THE ELECTROMAGNETICS ACADEMY

The Progress in Electromagnetics Research Symposium (PIERS) is sponsored by The Electromagnetics Academy.

The Electromagnetics Academy is devoted to academic excellence and the advancement of research and relevant applications of the electromagnetic theory and to promoting educational objectives of the electromagnetics profession. PIERS provides an international forum for reporting progress and advances in the modern development of electromagnetic theory and its new and exciting applications.

Founded by the late Professor Jin Au Kong (1942–2008) of MIT in 1989, The Electromagnetics Academy is a non-profit organization registered in USA.

JOURNAL:
PROGRESS IN ELECTROMAGNETICS RESEARCH

Progress In Electromagnetics Research (PIER) publishes peer-reviewed original and comprehensive articles on all aspects of electromagnetic theory and applications. This is an open access, on-line journal PIER (E-ISSN 1559-8985). It has been first published as a monograph series on Electromagnetic Waves (ISSN 1070-4698) in 1989. It is freely available to all readers via the Internet.

PIER is a non-profit organization.

Abstract— Plasmonic metasurfaces combine strong light-matter-interaction with high design flexibility and functionality. Here, we demonstrate the potential of ultrathin metasurfaces for use with high efficiency, high resolution holography and beam shaping. The concept is based on a topological phase change of light passing through the metasurfaces. In such a way broadband phase masks with efficiencies surpassing 80% in the visible range can be obtained.

One of the great benefits of metamaterials arises from the flexibility in engineering their optical responses to achieve control over the propagation of light to an unprecedented level. Plasmonic metasurfaces that consist only of a monolayer of planar metallic structures, have shown great promise for leveraging full control of light and low fabrication cost as they do not require complicated three-dimensional nano-fabrication techniques. One of the interesting features of metasurfaces is the capability of generating abrupt interfacial phase changes across the interface, and therefore provide a unique way of controlling the wave front locally at the subwavelength scale. Shaping the spatial phase and intensity distribution is very important for all applications that require a propagation of light, like focusing, beam shaping, and 3D image reconstruction. Recently metamaterials were used to demonstrate wave plates for generating vortex beams, ultrathin metalenses and 2D holography. However, none of these techniques has achieved a more complex functionality like reconfigurable focusing or 3D image reconstruction in the visible range. Furthermore, the achieved efficiencies at visible wavelengths were rather low, preventing the usability in many applications.

Here we will demonstrate that geometric phase metasurfaces consisting of plasmonic nanorods with spatially varying orientations are capable of generating continuous phase profiles in the subwavelength scale and therefore facilitate new perspectives in designing complicated phase-only Computer Generated Holograms for 3D image reconstruction. The design that is presented exhibits high quality holographic images with very high fidelity and a broad bandwidth of operation between 630 nm and 1050 nm. Importantly, the overall efficiency, defined as the ratio of light intensity forming the holographic image to that of the incident light, reaches 80%, greatly surpassing previously demonstrated metasurface based holograms. The metasurface holograms with their accurate phase modulation, high efficiency, and simple fabrication procedure compared to conventional multi-step phase holograms, are highly promising for various practical applications ranging from laser holographic projection to data storage and beam shaping.

Nanoantennas from the Visible to the Mid-infrared: Materials Considerations and Applications

Stefan A. Maier
Imperial College London, London, SW7 2AZ, UK

Abstract— The light harvesting properties of nanoantennas composed of different materials such as metals, semiconductors, and polar dielectrics are evaluated. A particular focus lies on applications in surface enhanced spectroscopies and optoelectronics, for frequencies spanning from the visible to the mid-infrared.

Optical nanoantennas based on metallic nanostructures enable the controlled focusing of light from the far field to highly confined volumes below the diffraction limit, and have spurred a renewed interest in the field of plasmonics [1]. Here, we present an overview over plasmonic antenna designs operating in the visible part of the spectrum, and investigate how a change in materials to hybrid structures [2], semiconductors [3], polar dielectrics [4], and anisotropic van der Waals crystals [5] enables us to overcome the disadvantages of plasmonics for certain application areas, mainly related to the associated optical losses.

Firstly, hybrid nanoantennas composed of both metallic and in this case transition metal oxides are shown to be a viable and highly efficient platform for higher harmonic generation [2]. Specifically, dipolar Au antennas with a 20 nm ITO disc in the feedback exhibit an enhancement of third harmonic generation by about six orders of magnitude.

Dielectric nanoantennas composed out of semiconductors instead of metals also enable controlled near-field localization, without heating losses and the possibility to also manipulate the magnetic field distribution in a controlled manner. We evaluate this behaviour in terms of applications in surface enhanced spectroscopies [3], and show that GaP dimers are a promising platform for low-loss, zero-heat surface enhanced Raman spectroscopy in the visible part of the spectrum.

Finally, we turn our attention to the mid-infrared part of the electromagnetic spectrum, where polar dielectrics enable nanofocusing due to the excitation of surface phonon polaritons. Specifically, nano forests composed out silicon carbide nanopillars show Purcell factors up to 107 due to the combination of low-loss phonon modes and ultra-small mode volumes. Going one step further, the combination of polar behaviour with anisotropy due to van der Waals interactions in adjacent crystal planes allows the occurrence of hyperbolicity in natural materials such as hBN [5]. This enables truly three-dimensional nanophotonic confinement (Figure), with a high promise for applications in the mid-infrared.

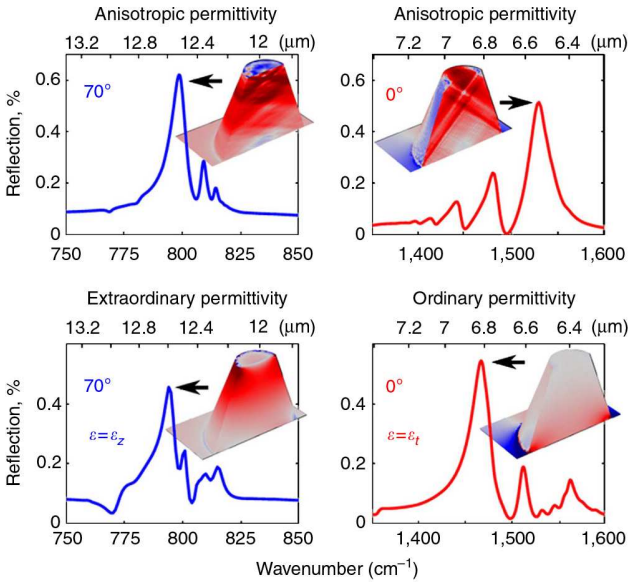

Figure 1: Comparison of field distributions in hyperbolic (top row) and isotropic conical nanoresonators [5].

Gap-plasmon Based Amplitude and Phase-gradient Metasurfaces

Sergey I. Bozhevolnyi
Department of Technology and Innovation
University of Southern Denmark, DK-5230 Odense, Denmark

Abstract— Plasmonic metasurfaces, i.e., nm-thin surface metal nanostructures with subwavelength-sized lattice units, have recently attracted considerable attention due to their abilities to efficiently control both phase and amplitude of transmitted and reflected radiation. We have recently shown that metal nanostructures, in which the top layer consists of a periodic array of nanobricks, thus supporting gap surface plasmon (GSP) resonances, offer improved control of the phase of the reflected light. At the same time, by choosing a subwavelength periodicity and weak coupling between the nanobricks and the metal underlay one can adjust the level of absorption, which is typically strong and can also be advantageously used for efficient and broadband suppression of light reflection for solar energy harvesting applications. The understanding of light reflection by arrays of GSP resonators led us to a number of potentially application-relevant developments, including the design of highly efficient and background-free (i.e., no diffraction and no scattering into other polarizations) plasmonic metasurfaces providing strong phase gradients in the reflected optical fields at the same polarization as that of the incident one. Moreover, we demonstrated also phase-gradient metasurfaces that diffract different polarizations into different directions that can be adjusted independently and exploited this approach for realization of efficient polarization-controlled coupling to surface plasmon polariton modes. Currently, following up on the recent theoretical proposal for mathematics with gradient metasurfaces [1], we develop a design strategy for independent control of phase and amplitude of the reflected radiation that is applied to realize Fourier optics based analog computing, including differentiation and integration of optical fields. Further results obtained in this direction will be presented at the conference.

Multiple Wavefront Shaping by Spinoptical Gradient Metasurface

Erez Hasman
Micro and Nanooptics Laboratory, Faculty of Mechanical Engineering
Russell Berrie Nanotechnology Institute, Technion-Israel Institute of Technology, Haifa 32000, Israel

Abstract— Photonic gradient metasurfaces are ultrathin electromagnetic wave-molding metamaterials that provide a route for realizing flat optics. Recently, we reported on a novel class of metasurfaces — spinoptical metamaterials — which gives rise to a spin-controlled dispersion due to the optical Rashba effect. The optical spin as an additional degree of freedom offers controlled manipulation of spontaneous emission, absorption, scattering, and surface-wave excitation. Spin-symmetry breaking in nanoscale structures caused by spin-orbit interaction, leading to a new branch in optics — *spinoptics* is presented. The spin-based effects offer an unprecedented ability to control light and its polarization state in nanometer-scale optical devices, thereby facilitating a variety of applications related to nano-photonics. However, the up-to-date metasurface design, manifested by imprinting the required phase profile for a single, on-demand light manipulation functionality, is not compatible with the desired goal of multifunctional flat optics. Here, we report on a generic concept to control multifunctional optics by disordered (random) gradient metasurfaces with a custom-tailored geometric phase. This approach combines the peculiar ability of random patterns to support extraordinary information capacity, and the polarization helicity control in the geometric phase mechanism, simply implemented in a two-dimensional structured matter by imprinting optical antenna patterns. By manipulating the local orientations of the nanoantennas, we generate multiple wavefronts with different functionalities via mixed random antenna groups, where each group controls a different phase function. Disordered gradient metasurfaces broaden the applicability of flat optics as they offer all-optical manipulation by multitask wavefront shaping via a single ultrathin nanoscale photonic device.

Wavevector Selective Metasurfaces and Tunnel Vision Filters

V. A. Fedotov[1], **J. Wallauer**[2], **M. Walther**[2], **M. Perino**[1, 3], **N. Papasimakis**[1], **and N. I. Zheludev**[1, 4]

[4]Centre for Disruptive Photonic Technologies, Nanyang Technological University, 637371, Singapore

Abstract— The recent demonstration of anomalous reflection and refraction of light in optically thin two-dimensional arrays of sub-wavelength metallic scatterers (planar metamaterials or metasurfaces) has opened a new exciting chapter in photonics. Planar metamaterials can be readily fabricated using existing planar technologies and offer unprecedented flexibility in the design and control of light propagation, replacing bulk optical components and exhibiting exotic effects of asymmetric transmission and optical activity without chirality.

Here we demonstrate for the first time both computationally and experimentally that a coherent metasurface can act as a wavevector selective surface: It discriminates incident waves by the wavevector and is transparent in a very narrow range of light propagation directions thus operating as a tunnel vision filter. The filtering results in an arbitrary-shaped wavefront appearing planar as it traverses the plane of the metasurface in the absence of any active/passive spatial phase modulation or adaptive feedback.

We demonstrated the effect of wavevector filtering computationally, by simulating the propagation of spherical wavefronts through a finite-sized coherent metamaterial. It was modelled by a planar array of 14×14 identical sub-wavelength metallic resonators shaped as an asymmetrically split ring (ASR). Such a metasurface was designed to operate with no diffraction in the lower part of the terahertz spectrum, at frequencies below 0.3 THz. The spherical waves were produced by an electromagnetic point source placed close to the metasurface, at the distance equal to just one period of the ASR-array. Our findings have been fully confirmed experimentally using a metamaterial sample fabricated as the exact copy of the modelled metasurface. The transmitted wavefronts were mapped using a state-of-the-art THz-field imaging technique, which enabled accurate spatial mapping of electric-field component of the transmitted waves with the spatial resolution of 160 μm. The obtained wavefront patterns, as well as their spatial-frequency spectra, showed a very good agreement with the results of our simulations demonstrating robustness of the predicted wavevector filtering effect.

Novel Topological States in Photonics

Marin Soljacic
Department of Physics, Massachusetts Institute of Technology
Cambridge, Massachusetts 02139, USA

Abstract— Topologically non-trivial states have been raising a substantial interest in the electronics community because of their novel and unique properties. Similarly, topological states in photonics display an equally diverse range of novel and surprising phenomena. Some of our recent results in this area will be presented.

Nonlocality in Discrete Metamaterials

M. A. Gorlach[1, 2] **and P. A. Belov**[1]

[1]ITMO University, Russia
[2]Belarusian State University, Belarus

Abstract— We discuss spatial dispersion effects in three-dimensional discrete metamaterials. In the present work, we consider two examples of discrete metamaterials whose behavior can not be adequately described by means of the effective medium model and where the nonlocality is important. These examples are (i) the discrete structure consisting of the uniaxial dipoles operating in the vicinity of transition from elliptic to the hyperbolic dispersion regime and (ii) the structure built from isotropic particles where anisotropy arises due to the spatial dispersion effects.

Strong spatial dispersion effects do not occur in natural materials. However, there exists a class of metamaterials where effects of spatial dispersion play an extremely important role. Therefore, it is of interest to find out what new physical effects may arise due to the nonlocality. It turns out that the use of the dyadic Green's function formalism and the discrete dipole approximation in the investigation of periodic metamaterials allows one to describe spatial dispersion effects in a rigorous and self-consistent way. We consider two examples of the discrete structures operation that can not be described properly by means of the effective medium model. The transition between elliptic and hyperbolic dispersion regime in the structure consisting of the uniaxial electric scatterers occurs when the effective permittivity calculated according to the Clausius-Mossotti formula approaches either zero or infinity. Following our recent work [1], we discuss the existence of the regime which is the transitional from elliptic to the hyperbolic dispersion (Fig. 1) and investigate the properties of the mixed dispersion regime in more detail. Moreover, possible experimental verification of the mixed dispersion regime existence is proposed.

We also discuss the anisotropy in the cubic lattice of isotropic particles that arises due to the second-order spatial dispersion effects. This feature can be easily detected plotting the system of the isofrequency contours. In the conventional isotropic medium two eigenmodes with transverse polarization correspond to the coinciding isofrequency contours. In the case of the discrete structure this degeneracy is removed and there exists a considerable difference between two transverse eigenmodes in the certain frequency range. Moreover, a longitudinal mode arises.

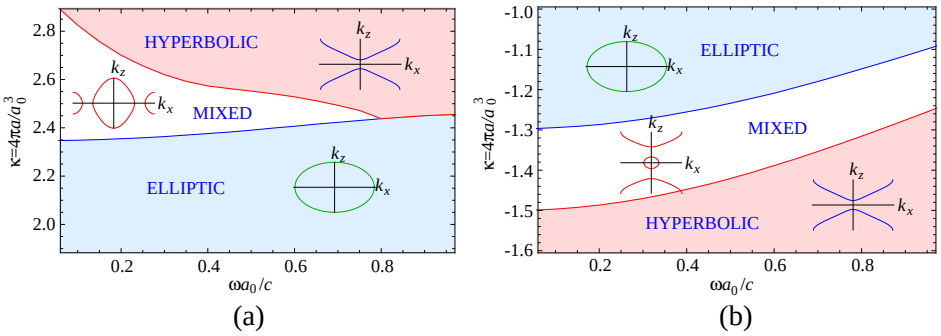

Figure 1: Different dispersion regimes in the discrete dipole structure composed of the uniaxial electric scatterers shown on "frequency-polarizability" diagram. The isofrequency contours typical for the given regime are sketched. (a) The vicinity of high ε mixed regime. (b) The vicinity of low ε mixed regime.

Pure Electric and Magnetic Hotspots by Dielectric Cylindrical Dimers

Ali Mirzaei and Andrey Miroshnichenko
Nonlinear Physics Centre, Research School of Physics and Engineering
Australian National University, 59 Mills road, Acton, ACT 2601, Australia

Abstract— Clusters of nanoparticles have been actively studied for controlling of light [1]. Near-field enhancement of electromagnetic fields by dimers with both spherical and cylindrical geometries have also been reported [2]. These studies are mostly concentrated on plasmonic materials to achieve high field-enhancement, however plasmonic structures are associated with strong losses in metallic components, even in nonresonance regimes. In this work, we analyze dimers made of a pair of dielectric nanowires in visible wavelength range and compare them with those for similar metallic dimer nanowires, using experimental data to describe the materials. We demonstrate the enhancement of both electric and magnetic near-fields, and show that it is possible to achieve hotspots by dielectric nanowires comparable with plasmonic structures in TE polarization (magnetic field parallel to the axis of nanowires). We also show the possibility to achieving hotspots in TM polarization with dielectrics, which is not possible by using plasmonic nanowires. We demonstrate that the hotspots are not exactly in the middle of the dimers' gap. These displacements for electric and magnetic hotspots are opposite in plasmonic and dielectric dimers and lead to have both pure magnetic and pure electric hot spots close together simultaneously with dielectric nanowires [3]. Figure 1 summarizes our major results and the formation of hotspots in two polarizations.

