mu m$ and $2 \times 25\,\mu m$ gate widths. The design kit of PP10 WIN Semiconductor Corp. has been used. The simulation results show power and gain levels of 18 dBm and 12.5 dB, respectively, with a tolerance of ± 0.8 dB over the broadband range of 40–80 GHz. Microstrip Lange couplers are used as 3 dB quadrature power splitters and combiners. The amplifier has an acceptable performance with low input and output VSWRs, high stability, fairly flat gain and constant power over the whole bandwidth; and so it can be a good candidate for broadband millimetre-wave front end transceivers systems, and also, as an instrumentation amplifier in measurement systems. The MMIC amplifier is being sent for fabrication and will be tested when received.

Optimal Focusing by Means of Convex Programming: A Review

T. Isernia, D. A. M. Iero, and A. F. Morabito
DIIES, University 'Mediterranea' of Reggio Calabria, Italy

Abstract— Two decades ago, two different research groups [1–3] showed how the problem of focusing a field in a given direction subject to arbitrary sidelobe bounds elsewhere, and where excitations are the unknowns of the problem, can be formulated as a Convex Programming problem. Later, the same result was re-discovered by Balanis and Bevelacquain [4]. Notably, the approach in [3] already allowed to take into account near field constraints.

The basic approach has then evolved in a number of different directions, including the case where you cannot define an array factor [5], the extension to the optimal synthesis of delta patterns [6], and the exploitation of these results and procedures to the case when both excitations and locations were to be determined [7].

More recent results include the extension of the basic result to the synthesis of continuous sources (under given sidelobe constraints) for both cases wherein one wants to maximize directivity, or to maximize separation amongst the main beam and peak sidelobes [8], as well as the optimal synthesis of sum-delta reconfigurable beams by means of phase only control [9]. Extension to spatial (rather than angular) focusing has also been provided in [10]. A very recent further extension tackles the optimal spatial focusing of the power associated to a vector field [11].

Contribution will briefly discuss basics, relevance (per se as well as for creating reference solutions for more cumbersome synthesis problems), and possible extensions of the results above.

F/S Ratio Improvement of Directional Bow-tie Antenna with Parasitic Elements

K. Kanai[1], **M. Nagasawa**[1], **R. Suga**[1], **T. Yasuzumi**[2], **T. Uwano**[1], **O. Hashimoto**[1], **and Y. Hasegawa**[2]

[1]Aoyama Gakuin University, Japan
[2]Toshiba Corporation, Japan

Abstract— Electromagnetic interference (EMI) levels of appliances should meet the electromagnetic compatibility standard. A large wide-band antenna is used for the radiation EMI measurements. The finding of noise sources is highly important to suppress the radiation EMI efficiently. Thus a small wide-band directional antenna with high front to side (F/S) ratio is expected for the measurement. A bow-tie antenna is known as a compact and broadband antenna, however it has omnidirectional radiation characteristics and its sidelobe levels increase at higher frequencies due to the higher order modes. In this paper, a directional bow-tie antenna suitable for specifying the noise sources is proposed.

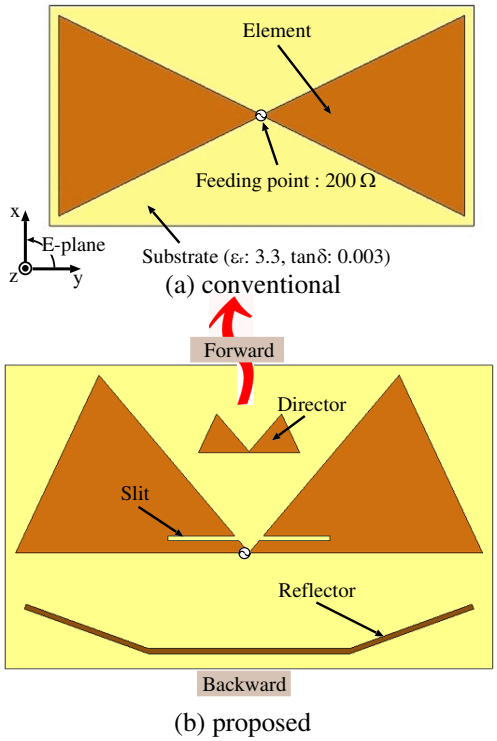

Figure 1: Simulated reflection characteristics.

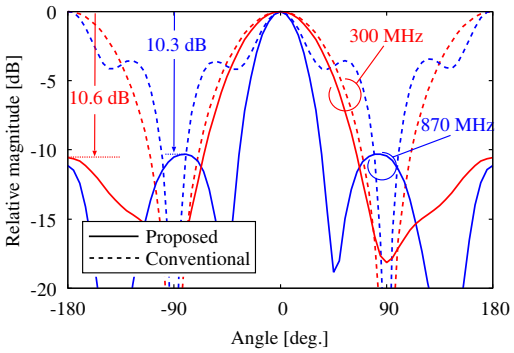

Figure 2: Simulated radiation patterns in the *E*-plane.

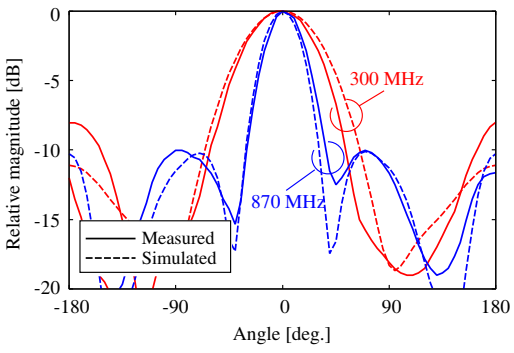

Figure 3: Measured radiation patterns of the fabricated bow-tie antenna.

Figure 1 illustrates (a) conventional and (b) proposed printed bow-tie antenna. A broadband 1 : 4 balun is used for the antennas to obtain 50 Ω input impedance. The target frequency band is assumed between 300 and 870 MHz considering EMI measurement application and the balun characteristics. For obtaining the directionality, two backward edges of each half element are on the straight-line, and two slits are placed on the elements to suppress the sidelobe level at 870 MHz. The director and reflector are placed to improve F/S ratio in the high and low frequency.

Figure 2 shows the simulated radiation patterns in the E-plane. The F/S ratio of the proposed antenna at 300 and 870 MHz is improved to be 11.1 dB and 10.1 dB, respectively. Figure 3 shows the measured radiation pattern in the E-plane. As the results, the measured results agree well with the simulated ones.

Ultra-wideband Butler Matrix Fed MIMO Antennas

Abstract— Modern wireless systems, such as communications and Radar, are in the need for wide operational bandwidths, in order to satisfy the increased demands of their operation. This characteristic has become even more essential in the latest Long Term Evolution (LTE) communications systems, where there is the need for high and robust data rate transmission. Moreover, modern multifunctional phased array Radars demand for wide operational bandwidths, which they enable different operational modes, such as simultaneous air and weather surveillance.

As a result, significant work is taking place on the design and development of wideband antenna systems and RF front-ends. A critical part of the research deals with the design of the antenna array and its feeding network. One of the mostly used wideband antenna elements is the so-called Vivaldi slot antenna, which can offer an operational bandwidth extending to multiple octaves. Regarding the feeding networks, various approaches have been followed, mainly focusing on the design of wideband circuits and subsystems.

In this paper, we make an effort to extend the results of our previous work [1] on the design and development of ultra-wideband (UWB) antenna array systems for communications and Radar applications. The emphasis is given on the implementation of a MIMO beamforming scheme enabling high data rates, interference and noise suppression and suitable for use under different wireless applications scenarios. Specifically, the proposed system consists of a Vivaldi antenna array fed by an UWB Butler matrix type network. It could be used in modern multifunctional Radar systems with analog beamforming, as well as in future LTE communications applications. The Butler matrix is designed using UWB couplers and phase shifters [2, 3], being able to support the wideband Vivaldi array operation up to several octaves. The system design is presented, along with the beamforming procedure and the resulting array radiation patterns. Different MIMO beamforming scenarios are applied to maximize system performance, with particular emphasis on a 4×4 and 8×8 configurations. The possibilities of achieving low sidelobe levels and radiation pattern null steering are investigated, in order to suppress and minimize noise and interference. Conclusions and some aspects for future work are adduced in the last part of the paper.