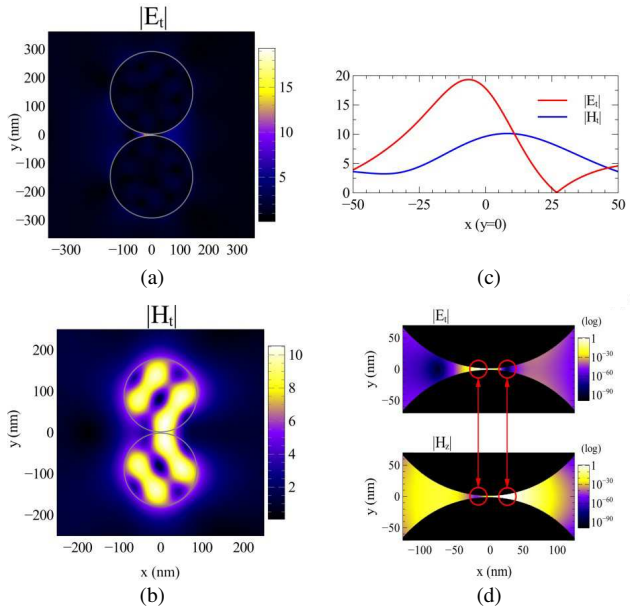

Figure 1: Dimers made by silicon nanowires, optimized for (a) electric hotspot in TE polarization and (b) magnetic hotspot in TM polarization in $\lambda = 614\,\text{nm}$, using a genetic alghorithm. (c) and (d) demonstrate that the hotspots are not exactly in the centre of dimer's gap, causing two pure magnetic and electric hotspots (related to structure in Fig. 1(a)).

Controlled Photonic Surface Modes in 'Cholesteric Liquid Crystal — Phase Plate — Metal' Structure

M. V. Pyatnov[1], **S. Ya. Vetrov**[1, 2], **and I. V. Timofeev**[1, 2]

[1]Siberian Federal University, Krasnoyarsk 660074, Russia
[2]Kirensky Institute of Physics, Siberian Branch of the Russian Academy of Sciences
Krasnoyarsk 660036, Russia

Abstract— We demonstrated the existence of surface electromagnetic states localized in the structure of the cholesteric liquid crystal (CLC) — the phase plate — the layer of silver [1]. These states are similar to optical Tamm states (OTC). Spectral properties of such a system can be efficiently controlled due to high sensitivity of CLC structural parameters to external factors. Unlike the case with OTS observed at a photonic crystal (PC) — metal interface, it is doubtful to obtain a surface state at a CLC — metal interface under normal incidence of light. The difficulty is that Bragg reflection exists not for every arbitrary polarization. For light localization between CLC and metal to occur, we need to change the phase of the wave. To this end, between CLC and metal we introduce an anisotropic quarter-wave plate cut parallel to the optical axis and shifting the wave phase by $\pi/2$. Cholesteric molecules at the CLC — phase plate interface align along the optical axis. Fig. 1 shows individual transmission spectra of the CLC, silver film and the structure.

Light of any polarization will be localized near metal with the field intensity maximizing at the phase plate — metal layer interface. However, different degrees of ellipticity of transmitted waves and their polarization properties result in different transmission coefficients for each polarization. A possibility to control the passband position by varying the thickness of the phase plate or the CLC pitch by external fields has been demonstrated.

It was established that the transmission spectra of the propagation of light in the forward and inverse directions are different (Fig. 2). This property is inherent only in chiral environments, which include the CLC. On the basis we proposed design of the polarization optical diode based on surface photon modes. Note also that creating direct contact of the CLC with the metal is not possible. This requires the use of orientant which aligns layers of anisotropic material. Therefore orientant can simultaneously be a quarter phase plate, picking up the thickness of which it is possible to implement a localized state.

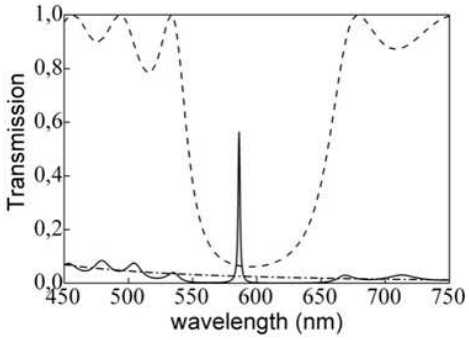

Figure 1: Transmission versus wavelength with light incidence normal to CLC (dashed line), to the silver film (dash-dotted line) and to the 'CLC — phase plate — metal' structure (solid line).

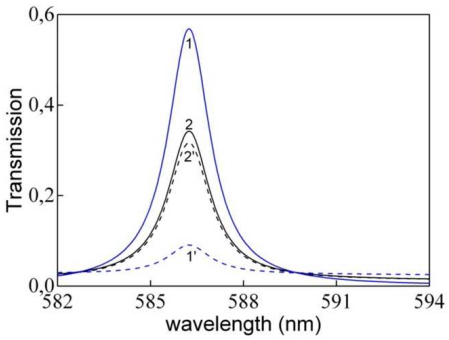

Figure 2: The transmission spectrum of the structure: 1 and 1′ for the right and left polarizations for light incident on the CLC; 2 and 2′, for the left and right polarizations of light incident on the metal.

Abstract— The current technological advances on the nanoscale have allowed for remarkable progress in the fabrication of ever smaller lasers. High promise is expected from these unusual devices, whose potential application range from on-chip integration, fast and compact data handling, inclusion on non-invasive probes, etc.. However, satisfactory modeling of the optical properties of these devices has so far proven to be quite elusive, in particular concerning their threshold and optical coherence.

Modeling approaches range from the standard rate equations, proven to present intrinsic difficulties in the characterization of threshold [1], to quantum mechanical models [2], to innovative approaches based on quantum-optical models showing non-classical statistics for few emitters [3]. Recently, we have introduced a new way of modeling lasers using a Stochastic Simulator [4] which operates on the (semiclassical) description of the physical processes which take place when lasing occurs.

We apply our model to explore the more elusive optical features of nanolasers to characterize their threshold, to infer the transition towards coherence and to predict their dynamics in the threshold region, as a function of the cavity size (quantified by the β-parameter — spontaneous emission fraction coupled into the lasing mode).

SC2: THz Metamaterials: Fundamentals and Applications

Electromagnetic Metamaterials for Terahertz Devices

W. J. Padilla
Department of Electrical and Computer Engineering, Duke University, Durham, NC, USA

Abstract— Electromagnetic metamaterials provide unprecedented control over light matter interactions and are viable candidates for realization of devices in the terahertz frequency regime. The ability to dynamically control novel responses exhibited by electromagnetic metamaterials is a key enabling feature and further bolsters this quest. We overview our work in terahertz metamaterials and present examples of metamaterial-based systems.

The interaction of electromagnetic waves with natural materials forms the basis of many modern opto-electronic devices. At microwave and lower frequencies electrons form the basis for a myriad of devices, while at optical and infrared wavelengths, photons are the key fundamental particle utilized. However, the effectiveness of both the electron and photon is not distributed equally across the electromagnetic spectrum and both realize a diminished utility reaching a collective minimum at terahertz frequencies. Although significant effort has been exerted by scientists and engineers in search of suitable terahertz materials, all terahertz devices pale in comparison to the performance of microwave or optical components.

We present electrically controlled metamaterial modulators using both liquid crystals and semiconducting epi-layers. Our metamaterial modulators are pixelated and function as real-time tunable, spectrally sensitive spatial light modulators. We implement a terahertz optical imaging system with our metamaterial spatial light modulator and demonstrate single pixel imaging. Utilization of a technique from communication theory — called binary phase shift keying — enables complex valued masks to be displayed on our metamaterial spatial light modulator. Images are encoded with both the coefficients of the Hadamard matrix and the closely related S-matrix and both are decoded with their respective inverse matrices. The demonstrated single pixel imaging systems verify the usefulness of metamaterials and establishes a new path forward for the terahertz regime.

Electrically Driven Terahertz Metamaterial Diffraction Modulators

Abstract— Teraherz (THz) waves have played an important role in both fundamental research and practical applications; however, arbitrary control of THz waves remains a significant challenge. In order to take full advantage of THz waves, there is an urgent need in developing functional THz materials to construct various kinds of THz devices and components. Metamaterials have emerged during the past few years that provide new opportunities due to the realization of tailored interactions with THz waves, which are often unavailable or very difficult to obtain from natural materials. Combining the resonant response originating from the planar metamaterial structures and tunable refractive index or conductivity of integrated functional materials, hybrid metamaterials have been developed during the past few years where the metamaterial resonances can be switched or tunable through the application of photoexcitation, temperature change, and/or voltage bias [1, 2]. Of particular interest for THz modulation are planar metamaterials that can be electrically switched [3, 4], which provides a mechanism for high-speed modulation of THz radiation relevant to practical applications, a result that is otherwise difficult to achieve. Furthermore, the metamaterial can be pixelated to enable independent control of individual pixels, forming the so-called THz spatial light modulator [5].

So far state-of-the-art demonstrations still exhibit a relatively low on/off ratio less than 10 dB [4], which may limit their applicability. In all previous works the THz modulation is attributed to the change of the direct transmission beam and, therefore, the modulation depth is limited by the transmission values of the device's ON and OFF states. In this work we present the design and experimental demonstration of an electrically switchable metamaterial diffraction grating for background-free THz modulation. We take advantage of metamaterial pixilation to form columns of electrically switchable metamaterials that are independent each other. The active metamaterial grating is created by applying the voltage bias to alternating columns, resulting in a contrast of transmission property and diffraction of the incident THz beam. The diffraction behavior disappears without the voltage bias or when a uniform voltage bias is applied to all of these columns. As such, we have created a background-free metamaterial diffraction THz modulator [6]. Experimentally, we observe that the device can function as a relatively high speed, wide-bandwidth, high-contrast THz off-axis diffraction modulator, with more than 20 dB of dynamic range.

Abstract— Phase modulation of electromagnetic (EM) waves plays a central role in photonics research. The ability to control the local EM phase underpins important applications such as holographic imaging, polarization manipulations, and wave-front controls [1–3]. Such phase modulation was conventionally achieved via modulating the refractive index of bulk materials. The dimension of such systems is typically on the order of wavelength, and therefore too bulky for optical integrations. Metasurfaces, ultra-thin MTMs composed of planar sub-wavelength units, were utilized to achieve phase changes covering full range of 360 degrees. However, the metasurfaces-based phase modulators currently available are mostly passive elements which cannot be tuned externally.

Here we experimentally demonstrate full-range gate-tunable THz phase modulation, realized by an ultra-thin meta-system integrating graphene and a specially designed metasurface [4]. We show that a gate bias applied on graphene through ion liquid tunes its optical conductivity, turns the coupled system from an under-damped resonator to an over-damped one, and induces drastic modulation on the phase of the reflected wave. This is in stark contrast to the two-port resonator (with both reflection and transmission channels) commonly used in previous studies, where only a small phase modulation was possible. Our findings represent a significant advance over previous attempts on photonic devices with tunable responses, and our method points to new design strategies for future active phase modulators.

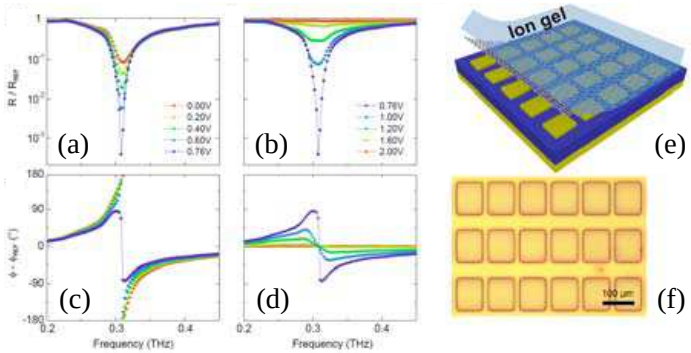

Figure 1: Experimentally measured reflectance and phase modulation and designed meta-system. (a)–(d) Dramatic phase modulation realized upon increasing the carrier concentration through gating, accompanied with a drastic change on reflection amplitude. (e) Schematics of our metasystem, a gate-controlled graphene on a reflective metasurface. (f) Macroscopic photo of our sample.

Abstract— The versatile nature of semiconductors with a permittivity that can be controlled by the amount of free carriers, makes them excellent candidates for active metamaterials and metasurfaces. Structures made out of semiconductors can give rise to the localized resonances at THz frequencies that define the behavior of the metamaterial. The precise behavior of these structures depends on their geometry and permittivity; parameters that can be actively tuned [1, 2]. Subwavelength local field enhancements are the most relevant characteristic of localized resonances. These enhancements have triggered the interest for resonant metallic structures in sensing and spectroscopic applications.

In this contribution, we demonstrate the THz near-field enhancement in the proximity of silicon and gold resonant structures. These near fields are measured in a broadband THz time-domain near-field microscope with micro-structured photo-conductive antennas that enable the independent measurement of the two in-plane field components. The measurements clearly show the resonant response of the structures and the concomitant subwavelength field enhancement. In order to achieve a full optical control of local THz resonances, we demonstrate the feasibility of the photo-generation of resonant structures on semiconductors by shaping an optical pump beam incident on a flat GaAs layer [3]. This beam shaping has been realized with a spatial light modulator that structures the optical beam with the form of the structures. The incidence of the shaped beam on the semiconductor locally induces a metallic behaviour on the illuminated areas, with photo-excited free charges that are resonantly driven by the THz electric field. This approach provides an unprecedented flexibility in designing the far-field properties of the THz field, such as extinction and beaming [4], as well as the near field at the surface of the semiconductor. The photo-generation of metallic structures in semiconductors can be also extended to create THz waveguides [5].

Abstract— A perfect absorber, which fully absorbs the incoming electromagnetic (EM) wave and transfers it into other forms of energy, is intensively studied for its wide applications in energy harvesting, military defense, EM wave modulation and communications, etc.. The metamaterial, an artificial material consisting of subwavelength meta-atoms, has been designed for perfect absorption by utilizing the impedance matched meta-atoms. Although successfully demonstrated, they are usually limited in a narrow working bandwidth. The rigid structure of the design also hampersits real life applications that require all-directional absorption.

In this talk, a soft metamaterial is proposed to realize the perfect absorption in microwave regime, which can be easily deformed to face to different directions. The polymer polydimethylsiloxane (PDMS) is used as the soft substrate, which is filled with the most common material in nature, i.e., water. Due to the extremely high dielectric constant and high absorption by its polar molecules in microwave regime, water is a perfect candidate for perfect absorption. By properly patterning the PDMS channels, which are filled with water, the microwave across a wide band is well confined and fully absorbed. The perfect absorption is further manipulated in two aspects: first, the absorption band is shifted by deforming the water pattern under different inlet water pressures applied in the PDMS channel. Second, the absorption coefficient of the soft metamaterial can be effectively controlled by mixing water with other organic solvent, such as ethanol in this work. By controlling the volume ratio of the water and ethanol, the tunability from zero absorption to full absorption is realized. With the wideband and tunable capability, the proposed perfect metamaterial absorber gives a promising applications in energy harvesting, stealth system and microwave communications.

Studies of Metamaterials with Near-field Scanning Terahertz Microscopy

Abstract— Terahertz Science and Technology has been one of the promising and active research fields, especially in military, state security and communications. From the view of current situations and tendency of terahertz science and technology, there are three major significant aspects: fundamental research, advanced technology and terahertz market. It is expected that a rapid progress will be achieved in information science, physics, astronomy, medical science, biology, and so on. The key components for terahertz include the transmitter, receiver and devices. Here we will present the recent achievements on the terahertz devices based on metamaterials, especially by using the near field technology. Although over the last decade, optical near-field technology has become an intense area of research, in the terahertz regime, this is not to be outdone. In this talk, we will give a brief discussion on the terahertz near field measurement of metamaterials based on a metal tip-terahertz system [1–3].

Heterogeneous 3D Construction of Metamaterials and Metadevices by Modular Transfer Printing

Bumki Min
Department of Mechanical Engineering, KAIST
291 Daehak-ro, Yuseong-gu, Daejeon 305-751, Republic of Korea

Abstract— Metamaterials make possible exotic control of the flow of electromagnetic waves that is ultimately impossible to achieve with naturally occurring materials. Over the past decade, the fabrication of metadevices synergistically benefitting from enhanced light-matter interaction through combining metamaterials and active functional natural materials has shown immense potential to develop highly efficient photonic devices. However, complex and heterogeneous architectures enabling diverse functionalities of metamaterials and metadevices have been challenging to realize due to the limited manufacturing capabilities of conventional fabrication methods. In this work, we report three-dimensional (3D) modular assembly based on transfer printing to construct metamaterials and metadevices with complex structural architectures for achieving on-demand photonic properties. Transfer printing-based 3D assembly provides access to the integration of dissimilar, active materials regardless of roughness and surface chemistry which is quite attractive to employ for the fabrication of metadevices exhibiting unprecedented device fidelity. The minimum repetitive process steps and rapid construction are the additional advantages of the transfer printing-based 3D modular assembly. The method presented here suggests a fascinating route to generate 2D/3D metamaterials and metadevices with heterogeneous material combination, complex device architectures, and effective functionalities for future practical use for advanced photonic applications.

Active Modulation of Terahertz Wavefront

Y. Zhang[1], **X. K. Wang**[1], **and Z. W. Xie**[2]

Abstract— Terahertz (THz) radiation has attracted a lot of attentions due to its fascinating potential applications. Wavefront modulation of the THz radiation will benefit the applications of THz imaging and communication. We propose a novel approach to actively modulate the wavefront of the THz radiation based on the THz hologram formed with photon-generated carriers. The diffracted THz beam will come into special amplitude and phase distribution. Experiment results demonstrate the validity of this new method.