CRLH Waveguide Based Ka-band Beam-steering Leaky-wave Antenna for Radar Application

Qingshan Yang[1, 2], **Xiaowen Zhao**[1, 2, 3], **and Yunhua Zhang**[1, 2]

[1]Key Laboratory of Microwave Remote Sensing, Chinese Academy of Sciences (CAS), China
[2]Center for Space Science and Applied Research, CAS, Beijing 100190, China
[3]University of Chinese Academy of Sciences (UCAS), Beijing 100049, China

Abstract— Beam-steering capability is highly desired for many radars, especially for tracking radars. Frequency scanning and phase scanning are two general approaches for beam-steering. Traditional frequency scanning array antennas is hard to achieve continuous beam scanning from backward to forward directions because of their forward-wave propagation nature. While phased arrays have been applied widely due to their continuous beam scanning capability from backfire to endfire, however, the feed networks are often bulky and very complicated. In the past decades, composite right/left-handed (CRLH) metamaterials have been investigated extensively due to their unique properties such as backward wave and infinite wavelength propagation, which can be applied to leaky-wave antennas (LWAs) to realize continuous beam-steering from backfire to endfire.

In this work, we exploit the CRLH waveguide with double ridge corrugations to realize a Ka-band LWA with continuous beam-steering capability from backward to forward quadrants. The CRLH waveguide is composed of a traditional rectangular waveguide with one of its broadwalls periodically loaded with short-circuited double ridge corrugations [1]. This CRLH structure is air-filled to avoid dielectric loss. An offset straight long slot is made on the other broadwall of the rectangular waveguide acting as the radiating aperture to realize a LWA (see Figure 1). The LWA is composed of 100 CRLH radiating unit cells. Stepped transitions are included in the two ends of the LWA for connecting the structure to standard WR-28 waveguides.

The continuous beam-steering capability is validated by simulation, which shows that the main-lobe can scan continuously from $-32°$ to $+29°$ as the frequency changes from 32.4 GHz to 40 GHz, and correspondingly the realized gains changes from 15 dBi to 20 dBi. Compared with planar CRLH LWAs, the waveguide LWA proposed in this work has the advantages of high power capacity, low loss and consistent high gains and high radiation efficiency, which is very suitable for actual radar systems.

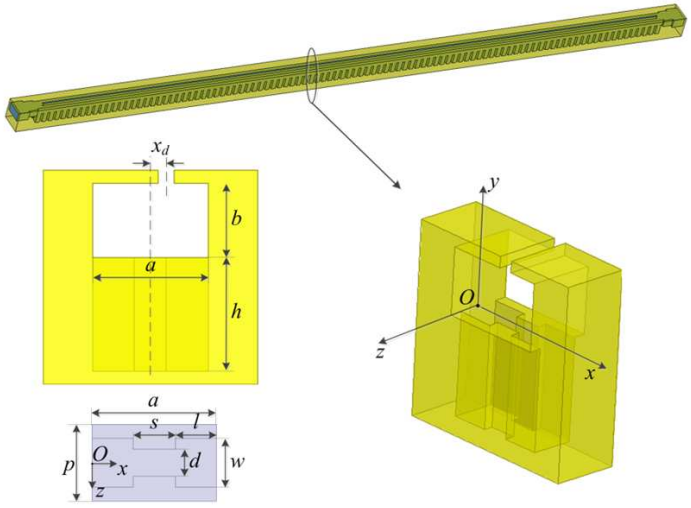

Figure 1: Configurations of the proposed CRLH waveguide LWA and its unit cell.

Performance Analysis of Directive UWB Antennas as Reflector Feeds

Hazel Kara and Nurhan T. Tokan
Department of Electronics and Communications Engineering
Yıldız Technical University, Istanbul, Esenler 34220, Turkey

Abstract— In reflector applications, it is desirable to have a single feed that covers the entire frequency band of operation with a symmetric, directive pattern, dual-linear polarization, and frequency invariant phase centre and radiation pattern. To obtain a highly directive antenna, the size of the feed antenna should be enlarged which results with more phase centre movement with the change in the frequency. Long antenna elements exhibit high phase-center instability, which is very undesirable characteristic when the antenna is used to illuminate a reflector. A trade-off is necessary between directivity and phase errors. In order to avoid phase-center instability, short elements can be used but then higher losses for spillover are obtained.

When a wideband antenna is to be used as a reflector feed, the phase center variation with frequency introduces an error on the phase of the primary field impinging on the reflector surface. This is because the antenna phase center will be coincident with the focus only at one particular frequency and displacement at other frequencies will result as the phase error losses due to axial defocusing (Fig. 1). Tapered slot antennas are the most utilized antennas in Ultra Wide Band (UWB) high-performance applications. In this work, performance of the UWB Vivaldi antennas (exponentially tapered slot antennas) in reflector feed applications is investigated. A long Vivaldi is designed, manufactured (Fig. 2) and its phase center movement with frequency is measured. The correspondent phase error loss is estimated. Besides, spilover, amplitude taper and crosspol losses are calculated.