Introduction: Terahertz (THz) imaging is one of most important applications of the THz radiation. Modulation of THz wavefront will profit the applications of THz imaging and communication. Active modulation of wavefront can help us to reduce the size of the focal point, to improve the resolution, and to achieve compressed imaging, which will greatly enhance the application of the THz technology. We adopt the photon-generated carriers to form THz holograms on the surface of a semiconductor surface, which can diffract the THz to generate the desired amplitude and phase distribution.

Basic Idea: Under the illumination of a strong light, the semiconductor will generate free carriers on its surface. These free carriers can effectively block the transmission of the THz radiation. The diffusion range of the photon-generated carriers is just few micrometers, which is much less than the wavelength of the THz radiation. Therefore, we can project a computer generated hologram (CGH) pattern on the surface of the semiconductor to generate a photo-generated carriers based THz hologram. The diffracted beam will from the special amplitude and phase distribution.

In the experiment, 100 femtosecond pulses with a 800 nm central wavelength from a Ti: sapphire regenerator amplifier are split into three beams. The control beam is utilized to construct holograms on a 500 mm thick silicon wafer, the pump beam to generate the THz radiation using a ZnTe crystal and the probe beam to detect the two-dimensional THz information. A spatial light modulator (Holoeye LC2002, resolution 800×600, pixel size $32\,\mu$m) is inserted into the control beam to excite the carrier distribution of the designed THz CGHs. In order to achieve better results, an off-line holography configuration is adopted. The THz radiation is reflected onto the silicon wafer with an incident angle of 37 degrees. Three letters C, N and U are required to be shown on the plane which is 2 cm away from the silicon wafer. The size of each letter is about $4\,\text{mm} \times 6\,\text{mm}$. The calculated CGHs are displayed on the optical SLM and projected onto the surface of the silicon wafer, respectively. The complex amplitude distribution of the THz beam on the observation plane is captured with the THz focal plane imaging system. The three letters C, N and U are clearly reconstructed. The experimental results meet the theoretical expectations quite well.

This technology can also be combined with a sub-wavelength grating to generate an arbitrary THz vector beam. The circularly polarized THz beam illuminates to a sub-wavelength ring metal grating fabricated on the high-resistance silicon substrate. Meanwhile, the projected visible light generates a photo-generated carrier THz vortex hologram on the surface of the silicon wafer. The first-order diffraction of the THz beam will form a radially polarized beam. A good match between the experiment and simulation results has been found. Furthermore, this method can work well for a broad THz band.

Conclusions: In conclusion, a scheme for generating arbitrary THz beams is exhibited. A sub-wavelength metal grating is utilized to adjust the polarization of the THz radiation. The amplitude and phase distribution of the THz beam are dynamically regulated by the THz CGH pattern formed with the photo-generated carriers. The experimental results, which correspond to the theoretical expectations well, demonstrated the effectiveness and validity of the proposed method. The proposed method may benefit to the THz sensing, THz imaging, and THz communication.

Abstract— Metamaterials as the design concept and umbrella name have demonstrated a broad range of useful properties in different ranges of frequencies. The main advantage of the metamaterial-based devices is the possibility to broaden both passive and active photonic component functionalities. While in the visible, near infrared or microwave regimes these issues in principle have strong alternatives via a conventional optics or electromagnetic approaches, at terahertz (THz) frequencies metamaterials are often considered as being the unique solution for the encountered problems. Several approaches involving metamaterials-based THz components have been proposed and show good potential for applications [1, 2]. Especially fruitful appears to be two-dimensional metamaterials or metasurfaces due to fabrication simplifications and practically the same as bulk metamaterials functionalities.

In the talk we will focus on employment of THz metasurfaces as polarizers and polarization converters, absorbers and conducting layers with enhanced transmittance, dichroic and chiral reconfigurable systems, waveplates and broadband filters.

As the unified approach we employ the transmission line theory providing a needed level of the generalization. We demonstrate its applicability in optical problems by analyzing the theoretical limits of a metasurface converter with orthogonal linear eigenpolarizations that allows for linear-to-elliptical polarization transformation with any desired ellipticity and ellipse orientation. Our analysis reveals that the maximal conversion efficiency with a single metamaterial surface is 50% in transmission and up to 90% in reflection. However, a double layer transmission converter and a single layer with a metallic mirror can have 100% polarization conversion efficiency. We tested our conclusions numerically reaching the designated limits of efficiency using a simple metamaterial design and checking them against the numbers reported in literature.

The metasurfaces performance was characterized by exemplifying them with free-standing membranes patterned with a grid of air slits perforated in a uniform large area (up to several cm^2) 2 μm-thick Ni film. Depending on arrangement of both slits and their sizes different optical properties of such metasurface can be acquired. We demonstrate linear polarization filtering with the parallel slits dimmers, and more complex chiral behaviour of dimers, when non-equal slits are non-parallel. In particular, strong optical activity and circular polarization conversion are reported.

Dynamic Control of Terahertz Wave with Graphene-based Metamaterial Structures

Yin Zhang, Junming Zhao, Bo Zhu, and Yijun Feng
School of Electronic Science and Engineering, Nanjing University, Nanjing, China

Abstract— Graphene, a two-dimension material consisting of one monolayer of carbon atoms, has been recently applied in electronic and photonic devices due to its exotic properties, such as optical transparency, flexibility, high electron mobility. In addition, its sheet conductivity can be continuously tuned in a broad frequency range by shifting the electronic Fermi level via chemical or electronic doping, which enables fast electrical modulation and on-chip integration. This makes the continuous or structured graphene sheet a promising candidate for designing tunable THz metamaterial.

In this presentation, we combine the metamaterials having different unit cells of metallic resonator with the double layer graphene wires to realize several terahertz devices that could manipulate the wave propagation. Firstly, a graphene based tunable metamaterial absorber with polarization independence has been designed and analyzed. The absorption performance with a peak frequency tuning range of 15% and almost perfect peak absorption has been demonstrated by controlling the Fermi energy of the graphene that can be conveniently achieved by adjusting the bias voltage on the graphene double layers. The mechanism of the proposed absorber has been explored by a transmission line model and the tuning is explained by the variation of the effective inductance of the graphene wires under gate voltage biasing. Secondly, we propose a polarization modulation scheme of terahertz wave by applying similar polarization dependent absorbers. Through the proposed polarization modulator, it is able to electrically control the reflected wave with a linear polarization of continuously tunable azimuth angle of the major axis from 0° to 90° at the working frequency. Finally, we explore a broadband terahertz wave plate that can dynamically switch the transmission wave among left-handed circular polarization, right-handed circular polarization or linear polarization by electrically controlling the Fermi energy of graphene gratings. These design approaches enable us to electrically control the absorption spectrum and the polarization state of terahertz waves more flexibly.

Abstract— Full control of the polarization of Electromagnetic wave is highly desired due to a wide range of applications, like quarter wave plate or polarization convertor. Conventional methods with dichroic crystals or birefringent materials suffer the energy loss or require thick system. Recently, polarization conversion using Metamaterial has attracted much attention. Although, the wide-band reflective wave-plates based on metamaterials have been demonstrated in GHz [1], THz [2] and infrared [3] regime, the general designing principle of the polarization conversion effect is not well reported yet.

In this work [4], we firstly show a general designing principle of the meta-surface to perfectly realize the polarization conversion derived based on the Jones Matrix analysis, which lead to two type of meta-surface with different symmetry properties. Such a principle is applicable at any frequency, here we design and fabricate two terahertz samples and perform experiments to demonstrate that both can realize the half wave-plate functionality with $> 90\%$ conversion efficiency on an ultra-broad frequency interval (0.4–1.05 THz, equivalent to **∼1000% relative bandwidth**). Finally, based on similar idea, we demonstrate experimentally high efficient and ultra-board band linear-circular polarization conversion with carefully designed meta-surface.

College of Electronic Science and Technology, Shenzhen University, Shenzhen 518060, China

Abstract— A THz twist polarizer formed by supramolecular Fermat's spiral chiral metamaterial (SFSCMM) is reported. Twist polarizers (TPs) are the 90° polarization rotators, in which transverse magnetic linear polarization is converted into transverse electric linear polarization and vice versa. The proposed SFSCMM consists of twisted bilayered supramolecular Fermat's spiral patterns, in which each layer is chiral in nature. The design is implemented in polyimide substrate using silver as a metal. Full-wave simulations demonstrated its function of TP, where the SFSCMM shows the zero-point ellipticity with the polarization rotation angle of 89.49° at 7.765 THz. The proposed SFSCMM has a dimension of $\lambda/1.38 \times \lambda/1.38 \times \lambda/10.3$ at the operating wavelength and can be fabricated through standard layer-by-layer method for the realization of optical logic gates and THz switches.

A Mixed Boundary through Wall Imaging Problem

Xiuzhu Ye
Beihang University, Beijing 100191, China

Abstract— The study of through wall imaging problem is of great interest in the field of security check and the anti-terrorism. In most literatures, the wall and the unknown scatterers are both assumed to be dielectric implicitly, while the problem of mixture of PEC and dielectric is not often addressed yet, which is a more commonly encountered case. Therefore, in this article, we mainly discuss the reconstruction algorithm of PEC and dielectric scatterers together under the circumstance of through wall imaging.

The T-matrix method is chosen as the modelling scheme. According to a recently published paper by the author, it is able to distinguish the PEC and dielectric scatterer simultaneously when the two kinds of scatterers coexist in the domain of interest. The optimization scheme is developed based on the subspace based optimization method, where the wall (obstacle) is considered as a known scatterer rather than part of the inhomogeneous background. Numerical results are given to show the effectiveness of the proposed algorithm.

The Lidar Sounding of the Atmosphere in St. Petersburg

Dmitry Samulenkov[1], **Maxim Sapunov**[1], **Irina Melnikova**[1], **Vladislav Donchenko**[1], **and Anatoly Kuznetsov**[2]

St. Petersburg State University, Universitetskaya nab., 7/9, St. Petersburg 199034, Russia
[2]Russian State Hydrometeorological University, Malookhtinsky, 98, St. Petersburg 196195, Russia

Abstract— The first results of vertical profiling aerosol particles and wind parameters above the central part of St. Petersburg in day and night time are presented. Results include profiles of the extinction and backscattering coefficients, particle size distribution, depolarization rate, particle concentration and real and imagine parts of refractive index at different heights. The wind characteristics are compared with radiosounding results. Lidar sensing in the center of St. Petersburg in the daytime and nighttime and the resulting vertical profiles of variations of the atmospheric parameters of the solid dust and soot particles in the pollution header over the city accomplished to study atmospheric pollution. The analysis of the influence of profiles of wind, temperature and humidity in the atmosphere on the properties and dynamics of solids is implemented. The areas and the speed of propagation of the atmospheric contaminants on the Vasilevsky Island in St. Petersburg at different altitudes are identified. Special attention is given to space and time variations of parameters. Atmospheric pollution in the atmosphere of a big city in case of St. Petersburg is revealed. It is shown that the meteorological parameters of the atmosphere and time of day affect the dynamics of changes hats pollution over the city. Measurements of the vertical profile of velocity and wind direction in the Observatory of ecological safety, Research Park, St. Petersburg University in the center of St. Petersburg was held within a few months of 2014, the height of laser sounding of wind characteristics of up to 12 km. The results are compared with the data of radiosounding measurements of Hydrometeorological service in St. Petersburg suburb Voeikovo. The distance between the sites of measurement is 25 km. Comparison is based on the assumption of homogeneity of the wind field in this scale. In most cases showed a good coincidence of the vertical profiles of wind, obtained by both methods. However, we should identify a few measurements when the results differ sharply or at high altitudes, or, on the contrary, in the surface layer. The results of the comparison and possible explanations for differences of measured data are presented.

ACKNOWLEDGMENT

Cloud Optical Parameters Retrieved from Airborne Observations

Irina Melnikova[1], **Charles K. Gatebe**[2], **and Anatoly Kuznetsov**[1]

[1]Russian State Hydrometeorological University, Malookhtinsky, 98, St. Petersburg 196195, Russia
[2]Goddard Space Flight Center, NASA, Mail Code 613.2, Greenbelt, MD 20771, USA

Abstract— Optical parameters of the extended cloudiness are retrieved from airborne observations of different kinds. Optical thickness, single scattering albedo, scattering and absorption coefficients are obtained for all available spectral channels from measurements over, under and within cloud.

Results of retrieving optical parameters of cloud atmosphere from airborne data are compared. Two airborne experiments are taken in Goddard Space Flight Center. Measurement of the diffuse solar radiance in eight spectral channels (0.340; 0.381; 0.472; 0.682; 0.870; 1.035; 1.219; 1.273 μm) at viewing zenith angles from 0° till 180° in 1° interval are accomplished above the Atlantic Ocean close to West-South Africa coast. The approach and algorithms of NASA data processing has been presented earlier.

Spectral semispherical solar irradiance in the spectral diapason 0.35–0.96 μm in 0.002 μm interval has been measured in the end of the last century in different geographical sites in ranges of international complex programs: GATE (tropical latitudes), CAENEX (mid-latitudes), POLEX (polar latitudes).

Results of solving the inverse problem of cloud optics (retrieving optical parameters of extended clouds from different observations) shows the single scattering albedo is not variable at different latitudes, but volume scattering and absorption coefficients are significantly changeable from Polar regions to Tropics. Obtained parameters (the ground albedo, optical thickness, single scattering albedo, volume scattering and absorption coefficients) provide the cloud optical model for estimation radiative divergence, heating rate and water content.

An Experimental Method for Estimating the Bistatic Diffuse Scatter from Anechoic Chamber RAM

S. J. Berry and F. C. Smith
QinetiQ, Room 1146 Building A7, Cody Technology Park, Farnborough, Hampshire, GU14 0LX, UK

Abstract— Characterisation of the specular reflection coefficient of a radar absorbing material (RAM) at microwave frequencies in free space is a comparatively routine measurement, although the measurement is frequently subject to high uncertainty due to edge diffraction and/or non-plane-wave illumination by the source antenna. Less well reported is the measurement of diffuse backscatter from RAM [1, 2]. For this measurement problem the use of a bistatic antenna arrangement is preferred [3]; however, at low frequencies the method may become inaccurate due to the size of the antennas relative to the test piece and the coupling that ensues.

In this contribution, a method is described and investigated which can be used to estimate the magnitude and direction of diffuse scatter from a RAM. The method is an extension to early work in [4] and is, in principle, similar to the optically modulated scatterer method (OMS) (e.g., [5]), except that specialist equipment is not required to implement the approach. A small subwavelength metal filament held by a 50 µm dielectric cord is scanned close to the RAM test piece using a 2D planar scanning system. The total complex electric field is recorded by examining the perturbation in the signal at the port of the launching antenna; these data are then used to reconstruct the propagating angular spectrum scattered from the RAM, which contains grating lobe and diffuse scatter data. The scanning system has been combined with a Quasi-Optical (QO) antenna system which is used to create a beam of microwave radiation with planar phase fronts and an approximately 2D Gaussian intensity profile in the constant phase planes. The gain provided by the QO system in part mitigates the low dynamic range normally encountered with passive scanning systems, which occurs due to the 2-way scattering process (rather than 1-way with an active probe). A dynamic range of up to 60 dB can be achieved using the QOs and a standard bench-top vector network analyser (VNA). The QO system also alleviates the need for a high quality anechoic environment for data collection.

Verification of the technique has been performed by measuring the grating lobes scattered from an array of parallel metal rods, where good agreement is shown with theoretical data. A typical anechoic chamber RAM is then used as a test piece and the grating lobes caused by the structure have been characterised for a range of angles of incidence and frequencies. The diffuse scatter from the anechoic chamber RAM is shown to be low for high angles of incidence until the geometry of the RAM produces direct specular reflection. Unsurprisingly, the direct specular reflection occurs at an angle where the facets of the pyramidal structure are normal to the incident microwave radiation.

A 16-Element Wideband Microwave Applicator for Breast Cancer Detection Using Thermoacoustic Imaging

Hao Nan[1], **Shiyu Liu**[2], **Nemat Dolatsha**[1], **and Amin Arbabian**[1]

[1]Department of Electrical Engineering, Stanford University, USA
[2]Department of Electronic Engineering, Tsinghua University, China

Abstract— Microwave-induced thermoacoustic (TA) imaging is a hybrid technique that combines the high contrast of microwave imaging, which is based on dielectric properties of different materials, with the high resolution of ultrasound detection. When tissue absorbs the incident microwave energy, stress waves are generated due to minute thermal expansions. An ultrasound transducer array is used to detect this signal and reconstruct the target image. This technique can achieve a penetration depth in excess of 5 cm, even in dispersive tissue. Unlike CT or mammography, TA imaging has no ionization radiation hazard and can be used more frequently to detect aggressive cancer types that progress in short time spans. With all these advantages, this technique is suitable for breast cancer screening, which needs a resolution of millimeter and high contrast between cancer and benign tissues.

The conventional and the most popular way to excite the tissue sample is to employ a waveguide, which is limited in bandwidth and is usually not well matched to target for TA imaging. We design the RF applicator with a compact size and high bandwidth in the optimal frequency range for breast cancer detection. The applicator is well matched to the target with a selected matching layer. The applicator can excite tissue efficiently in the near and quasi-near field. The high bandwidth of the applicator enables the flexibility of tuning exciting microwave frequency. A 16-element phased array based on the proposed applicator is designed to help focus the input microwave energy and to control the location of high specific absorption rate (SAR) region for TA imaging. This phased array applicator system can increase local SAR by conformal focusing of the microwave energy to a local area, which directly results in a higher SNR than a uniform excitation. Tuning the phase of each element can control the location of the high SAR region. Full 3D E&M simulations demonstrate the ability to control the high SAR region across the target and over the operation bandwidth.

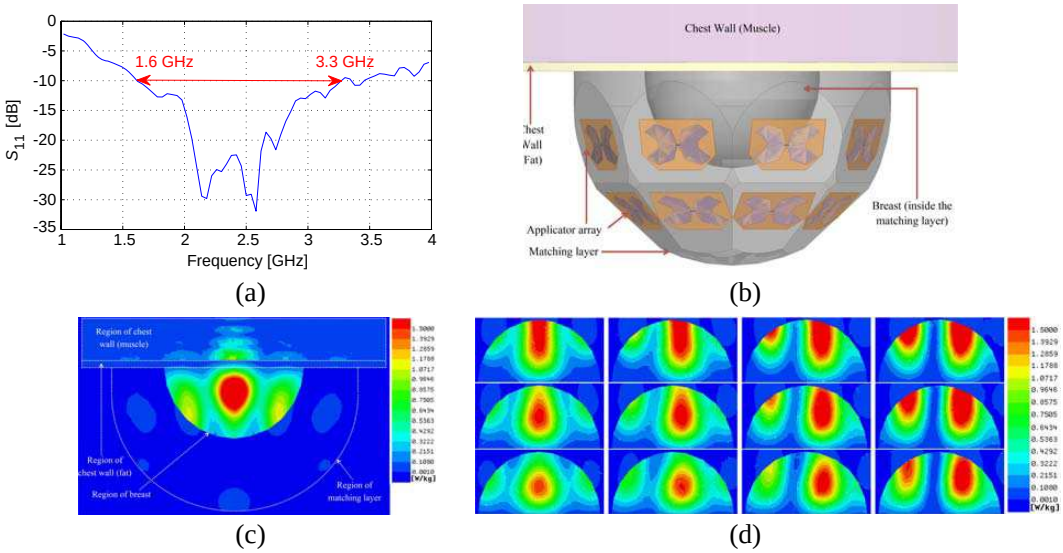

Figure 1: (a) Simulated S_{11} of the applicator. (b) Setup of the 16-element phased array applicator system. (c) Simulated SAR with same phase for each applicator. (d) Simulated SAR with tuning phase of each applicator to control the location of the high SAR region.

High Resolution Range Imaging via Model-based Compressed Sensing

V. Adler[1], **J. Moll**[2], **M. Kuhnt**[2], **B. Hils**[2], **V. Krozer**[2], **and K. Hoffmann**[1]

Abstract— This paper proposes a method for high resolution range imaging at millimeter wave frequencies (85 GHz to 100 GHz) based on model-based compressed sensing (CS). Besides a detailed description of the radar sensor, depicted in Figs. 1(a)–(b), and the theory of the underlying compressed sensing framework, the experimental setup is presented along with experimental results for one-dimensional range imaging. The measurement system is characterized by motorized reference measurements that form the dictionary matrix for the subsequent CS-processing, as well as measurements from a glass fiber reinforced polymer (GFRP) component. It is demonstrated that the proposed CS-method improves the range-resolution capabilities of conventional monostatic-radar systems that are usually based on FFT or matched filter processing. Resolution of these conventional radar systems is proportional to the inverse of its bandwidth and in our case ($BW = 15$ GHz) is approx. one centimeter. Compressed sensing results are shown in Fig. 1(c) and provide much better range resolution in the order of few micrometers, depending on the spacing of the motorized measurements, and significantly smaller sidelobes than conventional radar systems as shown in Figs. 1(d)–(e). This approach can be useful for a variety of radar applications, e.g., non-destructive material testing and precise time-of- ight measurements.

Fast Level Set Based Method for High Contrast Microwave Imaging

Pratik Shah and Mahta Moghaddam
Department of Electrical Engineering, University of Southern California, California, USA

Abstract— Microwave imaging has applications in through-the-wall imaging, non destructive testing, and medical imaging. The imaging problem is usually performed by formulating it using the volume integral equation. The integral equation represents the relationship between complex permittivitty and the electric field inside and outside of the inhomogeneous imaged domain. The equation is non-linear in general and common practice is to linearize by iteratively solving for the unknown complex permittivity and the field. Many numerical and experimental studies on microwave imaging have been performed, with common impediments being the inability to recover high dielectric contrasts and slow speed of computation.

For some applications, we have knowledge on what type of objects are present in the domain and their electrical properties. Although it is understood that the prior knowledge about contrasts in the imaged domain may not be very accurate or easily available, we will make the assumption that it is known to within some uncertainty. Having priors about contrasts, the microwave imaging problem essentially becomes locating the object and estimating the shape of the object. We consider an approach based on the level set method. The level set based shape recovery approaches for microwave imaging are very slow in general. The main computational burden is to estimate the adjoint field at each iteration. The adjoint operation for a linear system can be derived analytically so we explore a method, which is not based on the adjoint field evaluation. Hence, it can be very fast. The cost function is based on the variational level set functional, which regularizes the level set evolution without reinitializing it at each 'timestep'. Each iteration of the method comprises one forward solver and many iterations of the level set method. The desired results are obtained within 15 iterations of the method.

The applicability of the method is tested on synthetically generated data for a two-dimensional (2D) scenario. The data includes both lossy and lossless permittivity. The reconstructed images indicate that the method can produce accurate object localization and shape identification even for high contrast objects.

On the Connection between Jones Matrix and Sinclair Matrix

T. Dallmann and D. Heberling
Institute of High Frequency Technology, RWTH Aachen University, Germany

Abstract— The polarimetric behavior of scattering of radar targets can be described with two different 2×2 matrices: The Sinclair matrix which specifies the backscattering of a target and which is commonly used by polarimetric monostatic radar systems, and the Jones matrix which characterizes the forward scattering of a target and originates from optics [1].

Especially the decomposition of the Sinclair matrix into Huynen-Euler parameters has gained attention in some recent publications since it allows to characterize the system with so-called canonical scatterers [2, 3]. These primitives not only determine the polarization of the scatterered wave but also influence in which directions and at which frequencies the scattering occurs. Thus the Huynen-Euler parameters together with the canonical scatterers give a physical interpretation to the radar-cross section signatures of radar targets.

Unfortunately the extraction of Huynen-Euler parameters from the Sinclair matrix requires a coneigenvalue decomposition. Up to now, little research has been conducted in the field of consimilarity transformations and coneigenvalues. Some of the implications of these decompositions are therefore still unknown [5]. In contrast the Jones matrix can be decomposed with an eigenvalue decomposition. The mathematics of eigenvalues and similarity transformations are known and well understood [6].

In [4] a misleading, but simple connection between the Jones matrix J and the Sinclair matrix S was established:

$$S = AJ = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} J \tag{1}$$

This equation was derived for linear polarizations only. Unfortunately in some publications this connection is mistakenly emphasized as being generally valid [1]. If this would be the case, the decomposition of Sinclair matrices could be extremely simplified by transforming them to Jones matrices and performing an eigenvalue decomposition afterwards.

In this paper the following will be proved:

1. There does not exist a polarization basis-independent matrix A which allows to transform consimilar matrices S_i to similar matrices J_i for arbitrary polarization bases. This means that the transformation can generate Jones matrices with different eigenvalues even if the Sinclair matrices have the same coneigenvalues. Thus a decomposition utilizing the transformation matrix A can deliver diverging Huynen-Euler parameters in some cases.
2. If A is polarization basis-dependent then the transformation of consimilar Sinclair matrices will produce similar Jones matrices. However this means that the basis transformation connecting the Sinclair matrices must be known. In this case the transformation to Jones matrices using A is not beneficial any more.

Hence a simplification of the decomposition of Sinclair matrices as mentioned above is not possible. This emphasizes the relevance of coneigenvalue decompositions for radar polarimetry.

Detection of Breast Tumors by Applying FDTD Modelling of Holographic Radar

I. L. Alborova and L. N. Anishchenko
Biomedical Engineering Department, Bauman Moscow State Technical University
5, 2d Baumanskaya str., Moscow 105005, Russia

Abstract— This paper presents the results of mathematical simulation carried out to confirm the ability of holographic radar to detect breast tumors. The simulation software used the Finite-Difference Time-Domain Method. The simulations were performed for three different scenarios: in the first model the inclusion depth under the surface was varied; for the second model two inclusions were used; while the dielectric properties of malignant tissue were modified in the third model. The model is a 3D block with dimensions $200 \times 200 \times 100$ mm, which mimicked normal breast tissue, with one or two spherical inclusion — malignant neoplasm of breast tissue. Frequency dispersion of normal and malignant tissues dielectric properties (conductivity and permittivity) was taken into account.

The results showed that differences in the dielectric properties allow to use of the radiolocation method for detecting inclusion (diameter 4 mm) on a depth up to 5 mm. The results proved that the greatest impact on the detection of inclusion has a ratio of conductivity values of normal and malignant tissues. Also the proposed method makes possible to distinguish two different objects at the distance between them of 16 mm or more, otherwise they will be identified as one inclusion.

Characterization of the Electromagnetic Propagation through Building Rubble by Means of Numerical Random Models

I. Lucresi, E. Di Giampaolo, and P. Tognolatti
Department of Industrial and Information Engineering and Economics, University of L'Aquila, Italy

Abstract— The rescue of victims buried in building rubble because of earthquakes, landslides, explosions in industrial plants or terrorist attacks, can take advantage from real-time measurements employing wireless communications devices.

Rising technologies like rescue robots, allow rubble exploration and victims localization exploiting radio signal transmissions. Moreover, radio detection of vital signs or detection of radio signals emitted by personal RF devices (e.g., cell-phone, radios, RFID, etc.) that may be close to the owner (especially in case of rescuers involved in subsequent collapses) can be very useful in post emergency operations since immediacy of action may lead to a considerable reduction in the number of victims. For these reasons communications plays a big role in this kind of systems. These operations efficacy however, is strictly related to the characteristics of propagation channel in the disaster scenario. Attenuation, multipath and noise make the radio-link weak and untrustworthy, in spite of this adequate systems can be designed if a sufficiently accurate knowledge of the features of the propagation channel is available.

This work has been developed after the earthquakes which stroked the Italian territory in the last years. The considered scenarios are then composed by rubble and debris of collapsed buildings, that is a very complex environment because of different materials, morphologies of urban fabric involved and physical characteristics of rubble and debris (i.e., shape, dimensions, humidity and level of compression), for which no general channel model exists.

In this work, in a completely new way compared to the literature, we simulate different models of rubble to evaluate phenomena of attenuation and propagation of radio signal through an extremely heterogeneous transmission medium structured in a not predictable manner.

The aim of the work is the development of a random model of the rubble that would reflect a wide range of environments, for this reason random rubble scenarios were generated and simulated through an electromagnetic tool where the transmission source is represented by a dipole antenna buried into rubble. The model involves typical materials, in established and plausible proportions, of both modern buildings (concrete, bricks and iron) and ancient ones (stones and bricks). A number of parameters characterize the model of the rubble: the degree of compression (defined as the ratio between the empty and filled spaces), the graininess (i.e., the size of the blocks of homogeneous material), the number of different materials, the dielectric properties of each material, the moisture, the thickness of the layers (one or more layers are considered). A large number of simulations have been performed for different frequencies: at 13 MHz, 432 MHz and 900 MHz. These frequencies have been chosen because they mainly concern rescue devices and are near the frequency bands of many communication services in Italy and European Countries. The study is focused on the analysis of Path Loss at different heights from the ground and for various angles of incidence of the electromagnetic wave. A statistical analysis of data are also carried out by calculating mean, standard deviation and minimum value of Path Loss for a large number of simulations.

The proposed model takes cue from a measurement campaign carried out in a number of buildings collapsed or partially destroyed in L'Aquila territory that was stroked by a severe earthquake in 2009 [1, 2].

Comparison between model results and measurement data allow us the tuning of the model parameters and is under development.

Abstract— Several Computer-Aided Detection and Diagnosis (CAD) systems have been proposed in recent years for various breast imaging modalities, such as X-Ray Mammography, which generally involve pre-processing and segmentation of images followed by diagnosis. In the context of breast Microwave Imaging (MWI), the development of a dedicated CAD system combining features both from microwave images and recorded signals would greatly contribute to the performance of the technique in terms of specificity. In this submission, the authors focus on an improved method for automated diagnosis of breast cancer based on recorded backscattered signals.

MWI is based on the contrast between the dielectric properties of different types of breast tissue at microwave frequencies. The majority of existing studies which considered MWI of the breast have focused primarily on tumour detection, with automated tumour diagnosis seen as a secondary concern. A small number of studies have considered the use of the Radar Target Signatures (RTS) to identify tumours as benign or malignant, but it is unclear whether the performance of these algorithms can provide sufficient information in anatomically and dielectrically heterogeneous scenarios. Therefore, alternative methods need to be considered.

To address this problem, a combined breast microwave imaging and diagnosis system is proposed, where the breast images obtained using Microwave Tomography (MT) allow for the isolation of the RTS of the tumour in the recorded backscattered signals. A time-domain MT algorithm, known as Forward-Backward Time-Stepping (FBTS), is used to reconstruct the dielectric profile of the human breast, which in turn provides the location and extent of any tumour. Based on this information, a time-gating algorithm is applied to window the tumour RTS based on the average dielectric values of the breast tissues, and the round-trip distance between the antennas and the detected tumour. The estimated tumour signature is windowed from the backscattered signal with an approximate window length equal to twice the pulse width. Next, a sophisticated tumour-grading algorithm is applied to the windowed signals, which distinguishes tumours based on their level of malignancy. Since the tumour-grading algorithm processes isolated tumour signatures, rather than reflections from multiple scatterers within the breast, it can make improved judgements on the malignancy or benignancy of tumours.

The efficacy of the proposed combined breast microwave imaging and diagnosis system is benchmarked against previous studies which examined standard un-windowed microwave signals, by

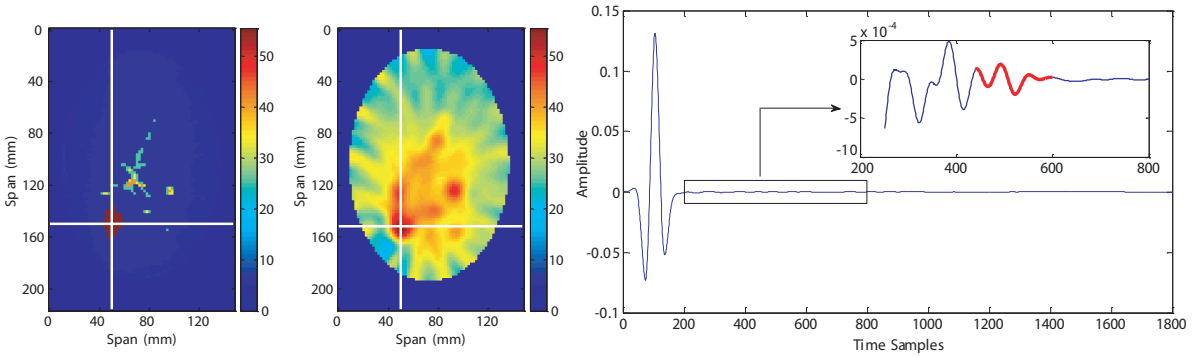

Figure 1: (a) FDTD model of a class 1 breast, with a tumour placed on the lower-outer quadrant (as identified by the cross-section of the white lines). (b) Reconstructed permittivity profile using FBTS: the tumour location is identified by thresholding the permittivity map based on dielectric properties of the tumour. (c) Backscattered signal from one of the recorded channels. The windowed tumour signature is highlighted in red.

simulating anatomically-accurate Finite Difference Time Domain (FDTD) breast and tumour models. By way of example, Fig. 1 shows a reconstructed breast image and the corresponding microwave signal, where the relevant tumour response is highlighted. Preliminary results — which will be presented in the final version of this paper — reveal an improvement in the performance of the automated diagnosis when the proposed windowing is applied to the backscattered signals, compared to the un-windowed approach. These results demonstrate the potential of windowed signatures to accurately diagnose tumour responses in high-clutter scenarios. Future work in this project includes combining the windowed tumour signatures with features extracted from the MT breast images for enhanced automated diagnosis.

Abstract— We will present a comprehensive model to follow the details of spatiotemporal dynamics of ultrashort-laser-induced modification of a bulk glass (fused silica as an example). The model is based on two sub-models, one of which solves Maxwell's equations supplemented with the equations describing electron plasma formation and the laser-induced electric current and another one utilizes the equations of thermoelastoplastics. Spatiotemporal dynamics of laser beam propagation through the focal zone with generation of free electron plasma is analyzed for the regimes typical for nanograting formation and for creation of micro/nanobubbles. A controversial question on free electron density generated inside transparent dielectrics by ultrashort laser pulses is discussed based on the laser energy balance. The map of absorbed laser energy is used as an input for modeling the spatiotemporal dynamics of excited matter relocation and determining the final density-modulated structure that conditions refractive index change. Conclusions on the different routes of material evolution at different excitation conditions (laser beam energy, NA, pulse duration) will be made. The geometry of laser energy absorption is studied as a function of pulse duration, laser energy, and numerical aperture. The double pulse irradiation has been modeled to get insight into "exciton-seeded multiphoton ionization" [1]. Furthermore, several consecutive laser pulses have been modeled to gain a better understanding of a qualitative tendency of memory effects related to defect accumulation. Such features of laser energy coupling into the bulk glass have been revealed as asymmetry of absorption for the cylindrically-symmetric linearly-polarized beam and formation of a defect shield developing in multipulse irradiation regimes. Modeling allows foreseeing and predicting the routes of material evolution at different excitation conditions.