Comparative Study on Stability of Total Gain and Input Impedance of Side Fed Bifilar Helix Antenna for Large Fixed Size Ground Plane

Muhammad Ahmad, **Muhammad Amin**, **and Asim Ali Khan**
COMSATS Institute of Information Technology, Lahore, Pakistan

Abstract— This research presents comparative study of input impedance and total gain of Side Fed Bifilar Helix Antenna (SFBHA) against the variation in height (in terms of wavelength) from large fixed size Perfect Electric Conducting ground plane (PEC). The simulations show that metallic ground plane of size $10\lambda \times 10\lambda$ approximate the infinite PEC ground plane with reasonable accuracy. The variations in input impedance and Voltage Standing Wave Ratio (VSWR) are noticed between the heights of 0.05λ to 0.35λ both in simulations and measurements. Above the height of 0.35λ, fewer variations are observed that are negligible. Measurement results of input impedance and VSWR are reasonably matched with simulations. The total gain pattern of SFBHA remains stable in simulations and measurements as height of SFBHA varies above PEC. The performance of SFBHA is compared with Horizontal Dipole antenna (HD), Vertical rectangular Loop antenna (VL) and with another orientation of rectangular loop antenna that is Horizontal and Perpendicular Loop (H&PL). Comparatively, the electromagnetic performance of SFBHA is better and affect of the ground plane above 0.35λ on total gain pattern, input impedance and VSWR is negligible.

Aperture Coupled Microstrip Antenna with Three Resonants

Mohsen Jafari Chashmi[1], **Ramezan Ali Sadeghzadeh**[2], **Hadi Ghobadi**[2], **Mahdi Oliaei**[2], **and Esfandiar Mehrshahi**[1]

[2]Electrical & Computer Engineering Department, K. N. Toosi University of Technology, Iran

Abstract— This paper presents improved aperture coupled microstrip antenna with three resonants which its bandwidth has been enhanced due to vary the current distributions. There is a compromise between radiation characteristics and the bandwidth. Radiation patterns indicate the appropriate propagation pattern of antenna is between 1.3 GHz to 2.3 GHz frequency band which clarifies a bandwidth more than 53%. There is bandwidth enhancement up to this limit by utilization of multiple radiating elements. The antenna operates in both linear and circular polarization (1.64 GHz to 1.76 GHz for less than 3 dB Axial Ratio). The simulated results done by two methods, i.e., Finite Element Method (FEM) and Finite Difference Time Domain (FDTD) collaborated by two full-wave softwares ANSYS HFSS and CST MWS have good agreements with the measurement ones.

Planar Dielectric Lens Antennas as Reflector Feeds

Fikret Tokan
Department of Electronics and Communication Engineering
Yıldız Technical University, İstanbul, Turkey

Abstract— In recent years, high dielectric lens antennas are widely used in millimeter-wave applications. The most important reason of that is these antennas have high directivity and high efficiency thanks to the high permittivity materials used as the lens core.

In this application, the focusing problems will be probably faced when planar lens antennas are used as the feeding of the reflector antennas and solution suggestions are deeply investigated.

The planar lateral wave antenna is selected as the reflector feed [1]. The lateral wave antenna is unique for ultra wide band applications (1 : 3) with its planar structure. The geometrical configuration of the antenna is given in Fig. 1(a).

Some problems will be faced when the planar dielectric antenna is used as the reflector feed can be summarized as follows:

- Phase center of the ultra-wide band antennas is not stable and strongly vary with frequency. In such a situation, it is almost impossible to place the feeding antenna to the focus of the reflector in the whole frequency range.
- The far-field radiation pattern of the antenna has different half-power beam width characteristics in E-($\pm 4°$) and H-($\pm 45°$) planes, thus to design a reflector having appropriate f/D value for both planes is the second problem.
- The phase center of the antenna in E-plane locates at the antenna aperture, while the phase center in H-plane is located behind the feeding point as sketched in Fig. 1(b). Accordingly, the antenna is characterized by astigmatism, being the phase center in different points for the E-and H-planes.

Consequently, the reflector antenna should be designed by considering these details. Such a design is completed and the radiation pattern given in Fig. 2 is obtained.