Self-consistent Modeling of Photoionization for Nonlinear Ultrashort Pulse Propagation in Solids

Jeremy R. Gulley and Thomas E. Lanier
Department of Physics, Kennesaw State University, Kennesaw, GA 30144, USA

Abstract— Simulations coupling ultrashort pulse propagation with laser material interactions have traditionally contained some oversimplifications. One notable inconsistency is that propagation models, such as modified nonlinear Schrödinger equations, account for the multi-chromatic nature of ultrashort laser pulses while the ionization models they are coupled to are intrinsically monochromatic. As such, the influence of nonlinear optical behaviors such as super-continuum generation and high harmonic generation on ionization and laser-induced modifications is not well understood. Another inconsistency is the use of simplified material models (such as the Keldysh photoionization formula) that are based on physical assumptions that are not well justified in many situations. Among these are assumptions of a parabolic or Kane-type band structure, as well as effective masses and collision times chosen to fit numerical data to a particular experiment. In this work we present simulations solving the quantum semiconductor Bloch equations in a 3D quasi-momentum space and couple this model to ultrashort pulse propagation in dielectric solids. This approach self-consistently provides a quantum calculation of the photoionization yield, the photoionization current, the current from free-carriers, the generation of field harmonics, the traditional Kerr effect, and any high-order Kerr-effects without resort to a perturbative description. The material band structure is taken in the tight binding limit and is periodic in the crystal momentum space, thus ensuring a realistic treatment of Bragg reflection. The required input values for the material model include a measure of the known lattice dimensions, a band gap, and the reduced electron-hole mass at zero momentum (this value being selected to produce the known linear index of refraction in the low field limit). As the model makes no assumption about the pulse spectrum, we examine the laser-material interaction of strongly chirped pulses and multi-color multi-pulse schemes of laser-induced material modification. We then examine how a reduced laser-material model, based on this approach, may be used for multi-dimensional pulse propagation simulations.

Nonlinear Energy Deposition into Aqueous Media by Tightly Focused Laser Pulses: Tracking of Free-electron Density, Temperature Evolution, and Hydrodynamic Phenomena in a Large Range of Laser Pulse Durations and Wavelengths

Alfred Vogel, Xiao-Xuan Liang, Sebastian Freidank, and Norbert Linz
Institute of Biomedical Optics, University of Lübeck, Germany

Abstract— To date, optical breakdown modeling has mostly focused on tracking the evolution of free electron density and predicting breakdown thresholds defined by a critical free electron density. Such thresholds cannot easily be linked to experimental observations of breakdown events, which commonly rely on the detection of plasma luminescence, phase changes (leading to transient bubbles in water or permanent cavities in solids), or shock wave emission. We developed modeling tools for optical breakdown events in water, which span various phases reaching from breakdown initiation via solvated electron generation, through laser induced-plasma formation and temperature evolution in the focal spot to the later phases of cavitation bubble dynamics and shock wave emission.

The rate equation model considers the interplay of photoionization, avalanche ionization and recom-bination, traces thermalization and temperature evolution during the laser pulse, and portrays the role of thermal ionization that becomes relevant for $T > 3000\,\mathrm{K}$. Modeling of free-electron generation includes recent insights on breakdown initiation in water via solvated electron generation that were obtained by bubble threshold spectroscopy of IR nanosecond breakdown. The wavelength dependence of the breakdown threshold indicates that avalanche ionization is initiated via multiphoton excitation of valence band electrons into a solvated state at $E = 6.6\,\mathrm{eV}$ followed by up-conversion into the conduction band level that is located at $9.5\,\mathrm{eV}$ [1].

The ability of tracing the temperature evolution in the focal volume allows for a comparison with experimental data on bubble thresholds and bubble size. The model of laser-induced plasma formation is linked to a hydrodynamic model of plasma-induced pressure evolution and phase transitions that enables to trace bubble generation and dynamics as well as shock wave emission. This way, the amount of nonlinear energy deposition in transparent dielectrics and the resulting material modifications can be assessed as a function of incident laser energy. The unified model of plasma formation and bubble dynamics yields an excellent agreement with experimental results over a large range of pulse durations and wavelengths, as shown in Fig. 1.

Future challenges are to include spatio-temporal aspects of optical breakdown associated with nonlinear light propagation and with the plasma growth during the laser pulse.

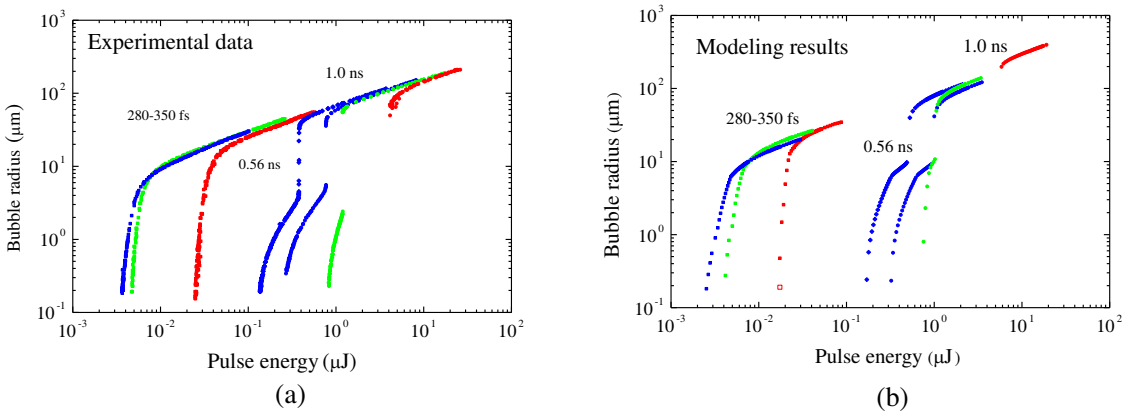

Figure 1: Maximum cavitation bubble radius in water as a function of laser pulse energy for different pulse durations and wavelengths; NA = 0.8. The colors denote the wavelengths: blue = 347 nm for fs pulses, and 355 nm for ns pulses; green = 520 nm and 532 nm, red = 1040 nm and 1064 nm. (a) Experimental data, (b) modeling results.

Multiphoton Absorption-induced Delocalization of fs Laser Pulse Energy in Si Bulk

Abstract— Modification of bulk of various transparent materials by means of writing by focused fs laser beam is well known technique nowadays. Recently, a number of experimental attempts to apply this approach to crystalline silicon were done. To our knowledge, all experiments with ultrashort pulses failed to modify deep silicon bulk. Most of them were carried out at wavelengths at which two photon absorption (2PA) occurs ($\sim$ 1120–2250 nm). Strong prefocal losses of laser energy, attributed to 2PA, and, as result, limitation of laser-induced free carrier plasma density to $\sim 10^{19}$ cm^{-3} were demonstrated [1, 2]. So the question arises: could this limitation be overcome by switching to longer wavelengths at which the number of absorbed photons increases?

The number of experiments in this field is rather poor up to now. This stimulated us to perform simulation of propagation of mid-IR fs pulse through Si bulk. We solved numerically nonlinear Schrödinger equation (NLSE) in paraxial approximation. The wavelength range in the calculations was 1200–4400 nm. The nonlinear absorption coefficients and nonlinear refractive indexes were taken from experimental works. The solutions of NLSE revealed that the prefocal depletion of the beam energy at high initial pulse energies remains strong even in 3- and 4-photon absorption cases.

Additionally, the strength of free-carrier plasma defocusing and diffraction increases with growth of wavelength, so maximum plasma density in the focus decreases. Density of absorbed energy is 2–3 orders of magnitude less then needed for melting of silicon. Thus, internal modification of c-Si structure by mid-IR fs pulses is most probably unfeasible at least at wavelengths shorter than 4400 nm.

Nonlinear Mechanisms of Light Absorption in the Laser Processing of Transparent Materials

Irina N. Zavestovskaya[1, 2]

[1]P.N. Lebedev Physical Institute of RAS, Moscow, Russia
[2]National Research Nuclear University MEPhI, Moscow, Russia

Abstract— The nonlinear mechanism of optical power consumption has been considered. This mechanism occurs in the transparency region of the solid under irradiation with ultrashort laser pulses of high-intensity.

Laser ablation under exposure to ultrashort laser pulses was shown to be a promising technique for processing and machining of transparent materials such as nitride semiconductors, sapphire, and other hard and inert materials. The clean treatment of the surface was demonstrated in contrast to the ablation with longer pulses. The typical range of treatment parameters is within the power densities of 30–50 TW/cm^2 at pulse width of $\sim$ 135 fs and wavelength of 400 nm for the process of laser ablation in GaN.

Clean pits were obtained in all experimental results under a single-shot irradiation. No signs of melting, no debris of re-deposition was found. There was no collateral damage of the not-irradiated regions as well. The results obtained testify that the femtosecond laser ablation of transparent materials keeps the chemical properties of the ablated surface unchanged.

The critical pulse energy can be compared with that in highly transparent fused silica and some other optical materials. The dependence of the laser-induced damage threshold on the energy band gap E_g was shown for several transparent materials tested under the same experimental conditions. A power function corresponds to the dependence of $E_g^{3.1}$.

The optical power consumption process leading to the laser ablation is considered theoretically. The goal is to determine the laser-induced damage threshold as a function of the material properties and laser parameters.

The effective absorption under this irradiation is estimated as $\sim 2.5 \times 10^4$ cm^{-1}, which is 20–100 times greater than the background linear absorption in GaN. This means that there is an efficient nonlinear mechanism of absorption of powerful radiation in the transparent frequency region for power densities of several TW/cm^2.

The tunneling absorption mechanism has been found to be the most efficient one for wide gap semiconductors and dielectrics processed with multi-TW/cm^2 and femtosecond laser pulses. The laser-induced damage threshold has been determined. The correlation of the threshold with the band gap is demonstrated. The threshold increases as nearly the third power of the band gap in satisfactory agreement with the experimental results.

Numerical Realizations of the Problem of Focused Laser Beam Propagation in Transparent Materials Based on Nonlinear Maxwell's Equations

Abstract— We present the model describing propagation of femtosecond laser beams in transparent solids based on nonlinear Maxwell's equations supplemented by the hydrodynamics-type equations for laser-generated free electron plasma. The model takes into account linear dispersion, nonlinear Kerr effect, multiphoton and impact ionization, multiphoton light absorption. Numerically the model is realized based on Yee's FDTD scheme with the use of implicit approximation to ensure numerical stability. The scheme has been adapted for solving the specific problems under consideration and allows making sufficiently complicated simulations to be fast and accurate. Computer solution of a typical 2D problem requires around 20 hours on a usual PC without parallelization. The codes for simulations of 2D cylindrical and slab geometries as well as of 3D case for cylindrically-symmetric incoming beams have been developed. The last-mentioned code enables us to study axial symmetry violation upon laser beam propagation. The codes for cylindrical geometry require application of a specific grid to avoid the problems encountered in the calculations on the axis. This and other peculiarities will be discussed in the report.

Abstract— We will present our recent experimental works on generation of nanometer-scale structures on various thin-film structures, using femtosecond laser beams shaped to zeroth and first order Bessel beams. The advantages of ultrashort laser pulses in materials processing and also their ability to form sub-diffraction-limit structures through nonlinear-optical processes are broadly investigated by many researchers. On the other side, the so-called diffraction-free beams also receive increasing attention due to their exotic physical behaviors such as extremely long depths of foci and self-reconstruction. Bessel beams are the most commonly used type of such beams. We show that diffraction-free beams provide significant advantages for processing of thin-layer materials, especially when high resolutions (small structures) are needed. These advantages include relaxed alignment constraints, reduced aberrations and easier scalability to shorter wavelengths. We demonstrate nanometer-scale fabrication of gold thin films and generate structures which exhibit plasmonic excitation effect. We also show that single-layer graphene can be ablated via a similar approach, although greater care is needed to avoid substrate damage. Finally, we will present ablation properties of vortex-type first order Bessel beams, on metal thin films.

Laser Energy Deposition in Glasses with Bessel Beams

Abstract— I will present recent theoretical and experimental investigations on the propagation dynamics of ultrashort laser pulses focused with an axicon lens in glass, forming Bessel beams, filaments and plasma strings in the bulk of transparent solids. Numerous potential applications of bulk laser-induced plasma string range from laser micromachining to controlled temporary refractive index change or permanent damage in glasses. Recently, high angle Bessel beams delivered by femtosecond laser have been used for extremely high aspect ratio nanochannels generation and microstructuring in glass with a single laser shot. I will focus on fundamental light-matter interaction studies, devoted to the understanding of laser energy deposition in bulk glasses, with picosecond and femtosecond pulses.

I will present experiments and simulations highlighting the plasma generation dynamics and absorption when a Bessel beam of picosecond duration propagates in glass. We performed transmission measurements in the angular and wavelength domains allowing us to retrieve clear indications of the formation of the plasma in the material with a single chirped pulse playing the role of pump and probe simultaneously thanks to the spectral-temporal correspondence in the measured signal. Results showing the plasma non linear absorption effect on the trailing part of the pulse will be discussed and compared to the results of numerical simulations.

Laser propagation was modeled by a unidirectional propagation equation. Two different models were used for the matter response: (i) A classical model relies on rate equations for the generation electrons in the conduction band of the dielectric and a phenomenological Drude model for the permittivity. (ii) A computationally more expensive model but more realistic relies on a quantum- kinetic approach based on a system of Boltzmann transport equations describing electron and phonon distributions.

In the femtosecond pulse regime, we investigated numerically the propagation properties of large cone angle Bessel beams in the bulk of transparent solids and associated light-matter interaction. We compared the results to experimental results, in particular for multiple shot measurements of transmission as a function of pulse energy. Results from the classical model show that high angle Bessel beams allow the generation of a plasma channel with sub-micrometric diameter, tens of micrometers length and densities higher than the critical plasma density value. The Bessel filamentation dynamics is explained by the strong plasma absorption and is quasi-stationary. Agreement with measurements requires fine tuning of the parameters. We show that the quantum-kinetic approach is in quantitative agreement with the transmission measurements without the need for fine-tuning phenomenological parameters.

Time-resolved Modeling of Ultrafast Laser-excited Semiconductors and Dielectrics

B. Rethfeld, A. Rämer, K. Huthmacher, and N. Brouwer
Department of Physics, OPTIMAS Research Center, Technical University of Kaiserslautern, Germany

Abstract— Exciting transparent matter with an ultrashort laser pulse induces a number of processes on a broad range of timescales. We apply several different methods to describe the material's response from the initial laser absorption to the final material modification. Kinetic approaches like Boltzmann collision integrals [1] or Monte Carlo simulations of electron traces [2] are capable of following the initial excitation and the nonequilibrium electronic energy distribution. A reduction to an effective model like the multiple rate equation is possible [3]. The initial excitation and ultrafast thermalization occur on a subpicosecond timescale. The further energy dissipation can be followed by temperature-based models, which allow for additionally including the transport of particles [4]. A description of material's response with this so-called density-dependent two temperature model (nTTM) is possible up to the picosecond range [5, 6]. For the atomic movements occurring on a pico- to nanosecond range, molecular dynamic simulations are appropriate [7].

Here, we show exemplary results of these methods. In particular, we study how such processes influence each other and the further course of energy dissipation up to material modification: Electron-electron as well as electron-phonon collisions quickly lead to an isotropic momentum distribution. The particular energy distribution of the electrons might influence the propagation of the laser pulse [8]. The thermalization of laser-excited carriers to separate electron and hole temperatures occurs faster than the equilibration of the subsystem's chemical potentials. These kinetic results justify a number of assumptions made by the nTTM. However, the description of optical parameters, especially reflectivity and energy absorption, appears to be crucial for the final damage thresholds [5, 6]. The kinetics of the melting process is influenced in turn by the dependence of melting temperature on pressure known from static measurements [7].

Energy and Particle Propagation and Relaxation in Laser-excited Silicon

A. Rämer and B. Rethfeld
Department of Physics, OPTIMAS Research Center, Technical University of Kaiserslautern, Germany

Abstract— When studying the excitation of semiconductors with an ultrashort laser pulse, the evolution of the free carrier density and the subsequent transport of energy and carriers has to be treated explicitly. To that end, we apply a density-dependent two temperature description (nTTM) similar to Ref. [1] and study the influence of different modeling assumptions on the numerical result.

An 800 nm-laser pulse is absorbed in silicon via single photon and multiple photon absorption processes. Free electrons are allowed to excite further electrons-hole pairs via collisional excitation and to recombine with holes in the valence band via Auger recombination. In addition to heat transport, particle transport is considered as an ambipolar process, thus electrons and holes are assumed to move together as electrons-hole pairs. A Drude model is implemented to account for the highly transient optical parameters. The melting thresholds calculated with our model compare well with experimentally determined ones for a wide range of laser pulse durations.

Here, we study the importance of optical parameters, degeneracy and transport effects on these calculated damage thresholds. We report that the choice of the Drude collision frequency strongly influences the resulting lattice temperature and thus measurable quantities like damage thresholds [2]. Moreover, we show that it does not suffice to assume a constant carrier collision frequency at least when treating a wide range of pulse durations. In this case, a transient carrier collision frequency considering both, electron-hole and carrier-phonon collisions, has to be applied to best reproduce experimental data.