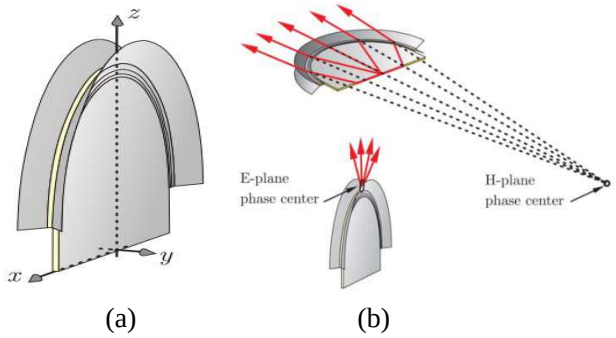

Figure 1: Feeding antenna (a) geometrical structure; (b) phase centers in both planes.

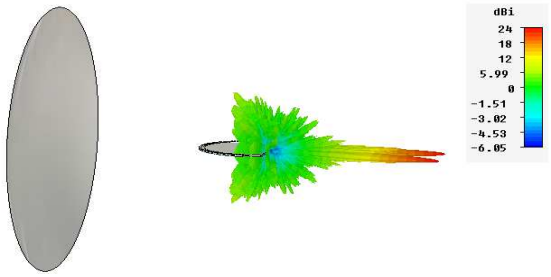

Figure 2: The radiation pattern of a reflector fed by planar dielectric lens antenna.

Abstract— Inkjet antennas that are fabricated by metal printing on paper or similar substrates have recently become popular as they are relatively inexpensive, flexible, and environmentally friendly [1]. In addition to special material printers designed for this purpose [2–4], one can use silver-based toners in standard inkjet printers to manufacture this type of antennas with reduced costs. Different types of inkjet antennas, including dipole antennas, meander antennas [1], bowtie antennas [2], Vivaldi antennas [3], and arrays [4] have been proposed, fabricated, and analyzed in the literature, while less attention has been paid to more detailed antenna structures [5], even though inkjet printers can offer quite high resolutions. In this study, we present fractal antennas with Koch snowflake shapes that are produced by fully exploiting the advantages of the inkjet printing technology.

As depicted in Figure 1, we print antennas on photograph papers using silver toner in a standard commercial printer. Before manufacturing, antennas are designed and simulated using a fast solver based on the multilevel fast multipole algorithm [6]. For a high-quality fabrication, many factors are considered and optimized, including the printer parameters and style, paper and toner types, curing duration and temperature, and post processing. As also shown in Figure 1, measurements are compared with simulation results to confirm the multi-band characteristics of the produced antennas. The constructed and optimized manufacturing process is efficient and inexpensive, enabling fast fabrications of the designed antennas with small details.

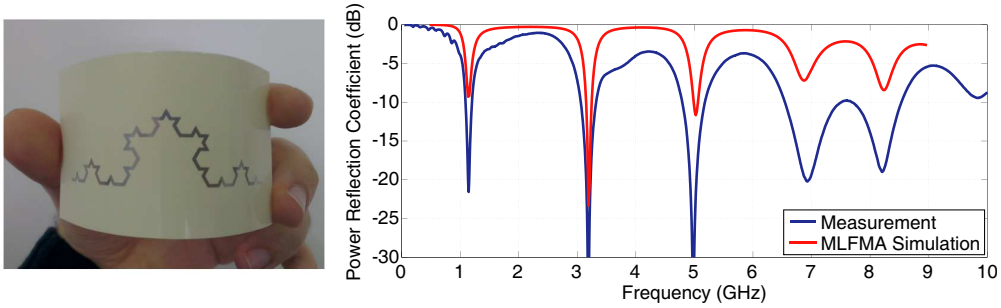

Figure 1: A Koch snowflake antenna produced by inkjet printing on a photograph paper and power reflection coefficient values when the antenna is matched to 50 Ω.

Design of Integrated Triple Band Notched for Ultra-wide Band Microstrip Antenna

Yahya S. H. Khraisat
Electrical and Electronics Department, Al-Balqa' Applied University/Al-Huson University College
P. O. Box 1375, Irbid, Irbed 21110, Jordan

Abstract— This paper demonstrates the design of integrated triple band notched for ultra-wide band Microstrip antenna. We used UWB (ultra-wide band) short range systems which require low power and these are built using inexpensive digital components. Microstrip antenna is used for implementing UWB systems as it shows good broadband characteristics.