We also plan to examine the influence of laser-induced nonequilibrium in this context. The extended multiple rate equation [3] allows to study the electronic relaxation processes in laser-excited semiconductors in a simplified way. First estimations show that electron degeneracy influences the energy transfer to the lattice. These findings may have impact on the description of energy relaxation and transport in silicon.

Internal Photoeffect under the Action of Ultrashort Electromagnetic Pulses: Dependence of Pulse Duration

Valery A. Astapenko and Sergey V. Sakhno
Moscow Institute of Physics and Technology (State University)
9 Institutskii lane, Dolgoprudniy, Moscow Region 141700, Russia

Abstract— The presentation is devoted to theoretical analysis of internal photoeffect induced by ultrashort electromagnetic pulses (USP). We calculated the total probability (during all time of USP action) of photo-excitation of impurity state into energy band in semiconductor matrix. The calculation based on the expression for probability of photo-induced processes derived in paper [1] in the frame of perturbation theory:

$$W = \frac{c}{(2\pi)^2} \int_0^\infty \sigma(\omega') \frac{|E(\omega')|}{\hbar\omega'} d\omega'. \quad (1)$$

here $\sigma(\omega')$ is cross-section of the impurity-band photoexcitation, $E(\omega')$ is Fourier transform of electric field strength in the pulse, c is light velocity.

In the contrast of paper [2] where only carrier distribution function in valence band was considered in the present work main attention is given to the dependence of excitation probability (W) on the pulse duration τ for various values of pulse carrier frequency (ω).

It is shown that for frequency ω smaller that the excitation threshold ($I_{\rm th}$) dependence $W(\tau)$ looks as a curve with maximum and $W(\tau \to \infty) \to 0$. On the contrary for $\hbar\omega > I_{\rm th}$ excitation probability rises with the increase of pulse duration and goes to the linear dependence at sufficiently large parameter τ.

Calculations were made in the frame of continuum model and isotropic effective mass of charge carrier with the use of cross section formula obtained in papers [3, 4].

Several types of USP are considered, namely, traditional and corrected Gaussian pulses [5], pulses with frequency chirp and also wavelet pulses with different parities.

We also calculated the spectral probability of total photo-excitation for various pulse durations and analyzed obtained spectra.

It is established that internal photoeffect induced by USP has specific features which differ from characteristics of this phenomenon under the action of long electromagnetic pulses.

Session 1A5
Antennas, Signals, HPEM and EMC Problems 1

High Definition Multimedia Interface in the Process of Electromagnetic Infiltration

Rafal Przesmycki
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— The protection of information against the penetration of electromagnetic devices and electronic systems (information technology) is very important. This problem increases with ever greater use of IT equipment for the processing and transmission of information, which should not fall into the wrong hands. This is due to the fact that every electronic device is a source of undesirable (secondary) emission of electromagnetic energy induced in the surrounding area, any electrical wiring and metal structures.

When the emission undesirable signals are correlated with the non-confidential information, they can be used to reproduce the information by intelligence services. The phenomenon of the emission undesirable is called disclosing emission. The use of disclosing emission by intelligence services we call penetration or electromagnetic infiltration. Projects designed to blocking identifying systems based on disclosing emissions we call information protection against the penetration of electromagnetic emissions or safety emissions.

The article concerns problems of electromagnetic compatibility and compromising emission that is the information security. The article describes the electromagnetic channels of penetration information, and then focuses on High Definition Multimedia Interface for which shows signals of extortion used during of disclosing emission measurements. The article presents the results of compromising emissions measurements derived from High Definition Multimedia Interface. In addition, the article discusses the laboratory stand for measuring disclosing emissions.

Analze the Impact of Discretization on the Structure of the Simulation Result

Marek Bugaj and Jarosław Bugaj
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— The demands of modern radio systems forced to look for new solutions in antenna. This requires designers conduct many tests and measurements.

Researches of antennas are a complex, time consuming and relatively expensive. In the laboratory, often we don't have possibilities to investigate the effect of the relationship between physical parameters of the antenna and its electrical parameters and radiation pattern.

The basic methods of solving complex antenna structures in the frequency domain are the method of moments and FDTD. The main condition for the correct calculation results in these numerical methods is a step structure on cell division — discretization. In the paper shows influence of discretization structure on the simulation results — VSWR, radiation patterns and impedance. The paper shows how shape of radiation patterns in discretization functions depends. It lets you see how important problem is the discrediting give correct structure.

Another equally important concern is the duration of the simulation. Simulation time depends on the degree of discretization structure. For a simple antenna structure simulation time are not too long and it does not pay to increase the size of the cell.

Directed Energy Applications to the Destruction of Informatic Devices

Rafal Przesmycki
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— Relatively new threats for military and civil systems in the high power electromagnetic environment (HPEM) are high power microwave (HPM) sources. An attack with this kind of source is typically defined as intentional electromagnetic interference (EMI). Radiated HPEM environments which are malicious in nature can also occur at frequencies down to a few tens of MHz.

Generate an high power electromagnetic pulse in the direction of the electronic system makes electronic circuits accumulates very high voltage. This phenomenon causes damage to the circuit elements which makes the device unfit for further operation. In the case of intentional impact pulse is very important in terms of its effectiveness to generate sufficiently a strong impulse for a given frequency. The article presents an example of system for generating HPM pulse for which it can be seen that the maximum pulse is present at a frequency about 350 MHz.

The article concerns the problems of high energy electromagnetic environment. The article describes an high power electromagnetic pulse and discusses the laboratory stand for generate HPM pulses. In addition, the paper presents an analysis of possibilities of shaping the pulses spectrum generated for the destruction of IT devices, and presents the results of measurements.

Measurement of the Pulses Generated by the High Power Electromagnetic Pulse Generator

Leszek Nowosielski
Faculty of Electronics, Military University of Technology, Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— In the article the measurement methodology of the pulses parameters generated by the high power electromagnetic pulse generator HPEM-RF DS110 is presented. The block diagram of the meter of the pulses generated by the high power electromagnetic pulse generator is presented too. The meter of the pulses consists of: operating computer, oscilloscope with RF attenuators and sensor (AD-70D or AD-80D) with matching block. Display of data collected from sensor in the time domain occurs in the oscilloscope. Installed software of the operating computer allows, on the basis of high power pulse recorded in the time domain, to determine the frequency spectrum with the use of FFT.

In order to conduct validation of the meter of the pulses equipped with electric field sensor AD-70D and AD-80D the measuring results acquired with the use AD-70D and AD-80D are compared.

Theoretical and Experimental Analysis of the Impact of Conformal Surface on Parameters of Microstrip Antennas

Jarosław Bugaj and Marek Bugaj
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— The article presents analysis of the impact of conformal antennas radius of curvature on their basic parameters and characteristics of radiation. In order to verify the numerical results there were built models of practically analyzed conformal antennas, their measurements were taken in anechoic chamber and compared to those of planar antennas. Numerical analysis has been carried out (for basic shapes: cylinder, sphere, toroid) using CST Studio Suite software. Analysed antennas worked within frequency range between 2200–2300 MHz and 5031–5090,6 MHz. Both ranges are used in aviation, the first one in telemetry systems, another one in Microwave Landing System (MLS).

The main reason for intensive development of conformal microstrip antennas is the fact that it is relatively easy to integrate them with the shape of the surface on which they are installed. Mainly this applies to aircraft, spacecraft, high-speed trains, rockets and missiles in which each projecting element affects adversely aerodynamics, fuel consumption, etc., while conformal antenna can be in a simple way mounted on the aircraft wings or on the outer surface of the hull.

In order to verify if numerical analysis carried out in previous chapters are correct some models of antennas were built practically and their basic parameters were measured. As part of research the following antennas were built: planar and three cylindrical antennas with radius of curvature $R = \lambda$, 2λ, 4λ.

As results from presented analysis the radius of curvature of the surface on which microstrip antenna was placed clearly affects the performance of this antenna for low values of $R < \lambda_0$. For large values of the radius of surface curvature the impact is negligibly low, for the transition areas it stays at several or ten-odd percent.

Analysis of Distinctive Features and Database Conception for Hardware Interface of It Devices in the Process of Their Identification Based on Radiated Emission

Rafal Przesmycki and Marian Wnuk
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— Modern information technology devices emit strong disturbances, which is caused by the fact that used in casing cheap plastic does not perform the function of electromagnetic shield. Because of that the concept of electromagnetic effluents from an IT device becomes significant. Based on the analyzes and measurements we can be concluded that it is possible to identify the computer's hardware interfaces based on radiated emissions. Distinctive feature of the work of the individual interfaces is therefore the working frequency and the level of emission allowing to identification of the hardware interface.

In the article distinctive feature for modern IT equipment present on the European Union market have been presented. The collected measurement results of radiated emission generated by particular components of IT devices allowed it to build data base which could be used for identification of components characterized by too high level of radiated emission.

This paper describes the concept of building a database for IT devices in the process of identification based on radiated emissions. In addition, the article presents a similarity measure radiated emissions for each hardware interfaces of PC computer.

The Analysis of the Radius Impact on the Properties of Cylindrical Antenna with Coaxial Feed

Jarosław Bugaj and Marek Bugaj
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— The article presents analysis of conformal multilayer antenna and array antenna with coaxial feed. The antenna has the shape of the cylinder with a radius R. It was examined an effect of change radius R on the basic operating parameters of the antenna.

Methods for modeling conformal antennas are currently developed to the extent which is sufficient to undertake a theoretical analysis of many cases of practical applications. An important direction in the development of methods for conformal antennas modeling was the extension of numerical techniques developed previously for the purposes of flat structures.

For the selected frequency range there was designed planar and cylindrical microstrip antenna with coaxial feed For conformal surface radius length was varied in the range 0.2–$50\lambda_0$. The full-wave analysis of antennas numerical parameters was carried out in CST Studio Suite.

The analysis of the tested antenna has been focused on the determination of the impact of the R-radius of the side surface of the cylinder, on which the conformal antenna have been installed, on the basic operating parameters of the antenna.

The analysis of structures of conformal antennas is a complex and complicated process. Presented analysis shows how many factors affect the final result.

Characteristics of radiation, as well as of the working bandwidth, are closely related to the value of R-radius measured on the side surface of the cylinder on which the analyzed antenna is installed (especially for low values of $R < \lambda_0$). Along with the increase in curvature of the antenna radiator (reduction in the R-radius), the radiation beam is widened, and the working bandwidth of the antenna narrows.

Implementation of Universal RF-shielded Enclosure for IT Equipment Protection

Leszek Nowosielski and Marain Wnuk
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— In order to decrease the level of radiated emissions from information technology (IT) equipment and in order to protect the IT equipment in high level of electric field strength environment the RF shielded enclosures are needed. In the paper the implementation of universal RF shielded enclosure is presented. The description and the block diagram of the RF-shielded enclosure is presented. In the article the shielding efficiency (SE) of real RF-shielded enclosure is presented. The presented results of shielding efficiency measurements show that the level of SE is above 50 dB for radiated emissions in the frequency range from 80 MHz to 2.5 GHz. The attenuation of conducted emission is above 60 dB. The characteristics of shielding efficiency and power supply filters attenuation in frequency axis are presented too.

Furthermore the paper presents the methodology and block diagram of laboratory stand for SE measurements conducted in anechoic chamber.

The Exposure Level of High Power Microwave Pulses

Roman Kubacki and Salim Lamari
Faculty of Electronics, Military University of Technology, Warsaw, Poland

Abstract— To protect against electromagnetic radiation in the human exposure the permissive exposure limits have been recommended by the International Commission of Nonionizing Radiation Protection (ICNIRP) and Institute of Electrical and Electronics Engineers (IEEE). The maximum permissible exposure (MPE) can be based on the highest rms or peak electric or magnetic field strengths or the plane-wave equivalent power densities associated with these fields. The most authoritative exposure guidelines recommends also specific absorption rate (SAR) as a basic restrictions. The SAR is the time derivative of the incremental energy absorbed by an incremental mass contained in a volume element of given density.

Additionally, for pulsed exposures in the frequency range 0.3 to 10 GHz and for localized exposure of the head, in order to limit or avoid auditory effects caused by thermoelastic expansion, the threshold level of specific absorption (SA) is recommended.

Electromagnetic pulse-radiation emitted from High Power Microwaves (HPM) generators can also be treated as ultra-wideband (UWB) signals. The UWB signals have different forms of interaction with biological structures comparing with continuous signals because the frequency spectrum of harmonics of such radiation sometimes exceeds 500 MHz. Taking into account that the electrical properties (complex permittivity) of biological tissues change the values over such frequency range the new attempt of the permissive exposure levels should be redefined.

Electromagnetic Compatibility Studies of Selected Components for Present Day Cars

Leszek Nowosielski and Marian Wnuk
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— A contemporary car incorporates more and more electronics. Today, each car is stuffed with integrated circuits. Some of them are responsible for correct operation of the engine, the others watchful over the security, and others yet control the equipment making travelling comfort better. The central lock, ABS, on-board computer or glasses opened electrically do not wonder anybody because today thanks to the electronics cars turn the lights and wipers themselves on, keep the driving path properly, park, and even apply brakes, when the driver will gape himself.

Although from one hand the electronics in cars yields enormous benefit, from the other hand however it is a reason for problems. From time to time they are small and irritating (glasses will not shut or ticking wipers) and another time they are so serious that immobilize the car. These statements were the basis for making emissivity measurements of one of fitting components of a modern car. Measuring circuits and positions as well as measurement results of disturbances emissions radiated and conducted from wiper motors vs. frequency were presented in the article.

Measurements of electromagnetic interference radiated emission levels of the tested motor No. 1 and motor No. 2 were done within the frequency range of 2 MHz to 1 GHz.

The metrological certification of the measurement path between the antenna and equipment for measurement data recording was done before making the measurements of radiated disturbances. In order to do so the EMC32 software application was used. The EMC32 application is used for calculating the intensity of electromagnetic field according to the dependence:

$$E = U_{wej} + T + K,$$

where:
E — electric field strength in the site of measurement antenna installation [dB(μV/m)],
U_{wej} — level of signal at the measurement receiver output [dBμV],
T — attenuation of the HF path connecting the measurement antenna with the measurement receiver input [dB],
K — antenna coefficient of measurement antenna used that takes the effective surface of the antenna into account [dB].

The results of measurements done together with their discussion will be presented in the article.

At the same time, basing on the model used for determining the signal attenuation inside the vehicle, calculations of interfering signal attenuation were done in order to check the possibility to interfere other components of the equipment.

Bandwidth Enhancement of a Microstrip Patch Antenna Using the Metamaterial Planar Periodic Structure

Salim Lamari, **Roman Kubacki**, **and Miroslaw Czyżewski**
Faculty of Electronics, Military University of Technology, Warsaw, Poland

Abstract— Today's wireless communications systems are mostly characterized by wide bandwidth, small size and profile, low cost, ... etc..

The arrival of metamaterials has injected a new breath in the design of microstrip antennas. Thanks to them, the microstrip antennas will still have good times ahead because they can improve their characteristic such as impedance bandwidth, the radiation direction, the gain, etc.. In this paper we present a wideband microstrip antenna based on the planar metamaterial concept. This later was applied to an ordinary microstrip patch antenna aiming to enhance its bandwidth. This concept consists of embedding the patch and the ground plane of an ordinary microstrip antenna with repetitive pattern, forming thus a periodic structure. The unit cell of the structure was used to model the metamaterial. Once the metamaterial property was verified by means of the dispersion diagram, the periodic structure was built upon this unit cell and applied to an ordinary rectangular microstrip patch antenna, which was designed and simulated using the CST Microwave Studio Software. To attest this approach, the design was experimentally verified by fabricating the antenna on the Rogers RT5880 substrate ($\varepsilon_r = 2.2$ and $h = 0.787\,\mathrm{mm}$). After measurements the antenna presented a $-10\,\mathrm{dB}$ impedance bandwidth more than $10\,\mathrm{GHz}$ and exceeding thus 100% fractional bandwidth. The proposed antenna can easily integer a recent wireless communication system with the above mentioned characteristics.

Session 1A6
SC4: Complex Analysis and Convex Optimization in Electromagnetics

Stored Energy and Convex Optimization

Mats Gustafsson
Department Electrical and Information Technology, Lund University, Box 118, SE-221 00 Lund, Sweden

Abstract— Convex optimization can be used to formulate and solve several fundamental problems regarding the optimal performance for small antennas [5]. The approach is based on reformulations of the antenna design problem as an easier convex optimization problem for the antenna currents, where it is used that the radiated power, stored energy, dissipated power, and radiated field are convex functions in the current density for many cases. This leads to a systematic and computational effective formulation for analysis of optimal currents and physical bounds on, e.g., $G = Q$, Q for superdirective antennas, Q for prescribed radiation patterns, antennas embedded in devices, and antennas with near field constraints [3, 5].

Accurate and efficient evaluation of the stored energy is essential for the optimization approach. The classical derivation of the stored energy is based in subtraction of the energy density related to the radiated power from the energy density [1]. This stored energy can be rewritten as a quadratic form in the current density for some antennas in free space [4, 7]. There are however cases with coordinate dependent stored energy and negative stored energy [2, 4, 8]. It is also very hard to generalize the methodology to antennas embedded in lossy media and dielectrics. Here, an alternative approach based on a state space representation is presented [6]. The state space model is constructed from a internal symmetric state space model derived from a positive real input impedance. Numerical results for antennas embedded in temporally dispersive media are presented.

Frozen and Slow Light Scattering in Photonic Crystals within a Transparency Window: A Fundamental Theorem

Aaron Welters
Florida Institute of Technology, USA

Abstract— In this talk we discuss a new theorem which has been shown to play a fundamental role in the analysis of certain electrodynamical scattering problems involving frozen and slow-light in one-dimensional photonic crystals consisting of periodic stratified layers of homogeneous passive linear media (such as anisotropic, bianistropic, or dispersive media) for frequencies in a transparency window. This theorem, related to the Bloch-Floquet theory, says that the local band structure near a stationary point of the dispersion relation (wavenumber vs. frequency) is completely determined at just the stationary point by the Jordan form of the unit cell transfer matrix and the sign characteristics with respect to the energy ux across the layers. We will elaborate on this theorem and it's proof which uses perturbation theory, linear algebra of indefinite inner product spaces, Floquet theory for periodic ordinary differential equations, complex analysis, and Herglotz function theory. A key to the result as we will show is the fact that due to the passivity and the transparency window the energy density is positive. Applications to the study of scattering in the slow light regime are emphasized.

Passive Approximation and Optimization

S. Nordebo[1], M. Gustafsson[2], and D. Sjöberg[2]

[1]Department of Physics and Electrical Engineering, Linnæus University, Sweden
[2]Department of Electrical and Information Technology, Lund University, Sweden

Abstract— An approximation problem is formulated where it is required to approximate a general "well-behaved" function on an interval of the real axis based on the set of symmetric Herglotz functions. Applications are e.g., with the optimal realizations of passive structures presented in [4].

A Herglotz function $h(\omega)$ is an analytic function with the property $\mathrm{Im}h(\omega) \geq 0$ for $\omega \in \mathbb{C}_+ = \{\omega \in \mathbb{C} | \mathrm{Im}\omega > 0\}$. It can be shown that $h(\omega)$ is a Herglotz function if and only if it can be represented as

$$h(\omega) = b_1\omega + \alpha + \int_{\mathbb{R}} \left(\frac{1}{\xi - \omega} - \frac{\xi}{1+\xi^2} \right) \mathrm{d}\beta(\xi), \tag{1}$$

where $b_1 \geq 0$, $\alpha \in \mathbb{R}$ and where $\mathrm{d}\beta(\xi)$ is a positive Borel measure with $\int_{\mathbb{R}} \mathrm{d}\beta(\xi)/(1+\xi^2) < \infty$, see, e.g., [1, 3, 5]. It is common to interpret the measure as $\mathrm{d}\beta(\xi) = \beta'(\xi)\mathrm{d}\xi = \frac{1}{\pi}\mathrm{Im}h(\xi + \mathrm{i}0)\mathrm{d}\xi$ in a distributional sense. Symmetric Herglotz functions have an even measure with $\mathrm{d}\beta(-\xi) = \mathrm{d}\beta(\xi)$ and $h(\omega) = -h^*(-\omega^*)$.

We consider general approximation problems, such as e.g.,

$$\begin{aligned} \text{minimize} \quad & \sup_{\xi \in \Omega} |h(\xi) - f(\xi)| \\ \text{subject to} \quad & f(\xi) \text{ continuous on } \Omega \\ & h(\xi) \stackrel{\text{def}}{=} h(\xi + \mathrm{i}0) \exists \text{ continuous on } \Omega \end{aligned} \tag{2}$$

where the approximation is with respect to the set of symmetric Herglotz functions $h(\omega)$ satisfying the constraints above. Here, Ω is a closed and bounded subset of $\mathbb{R}$.

It can be readily shown that (2) may have non-trivial solutions. Suppose for example that $f(\omega) = -h_0(\omega)$ is the negative of a Herglotz function $h_0(\omega)$ which is analytic in a neighbourhood of $\mathbb{C}^+ \cup \Omega$ and where $h_0(\omega) = b_1^0\omega + o(\omega)$ as $\omega \hat{\to} \infty$. It can then be shown that the following a priori lower bound holds: $\sup_{\xi\in\Omega}|h(\xi) - f(\xi)| \geq b_1^0 \frac{1}{2}|\Omega|$, see also [2].

Existence and convergence issues will be discussed regarding the approximation problem (2) and numerical examples will be presented based on convex optimization [4]. A suitable "test-problem" is to identify the Herglotz function $f(\omega) = \tan(-1/\omega)$ based on the partial knowledge $f(\xi) = \tan(-1/\xi)$ on Ω and where $f(\omega)$ is regular in a neighbourhood of $\Omega \subset \mathbb{R}$. It is noted that $\tan(-1/\omega)$ is meromorphic in $\mathbb{C}\backslash\{0\}$ and has a sequence of poles at $1/\pi(n - \frac{1}{2})$ accumulating at 0 and with residues $-1/\pi^2(n - \frac{1}{2})^2$ where $n \in \mathbb{Z}$. Mathematically, this approximation problem is trivial by analytic continuation. However, as is well known, analytic continuation may be a non-trivial task to execute numerically. Here, the example function above is considered to be as "diffcult as possible" to be represented by using a "blind" automated numerical scheme based on convex optimization.

Convex Optimization for Approximations of Positive Real Functions

D. Sjöberg[1] and S. Nordebo[2]

[1]Department Electrical and Information Technology, Lund University, Sweden
[2]Department Physics and Electrical Engineering, Linnaeus University, Sweden

Abstract— Passive systems are intimately connected to positive real functions. These are analytical functions $P(s)$ that map the right half complex plane $s \in \mathbb{C}^+$ to itself with the symmetry condition $P(s^*)^* = P(s)$, and can be identified with Herglotz functions, which map the upper half complex plane to itself. There is a representation theorem for these functions, stating that

$$P(s) = sC + \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{s\mathrm{Re}\{P(j\xi)\}}{\xi^2 + s^2} d\xi$$

On the frequency axis $s = j\omega$, this can be used to represent the imaginary part of an arbitrary positive real function in terms of the Hilbert transform of the real part (and vice versa), $\mathrm{Im}P(j\omega) = j\omega C + \frac{1}{j\pi}\int_{-\infty}^{\infty} \frac{\mathrm{Re}\{P(j\xi)\}}{\omega - \xi} d\xi$. Allowing a pole at $\omega = 0$, and taking the symmetry of the positive real function into account, an admittance function $Y(\omega) = P(j\omega) = G(\omega) + jB(\omega)$ can be discretized as

$$\begin{aligned} G(\omega) &= G_0 + \sum_{x=0}^{N} x_n\{p(\omega/\Delta\omega - n) + p(\omega/\Delta\omega + n)\} \\ B(\omega) &= C_\omega - \frac{1}{L\omega} - \sum_{n=0}^{N} x_n\{[\mathcal{H}p](\omega/\Delta\omega - n) + [\mathcal{H}p](\omega/\Delta\omega + n)\} \end{aligned}$$

where G_0, $\{x_n\}_{n=0}^N$, C, and L^{-1} are real parameters describing the admittance function, p is a suitable basis function used for discretizing the real part $G(\omega)$, and $\mathcal{H}p$ is the Hilbert transform of this basis function. A large collection of explicit Hilbert transform pairs can be found in [1].

Using this representation, we can consider any desired target system response $Y_t(\omega)$, and study how well this can be approximated by a physical admittance $Y(\omega; x)$ represented as above, where $x = (G_0, \{x_n\}_{n=0}^N, C, L^{-1})$ are the free parameters. This can be done by formulating the convex optimization problem "minimize $\|Y(\omega; x) - Y_t(\omega)\|$", under suitable restrictions on the parameters x. For instance, a passive system is characterized by all parameters x being non-negative, and some parameters can often be restricted by known asymptotic properties of the physical situation, such as the static values of the refractive index or similar.

The linearity of the representation formula implies the optimization problem is convex, and hence is easy to solve using convex optimization [2]. Adding linear or convex constraints does not change this property. Examples where this can be applied can be found in the study of optimal absorbers, high impedance surfaces, negative refractive index, and many other circumstances [3].

Physical Bounds of Patch Antennas

Doruk Tayli and Mats Gustafsson
Department of Electrical and Information Technology, Lund University, Lund, Sweden

Abstract— Patch antennas are widely used since their first emergence in the 70's [1, 2]. Although there is a significant amount of literature on the subject, accurate physical bounds for patch antennas do not exist. The main reason for this is the complexity of deriving the physical bounds for horizontal currents over a ground plane.

Current optimization [3] is a technique that allows the calculation of physical bounds for antennas of any geometry. Using the method of moments to compute stored electromagnetic energy matrices [3, 4] convex optimization is applied to quadratic forms of the energies to find the optimal G/Q ratio, which is the minimal Q-factor for a specified radiation pattern. It is simple to extend this technique to antennas above infinite PEC ground planes by adding the mirror currents to the Green's function.

Here we show the G/Q bound for different patch antennas above an infinite PEC ground plane. The computed physical bounds are then verified with numerical simulations using the commercial electromagnetic software FEKO [5].

Sum Rules and Physical Bounds on Frequency Selective Structures

Andreas Ericsson and Daniel Sjöberg
Department of Electrical and Information Technology, Lund University, Box 118, Lund 221 00, Sweden

Abstract—

Introduction: A frequency selective structure is an artificial electromagnetic structure that possesses selectivity with respect to incident signals of different polarization, frequency or angle of incidence. Classical frequency selective surfaces (FSS) are commonly represented as two dimensional periodic structures of conductive elements, and the design of which is thoroughly described in [1]. There it is concluded that a smaller element size leads to an improved stability with respect to the angle of incidence. Much work has been presented the last few years where the FSS elements have an extent in the direction of propagation of the incident signal, these structures are referred to as 3D frequency selective structures [2]. It is commonly stated that the three dimensional character of these structures implies an improved stability with respect to the angle of incidence, and a better agreement between the FSS performance for TE and TM illumination.

Physical Bound on the All Spectrum Transmission: In [3] it is proven that the all spectrum transmission blockage (transmission lower than a reference level T_0) of a periodic structure is bounded by the static electric and magnetic polarizabilities $\boldsymbol{\gamma}_e$, $\boldsymbol{\gamma}_m$, which in turn are bounded by the variational expressions in [4]. If a signal is incident in the xz-plane and the polarizability dyadics have vanishing off-diagonal terms, such that $\boldsymbol{\gamma}_e = \hat{\mathbf{x}}\hat{\mathbf{x}}\gamma_{exx} + \hat{\mathbf{y}}\hat{\mathbf{y}}\gamma_{eyy} + \hat{\mathbf{z}}\hat{\mathbf{z}}\gamma_{ezz}$, $\boldsymbol{\gamma}_m = \hat{\mathbf{x}}\hat{\mathbf{x}}\gamma_{mxx} + \hat{\mathbf{y}}\hat{\mathbf{y}}\gamma_{myy} + \hat{\mathbf{z}}\hat{\mathbf{z}}\gamma_{mzz}$, the total polarizability $\gamma(\theta)$ can be introduced as

$$\gamma(\theta) = \begin{cases} \gamma_{exx}\cos^2\theta + \gamma_{ezz}\sin^2\theta + \gamma_{myy}, & \text{TM} \\ \gamma_{eyy} + \gamma_{mxx}\cos^2\theta + \gamma_{mzz}\sin^2\theta, & \text{TE.} \end{cases} \tag{1}$$

This contributes to the maximum bandwidth of the transmission blockage of the FSS through the relation

$$B\ln\left(\frac{1}{T_0}\right) \leq \frac{\pi^2\gamma(\theta)}{2A\lambda_0\cos\theta} - \left(\sqrt{n_\infty^2 - \sin^2\theta} - \cos\theta\right)\frac{\pi^2 d}{\lambda_0}, \tag{2}$$

where λ_0 is the center wavelength, $B = (\lambda_2 - \lambda_1)/\lambda_0$ is the fractional bandwidth, n_∞ is the high frequency limit refractive index and A is the unit cell area of the FSS.

Application to 3D Frequency Selective Structures: The physical bound defined in (2) has been applied to a band stop FSS design. A comparison is made between the performance of the structure as a function of the angle of incidence for TE and TM illumination, with and without vias in the direction of propagation in each element. The outcome of this type of analysis is to prove the statement that when γ_{ezz} is increased, i.e., the FSS elements have an extent in the direction of propagation, the performance of the structure is improved for oblique angles of incidence, especially with respect to TM illumination.

On Multidimensional Passivity in Electrodymanics

B. L. G. Jonsson
Electromagnetic Engineering Lab, School of Electrical Engineering
KTH Royal Institute of Technology, Stockholm, Sweden

Abstract— Passivity of a system in a time variable is a key ingredient in the recent derivation of several interesting bandwidth limitations results. Passivity together with linearity and time-invariance ensure that the time-Laplace transform of the system response, of the underlying physical system, is a Herglotz function. These Herglotz functions have several attractive properties working towards the goal of finding a bandwidth limitation. They include a representation theorem and certain sum-rules. Explicit examples are given in the talk. These properties have been utilized to obtain bandwidth performance bounds. In electromagnetic theory we note that the Gustafsson bound [1] for small antennas is derived this way, similarly we have Rozanovs bound [2] on absorbers and the array figure of merit [3] for array antennas over a ground plane.

The concept of passivity carry over to multi-dimensional systems in the sense of Vladimirov [4], where it is shown that equations and systems with a kernel with support in a time-like cone, e.g., the light cone, have similar attractive properties. That is the multidimensional Laplace-transform over the cone is an analytic function in a tubular neighborhood of the dual of the cone. Representation theorems for this kind of functions are also known, however with weaker properties than in the one-dimensional case.

The goal of the presentation is to compare similarities and differences between the time-passivity and the corresponding multi-dimensional passivity. We discuss here how passivity carry over to multidimensional systems and if these properties are sufficient to obtain physical bounds on multidimensional electromagnetic systems. We investigate possible candidates that might have such a physical bound, and investigate what such bounds could limit. If time permit we will also discuss matrix and operator valued convolution systems.

Investigation and Comparison between Radiation Center and Phase Center for Canonical Antennas

Casimir Ehrenborg[1], **Jonas Fridén**[2], **and Gerhard Kristensson**[1]

[1]Department Electrical and Information Technology
Lund University, Box 118, SE-221 00 Lund, Sweden
[2]Ericsson Research, Ericsson AB, Gothenburg, Sweden

Abstract— The radiation center was introduced by Fridén and Kristensson in [1]. The need to define this parameter arose from the ambiguity of the phase center definition. The phase center is traditionally calculated by manually selecting a region in the main lobe of the radiation pattern, and minimizing the phase of the co-polarized field component. The choice of angular region to use is not obvious, and automatic calculation of beam width is hard to implement as a robust numerical algorithm. In contrast, the radiation center algorithm presented in [1] provides a unique point corresponding to the minimum of the squared angular momentum of the field.

This presentation investigates results from radiation center and phase center calculations for canonical antennas with frequencies varying inside their operational bands. The two methods are compared and evaluated against the expected phase center positions and the radiation center is investigated as a replacement parameter to the phase center. In [1] the radiation center was calculated using measured data with unknown errors in the absolute position of the antenna in the coordinate system. Therefore, in this study the concept is applied to simulated far-field patterns wherein the position of the antenna is known.

[1]Department of Electrical and Electronic Engineering, The University of Hong Kong, Hong Kong, China
[2]Department of Electrical and Computer Engineering
University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA

Abstract— Recently, electromagnetics related multiphysics, such as quantum and thermal electromagnetics, have gained more and more attention in academy as well as industry. The interaction between Maxwell's equations and other equations should be considered in a consistent way. In this case, a general purpose differential electromagnetic solver is highly demanded. However, the null space of the double-curl operator has been a bottleneck in solving Maxwell's equations for magnetostatic, quasistatic, and eigenvalue problems. Based on the vector calculus language, various gauge conditions and spectral shift methods have been proposed. From the viewpoint of differential forms, these gauge/shift techniques can be unified under the same framework. Then, a compatible finite element discretization of the governing equation can be obtained in a straightforward manner.

In this work, we apply a generalized gauge condition to the variable of interest, e.g., the magnetic vector potential A or the electric field intensity E. Hence, a penalty term is enforced as a counterpart of the double-curl term. As the null space of the double-curl term belongs to the range of the penalty term, a unique solution and better convergence can be achieved. Different from the previous gauge/shift techniques, the proposed gauge condition is in a generalized form. More importantly, the penalty term can be interpreted using the concept of differential forms, which inspires compatible expansions of the primary and intermediate variables in terms of edge and nodal Whitney elements, respectively. To reduce the computational cost brought by the inverse of a mass matrix, which is involved to remove the intermediate unknowns, a nearly diagonal inverse can be constructed due to the strong localization property of the mass matrix. Finally, the condition of the matrix system is significantly improved and the sparse nature of finite element method is greatly preserved. Numerical results successfully demonstrate the stable and efficient performance of the proposed method in solving magnetostatic problems and low-frequency circuit problems.