We proposed a compact triple band notched CPW (Co-planar Waveguide) fed MSA (Micro strip Antenna) for UWB (Ultra-Wide Band) applications.

This band-notched antenna has rejection characteristics at 3.2 GHz (for Wi-MAX band 3.16 to 3.32 GHz), at 5.5 GHz (for WLAN 2 band-5.3 to 5.72 GHz) and at 7.9 GHz (for ITU band 7.72 GHz to 8.13 GHz).

First a Primitive antenna is taken. This antenna consists of a beveled rectangular radiating patch and a CPW (co-planar waveguide) type feed structure. The essence of this design strategy is that three notching elements are embedded onto the primitive patch antenna to produce band-stop filtering function at those above mentioned frequencies. Notch elements are meticulously selected and embedded onto the antenna.

Pattern Reconfigurable Antenna Using Non-uniform Serpentine Flexure Based RF-MEMS Switches

Ashish Kumar Sharma[1] **and Navneet Gupta**[2]

[1]Department of Electronics & Telecommunication Engineering
Veer Surendra Sai University of Technology Burla, Odisha, India
[2]Department of Electrical & Electronics Engineering
Birla Institute of Technology and Science, Pilani, Rajasthan, India

Abstract— This paper presents the design and analysis of reconfigurable antenna using two circular microstrip patch antenna array with non-uniform RF-MEMS switches in L and S band. It consists of a pair of circular patch antenna with CPW on the same side of Si substrate. This reconfigurable antenna design consists of two RF-MEMS switches, to achieve pattern reconfigurability. Figure below represents the schematic view of reconfigurable antenna with RF-MEMS switch. The total width (W_{tot}) and length (L_{tot}) of this antenna are 94 mm and 67 mm, respectively. A CPW feed line with central conductor width $W = 4$ mm and ground signal gap $S = 0.45$ mm is used, resulting in a characteristic impedance (Z_0) of 50 Ω. Two RF-MEMS switches are used to electrically connect and disconnect the two circular radiating patches. These switches are positioned at 6 mm from the circular patch along x axis.

The analysis of reconfigurable antenna using RF-MEMS switch is done using the simulation performed on Ansys HFSS electromagnetic simulator for the frequency range of 1 to 10 GHz. The reconfigurability of the antenna is analyzed for L to S band (2 to 4 GHz) in terms of return loss and radiation pattern. The proposed antenna shows the pattern reconfigurability at 2.3 GHz and 3.4 GHz.

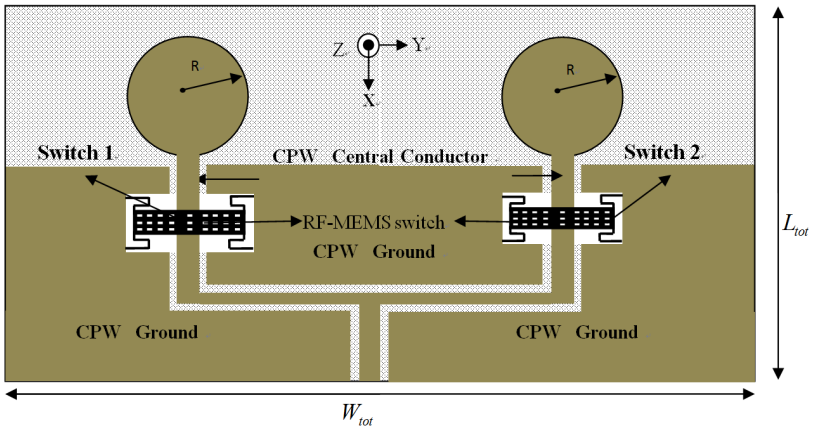

Figure 1: Schematic view of RF-MEMS switch based reconfigurable antenna.

Compact Band Notched UWB Filter Based on Open-load Stub

Xuemei Zheng[1, 2], **Yanyan Wang**[1], **and Tao Jiang**[1]

[1]College of Information and Communications Engineering
Harbin Engineering University, Harbin, China
[2]College of Information Engineering, Northeast Dianli University, Jilin, China

Abstract— In recent years, with the application and development of UWB (Ultra-Wide Band, UWB) technology in the communication field, the research of UWB filters and antennas has been one of the hot issues in the field. At present, the typical structure with the notched band performance is always aimed at the particular narrow-band interference sources, the research of UWB filters and antenna design which can adjust the number and width of notched stop-band is not systematic and deep enough. This paper reports on a new compact UWB band pass filter based on stepped impedance resonator (SIR) and open stub loaded resonator structure. The main advantage of the proposed filter is that the frequency of the notched band can be tuned easily in a wide frequency range. According to the odd/even resonant excitation conditions, the UWB filter characteristics are analyzed. The filter is simulated by 3D EM commercial software HFSS, The resulting indicates that the presented UWB BPF covers the UWB frequency range. The simulation results show that the proposed good UWB characteristics and the notch band can be changed optionally from 5 GHz to 10 GHz. The filters can efficiently enhance the interference immunity from undesired signals with certain application prospects.

Metamaterial Inspired Compact Antenna for UWB and GPS Applications

Sanjji N. Manjunath, **G. S. Karthikeya**, **Bharath Raj**,
K. Ullas, **and C. Vindhya**
Antenna Research Laboratory, Department of Electronics and Communication
B.M.S. Institute of Technology and Management, Bengaluru, India

Abstract— This paper proposes the design of a miniaturized antenna and is investigated for UWB and GPS applications. The main challenges faced in the design of UWB antennas are the miniaturization, improving the efficiency, uniform gain, larger operating range, optimized radiation pattern and polarization to provide wide coverage. It has been a greater challenge to accommodate both the UWB and the GPS band for a compact antenna and an effort is made in this paper such that these drawbacks are overcome.

One such effort to resolve the drawbacks is the implementation of metamaterial structures. Metamaterials are artificially engineered structures providing electromagnetic properties which are not

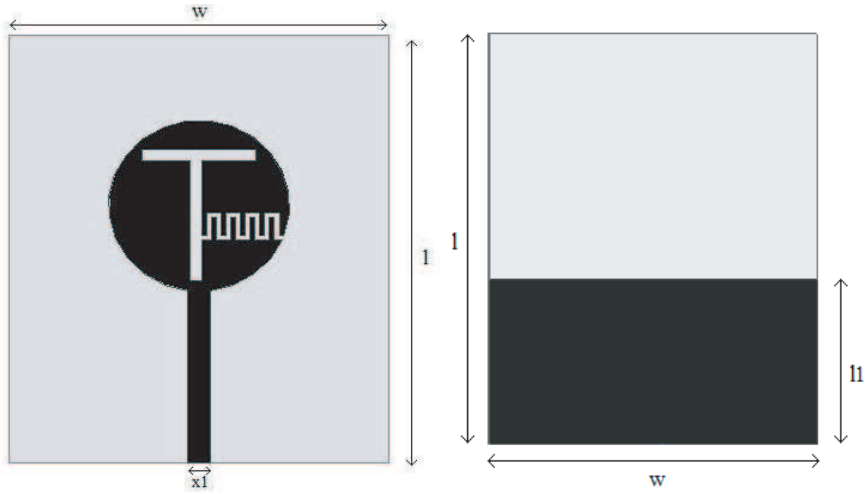

Figure 1: The proposed antenna.

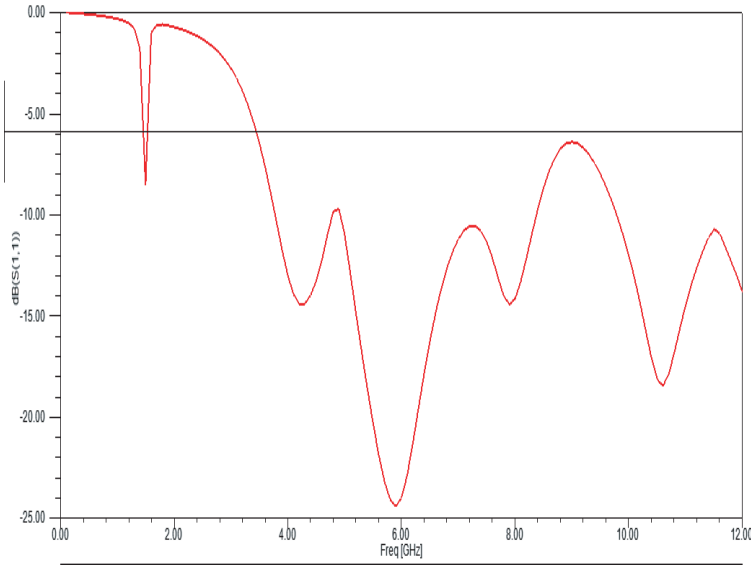

Figure 2: S_{11} graph of the proposed antenna.

encountered in nature. These materials simultaneously have negative permeability and permittivity which was first theoretically predicted by Veselago.

The proposed antenna consists of a planar circular monopole patch, ultrawideband antenna which is incorporated along with the GPS (1.5 GHz) band due to addition of four unit cells of Complimentary Meander-Line (CML) and a T-slot on the patch.

The antenna is designed on a low-cost FR4 substrate having dimensions $37.5 \times 31.5 \times 1.6\,\text{mm}^3$ and is excited by a 50 Ohms microstrip line of width 1.95 mm using line feed technique and fabricated on a 1.6-mm thick FR4 substrate. The relative permittivity and loss tangent of the substrate is 4.4 and 0.02 respectively.

The improvement in the performance and reduction of size in the antenna design is due to the t-slot made on the patch. This T-slot is a metamaterial inspired structure. Meander line cuts which are meta-structures are implemented in the proposed design such that a new resonant band is formed at a particular frequency.

The simulated S_{11} graph has a resonance at 1.5 GHz with a bandwidth of 100 MHz and an ultrawide band with a -10 dB return loss starting from a frequency of 3.7 GHz. It has fractional bandwidth of $> 100\%$ in the UWB spectrum.

It has a uniform gain in the S and C Bands and can be a used for GPS (1.5 GHz), WiMAX (3.45–3.8 GHz), WLAN (4.9–5.8 GHz) and other UWB (3.45–10.6 GHz) applications.

A Low-profile Wideband RFID Tag Antenna Attached to Metallic Surfaces

Y. J. Zhang, **G. C. Wan**, **J. Zhang**, **and M. S. Tong**
Department of Electronic Science and Technology, Tongji University
4800 Cao'an Road, Shanghai 201804, China

Abstract— The radio frequency identification (RFID) system in the ultra high frequency (UHF) band from 860 MHz to 960 MHz has become more popular in recent years and has been widely used in the labels of products and services. Compared to the RFID system working in the frequency band lower than the UHF, the system has several benefits such as the safer security mechanism, larger data storage, and better stability. Furthermore, it can read several tags simultaneously and rapidly, making it become the preferred choice in many applications. There are usually four important aspects that should be considered in the design of tag antenna, i.e., size, impedance matching, radiation pattern, and gain. Also, the RFID tags have to be attached to various materials in practical situations and the cancellation of electric current on the surface of antenna will significantly worsen the performance of tags if they are attached to metallic objects. Aiming to the problem, some solutions have been proposed, such as embedding a slotted via-patch in the middle of the dual layer RFID tag antenna, incorporating an artificial magnetic conductor (AMC) with a printed meander monopole tag antenna, and applying a proximity-coupled feed to a radiating patch.

In this work, we propose a different design for the UHF-RFID tag antenna which will be attached to metallic objects. The meandering technique, capacitive-tip loading structure, and T-matching network are wisely hybridized to improve the impedance matching of the RFID tag antenna. The simulated results show that the design can remarkably enhance the performance of tag antenna in both bandwidth and gain when it is attached to a metal sheet. We will show the details of design and testing results in the presentation.

A Long Range UHF RFID Tag for Metallic Objects

Manoel Vitório Barbin[1], **Michel Daoud Yacoub**[1], **and Silvio Ernesto Barbin**[2]

[1]Communications Department, Faculty of Electrical and Computing Engineering
University of Campinas, Brazil
[2]Telecommunication and Control Engineering Department, Polytechnic School of Engineering
University of São Paulo, Brazil

Abstract— The performance of passive UHF RFID tags, commonly available in the market, is significantly degraded when they are placed near a conducting surface. A possible solution to overcome this problem is to design tags based on PIFA (Planar Inverted F Antenna) the performance of which is less sensitive to the presence of objects in its surroundings. This ability is mainly due to the existence of a ground plane inherent to its structure. In this paper, a PIFA is utilized in the design of a passive tag that can be used to identify metallic objects with medium to large dimensions. A new type of antenna feeder is presented with a slot in the radiating element where the RFID IC is attached. The maximum range of utilization, covering all licensed RFID UHF bands (860 to 960 MHz), is in excess of 8 m, according to simulations using a MoM based software, verified by practical measurements. Further results from simulation and measurements show that the tag can also be used attached to other materials with good performance.