Computing the Electric and Magnetic Green's Functions in General Gyrotropic Media

V. G. Yakhno[1] and B. Çiçek[2]

[1]Electrical and Electronics Engineering Department, Dokuz Eylul University, Turkey
[2]Graduate School of Natural and Applied Sciences, Dokuz Eylul University, Turkey

Abstract— The study of the electromagnetic fields in gyrotropic materials is an important issue of the recent electromagnetic theory [1, 2]. The electric and magnetic fluxes **D** and **B** in general gyrotropic materials have the following form

$$\mathbf{D} = \varepsilon_0 \bar{\bar{\varepsilon}} \mathbf{E}, \quad \mathbf{B} = \mu_0 \bar{\bar{\mu}} \mathbf{H},$$

where **E** and **H** are the electric and magnetic fields, respectively; positive constants ε_0 and μ_0 are defined as the permittivity and permeability of free space; the relative permittivity and permeability matrices $\bar{\bar{\varepsilon}}$ and $\bar{\bar{\mu}}$ have the following form (see, for example, [1]):

$$\bar{\bar{\varepsilon}} = \begin{pmatrix} \epsilon_{11} & \epsilon_{12} + ig_3 & \epsilon_{13} - ig_2 \\ \epsilon_{12} - ig_3 & \epsilon_{22} & \epsilon_{23} + ig_1 \\ \epsilon_{13} + ig_2 & \epsilon_{23} - ig_1 & \epsilon_{33} \end{pmatrix}, \quad \bar{\bar{\mu}} = \begin{pmatrix} \mu_{11} & \mu_{12} + ih_3 & \mu_{13} - ih_2 \\ \mu_{12} - ih_3 & \mu_{22} & \mu_{23} + ih_1 \\ \mu_{13} + ih_2 & \mu_{23} - ih_1 & \mu_{33} \end{pmatrix}.$$

The main objects of our paper are the electric and magnetic Green's functions for Maxwell's partial differential equations in the general gyrotropic media. Green's functions for equations of mathematical physics can be considered as a useful tool for different methods in the presentation of acoustic, electromagnetic, elastic and other fields, in particular, for the method of moments and boundary element method. The dyadic Green's functions for an electrically gyrotropic medium with particular form of $\bar{\bar{\varepsilon}}$ and $\bar{\bar{\mu}}$ have been derived by matrix method with dyadic decomposition in [3–5]. The time-harmonic Green's dyadics have been constructed in closed form for a particular case of homogeneous gyrotropic materials by Fourier transform approach in [6]. However, the numerical computation of the Green's functions (fundamental solutions) of Maxwell's equations in general gyro-electric materials is not known. Moreover the numerical methods for the space of tempered distributions are not developed till now. In our paper we suggest a method of an approximate (regularized) computation of the infinite-body Green's functions for the time-harmonic Maxwell's equations in the general gyrotropic media. This method is based on the Fourier transform meta-approach where the Fourier image of the Green's function is computed by some matrix transformations and symbolic computations in MATLAB. After that the inverse Fourier transform is computed in an regularized (approximate) form. The parameters of the regularization have been chosen by the comparison of the regularized Green's function with Green's function obtained by the explicit formula for the isotropic case. The approximate computation of the inverse Fourier transform has been implemented by MATLAB tools. The computational experiments are presented in the paper and confirm the robustness of the method.

Diverging and Converging Beam Diffraction by a Wedge. Part I: The Multipole Expansion Approach

Michael Katsav[1], **Ehud Heyman**[1], **and Ludger Klinkenbusch**[2]

[2]Institute of Electrical and Information Engineering
Christian-Albrechts-Universität zu Kiel, Kaiserstr. 2, D-24143 Kiel, Germany

Abstract— The complex source (CS) method provides a canonical setting for the rigorous study of beam diffraction phenomena [1, 2]. In that approach one substitutes CS coordinates into the conventional real-source Green function solution of a specific environment, thereby converting the response of that environment to a spherical wave excitation into the response due to a collimated beam-wave excitation. Physically, the extension of the real source to the CS case implies that the field in the CS case is generated by an extended source distribution in real space (a disk or a line in the 3D or 2D configurations, respectively), and that the wave-field emerges outside (i.e., causally) with respect to this source distribution [4, 5]. This implies that the field emerging from the source is diverging.

In a recent paper [3], we have used this approach for the analysis of two dimensional (2D) beam diffraction by a perfect conducting wedge as a function of the beam parameters: collimation, direction and displacement from the edge. In that paper we have compared three analytic techniques: (i) complex multipole expansion, (ii) complex Sommerfeld integral, and (iii) complex ray analysis augmented by uniform theory for complex ray diffraction. In all these solutions we used the analytical continuation of the conventional real-source Green function to CS case. However, as follows from the discussion in the previous paragraph, the field is emerging from the source distribution toward the wedge, so that the beam is diverging as it hits the wedge.

We note that in this case the incident beam converges to a complex "sink" which is located in the shadow zone of the wedge, hence a straightforward extension of the Green's function solution to CS case is not applicable. However, it has been shown recently that the complex multipole expansion can describe converging beam diffraction but only if the complex source coordinates are defined in a particular way [6]. Our goal in the present two-part paper is to explore the application of the complex multipole expansion in the cases where the incident beam is diverging or converging as it hits the wedge, and in particular find the proper definition of the complex source coordinates for the diverging or converging beam cases that yield physically meaningful solutions. In the second part of this two-part paper [7] we shall examine the validity of these solutions by comparing them to the plane wave spectrum and complex ray solutions.

On the Theory of Transition Radiation in the Anisotropic Magneto Dielectric Plate in a Waveguide

Eduard A. Gevorkyan
Moscow State University of Economics, Statistics and Informatics
7, Nezhinskaya Str., Moscow 119501, Russia

Abstract— The transition radiation of charged particle in a regular waveguide of arbitrary cross section filled with anisotropic magneto dielectric plate of finite length is considered. It is assumed that the charged particle crosses the plate perpendicular to the waveguide axis. The wave equations and the analytical expressions for the transverse-electric (TE) field in various regions in the waveguide are obtained. Taking into account the obtained analytical expressions for TE field and using the Poynting vector the energy of transition radiation of moving particle is calculated. The case of rectangular waveguide is considered and the energy of transition radiation is analyzed in this case. The analytical expression of the transition radiation of charged particle for the case of thin plate in the waveguide (the wavelength in the plate is much grater than the length of the plate) is found. The possibility of appearance of Vavilov-Cerenkov radiation is analyzed. The conditions under which it occurs the Cerenkov radiation are found. The frequency of Cerenkov radiation is determined too.

Optical Soliton Perturbation with Semi-inverse Variational Principle

Anjan Biswas
Department of Mathematical Sciences, Delaware State University, Dover, DE 19901-2277, USA

Abstract— This talk will be on perturbed nonlinear Schrodinger's equation that models the propagation of solitons through optical fibers. The semi-inverse variational principle is employed to obtain analytical bright soliton solution in presence of several perturbation terms. This discussion will be carried out with five forms of nonlinear media. They are Kerr law, power law, parabolic law, dual-power law and log law nonlinearity. The constraint conditions (integrability criteria) will emerge for the soliton solutions to exist.

Scattering of an Obliquely Incident Electromagnetic Plane Wave by an Array of Magnetized Plasma Cylinders

V. A. Es'kin, **A. V. Ivoninsky**, **and A. V. Kudrin**
University of Nizhny Novgorod, Russia

Abstract— In recent years, the problem of electromagnetic wave scattering by arrays of gyrotropic elements has attracted increased interest. This interest is stimulated by numerous applications of the corresponding structures in, e.g., lithography, near-field microscopy, wave diagnostics of media, information processing and transmission, etc. [1–3]. Despite a significant progress in the studies of electromagnetic wave scattering by arrays of nongyrotropic elements [1], the recently obtained results for arrays of gyrotropic scatterers have revealed a variety of new interesting features [2, 3]. In particular, it has been found that the presence of gyrotropic properties in photonic crystals can significantly influence the reflection and transmission of electromagnetic waves [2]. For example, nonreciprocal properties of such crystals can be used for creating materials with one-path transmission of electromagnetic energy, as well as slow-wave systems and wideband isolators in the optical band. Moreover, it can be expected that the joint contribution of the individual and collective resonance scattering mechanisms to the diffracted field of an array containing frequency-dependent resonance elements can lead to some interesting phenomena which are yet to be determined.

It is the purpose of the present work to study the resonance scattering of an obliquely incident, linearly polarized electromagnetic plane wave by an equidistant array of parallel gyrotropic cylinders. The problem is analyzed using the scattering matrix method. As a gyrotropic medium filling the scattering elements of the array, we consider a cold collisionless magnetoplasma. The solution for the scattered field in the case of incidence at an arbitrary angle to the axes of the cylinders has been obtained. It is demonstrated that in this case, the scattered field is hybrid, i.e., the longitudinal (cylinder-aligned) components of both the electric and magnetic fields are nonzero. Analysis of the frequency dependences of the scattering coefficients of the electric- and magnetic-field components shows that near the resonant frequencies of the array, frequency ranges exist in which the absolute values of these coefficients are much smaller than the field amplitude in the incident wave. Moreover, at the resonant frequencies of the array, these coefficients vanish. Thus, the interaction of the individual and collective scattering mechanisms can lead to a significant weakening and even suppression of the scattered field. In the opposite case, the interaction of the individual and collective scattering mechanisms can lead to enhancement of the scattered field compared with the case of a single cylinder. It is shown that in the case of oblique incidence of the H-polarized wave on the array, the longitudinal component of the electric field can have, under certain conditions, a layered structure, whereas the longitudinal component of the magnetic field has a 2D-periodic chessboard-type structure.

Abstract— The zeros of Kummer confluent hypergeometric function $\Phi(a,c;x)$ with $a=c/2-jk$ — complex, c — real, ($c\neq l$, $l=0,-1,-2,-3,\ldots$), k — real, $x=jz$, z — real, positive and $n=1,2,3,\ldots$) are of special interest in the theory of anisotropic waveguides [1–6]. Until now the attention has been the focused mainly on the positive purely imaginary zeros $\zeta_{k,n}^{(c)}$ of $\Phi(a,c;x)$ with respect to its independent variable z [2–6]. It has been established that for them it holds: $\lim\limits_{k_+\to+\infty}\zeta_{k_+,n}^{(c)}=+\infty$ and $\lim\limits_{k_-\to-\infty}\zeta_{k_-,n}^{(c)}=0$, where the subscripts "+" ("−") label quantities, corresponding to positive (negative) sign of k ($k_+>0$ and $k_-<0$) [2]. The numerical analysis has shown that if $c\neq l$ the sequences $\{K_-(c,n,k_-)\}$ and $\{M_-(c,n,k_-)\}$ ($K_-(c,n,k_-)=|k_-|\zeta_{k_-,n}^{(c)}$ and $M_-(c,n,k_-)=|a_-|\zeta_{k_-,n}^{(c)}$) are convergent provided $k_-\to-\infty$, though the multiples in the products $|k_-|\zeta_{k_-,n}^{(c)}$ and $|a_-|\zeta_{k_-,n}^{(c)}$ become infinitesimal, resp. unrestricted. They tend to finite real positive limits, called $L_1(c,n)$ numbers (denoted by $L(c,n)$, too) [2, 6–9]. The definition of the latter has been extended for $c=l$, as well. Later on a similar property of the positive purely imaginary zeros in z of certain functions, incorporating several complex confluent and possibly also a few real cylindrical functions of specially chosen parameters has been found out. The discussion has been performed in the real case, too [8–11].

Recently, an investigation of the positive purely imaginary zeros $\kappa_{z,n}^{(c)}$ in k of the Kummer function of the parameters, pointed out above has been made, assuming z as parameter. It has been observed that on condition that z diminishes, $\kappa_{z,n}^{(c)}$ grow monotonously. This hinted that the quantities $\kappa_{z,n}^{(c)}$ might possess features, resembling the ones of the zeros $\zeta_{k,n}^{(c)}$ (new families of numbers may be determined, connected with $\kappa_{z,n}^{(c)}$) [12].

In this paper the theorem for existence and for the basic properties of the $G_1(c,n)$ numbers (new real positive numbers, connected with the zeros $\kappa_{z,n}^{(c)}$ of $\Phi(a,c;x)$ in which a, c and x take the values, indicated above, is formulated and proved numerically. Its statement is accepted as a general definition of the latter. The theorem is composed of three lemmas. Lemmas 1 and 2 demonstrate the existence of quantities and determine them in case $c\neq l$ and $c=l$ (in which $\Phi(a,c;x)$ is not defined) as the limit of the infinite sequence of real positive numbers $\{R(c,n,z)\}$, ($R(c,n,z)=z\kappa_{z,n}^{(c)}$) for $z\to0$, and $\{G_1(l-\varepsilon,n)\}$ and $\{G_1(l+\varepsilon,n+1)\}$, ($\varepsilon$ — infinitesimal real positive number) for $\varepsilon\to0$, resp. Lemma 3 reveals the main features of the numbers (recurrence relation, formula for symmetry and link of some of them with the Ludolphian number). Detailed Tables and graphs illustrate the influence of parameters c and n on $G_1(c,n)$. The application of numbers in the theory of azimuthally magnetized circular ferrite waveguides, propagating normal TE_{0n} modes is demonstrated.

Diffraction Radiation Phenomena: New Methods for Physical and Engineering Analysis

Merey Sautbekova[1], **Seil Sautbekov**[1], **Yuriy Sirenko**[1, 2], **and Alexey Vertiy**[1]

[1]L. N. Gumilyov Eurasian National University, 2, Mirzoyana St., Astana 010008, Republic of Kazakhstan
[2]A. Ya. Usikov Institute of Radiophysics and Electronics, National Academy of Sciences of Ukraine

Abstract— Advances in electrodynamic theory of gratings play an important role in the development of topical areas of science and technology. Nowadays, optics and spectroscopy, physics and engineering of millimeter and submillimeter waves, high-power electronics, quantum radio physics and solid state physics, acoustics and resonance quasioptics benefit from methods, models and results of the grating theory both in frequency and time domains. Gratings' abilities to change their transparency over maximal limits and to transfer energy between waves propagating in different directions in a controlled manner allows much room for utilizing them as polarization and frequency filters, anti-reflection and scattering coatings, screens of various types and purposes, selective mirrors for dispersive open resonators, pattern-forming planar and cylindrical structures. One major field of application for diffraction gratings is antenna equipment, in particular, antennas operating on the effect of diffraction radiation aka diffraction antennas. When this effect occurs, an exponentially decreasing surface eigenwave of any open guiding structure (or an eigenfield of charged-particle beam in diffraction electronics) is transformed by a nearby periodic structure into a radiation field, which characteristics (directivity, energy efficiency, frequency range, scanning sector, etc.) are optimized to suit practical requirements.

In this communication, we consider in details the diffraction radiation effect, and new methods for analysis and model synthesis of diffraction antenna components and units. We presented the models making possible more detailed observations of the processes associated with near-field to far-field conversion by infinite and finite periodic structures. For the first time all these problems were considered using rigorous models exploiting exact absorbing conditions. The theoretical results have been obtained in 2-D for planar and axially-symmetrical objects. Analysis of these objects (finite and infinite gratings, planar and circular dielectric waveguides, etc.) is based on solutions of open initial boundary value problems, which computational space is truncated by exact absorbing conditions.

Inverse Spectral Theory and Kramers-Kronig Relations

G. F. Crosta
University of Milan Bicocca, Milan, Lombardy, Italy

Abstract— Inverse problems aimed at locating cracks and voids inside a dielectric medium by means of electromagnetic waves involve knowledge of transmission eigenvalues. The subject has been actively investigated by many Authors for some years and results have been presented in articles and books. Unfortunately, the frequency dependence of dielectric permittivity and magnetic permeability of the material has not been taken into account. A theorem which provides existence and asymptotic properties of real transmission eigenvalues is shown to be physically inconsistent, because it ignores the Kramers-Kronig relations.

Algebraic Regularization of Universal Functions in EM via Self-induced Hadamard Finite Parts

A. R. Baghai-Wadji
University of Cape Town, South Africa

Abstract— In boundary element method applications there are contradicting requirements which need to be accommodated skillfully in order to achieve high accuracy and high speed at the same time. Regarding acceleration of computations, it is desirable, besides parallelization and other conventional measures, to extract costly "universal" features from the computations which are common to a certain class of problems. If successful the resulting Universal Functions (UFs) can be pre-calculated and stored and referred to whenever necessary. As can be shown the introduction of UFs, however, requires additive factorization of terms, leading to high-order algebraic singularity in infrared region in spectral domain (zero and small values of the wavenumbers). Thereby, the algebraic order of the additional singularity depends on the degree of smoothness of the basis- and testing functions employed — the smoother the basis and testing functions the higher the order of singularity at the origin of the coordinate system in the spectral domain. On the other hand smooth basis- and weighting functions improve the convergence of the involved Fourier-type integrals algebraically in ultraviolet region (large values of the wavenumber in spectral domain). The main result in this contribution is the fact that all the aforementioned seemingly contradicting requirements can be reconciled naturally. The magic is done by recognizing that Hadamard finite parts appear in the introduced Universal Functions automatically, with one additional pleasant surprise: Ordinarily Hadamard finite parts technique, as the name implies, considers finite parts of infinite integrals, thus throwing away the infinities in the calculations. In the proposed procedure the infinities add up to zero exactly. Finally it should be pointed out that the Hadamard finite parts in the UFs are induced by the basis- and testing functions, thus, justifying the "self-induced" property in the title.

In an accompanying paper a second renormalization technique has been proposed which ensures exponential decay of dyadic Green's functions in ultraviolet region in spectral domain. The exponential regularization has its genesis in the construction of problem-specific Dirac delta functions, and it tempers the divergent behavior of Green's functions. In contrast the algebraic regularization, proposed in this contribution, has its origin in the smoothness properties of the chosen basis- and weighting functions. Consequently, the next logical question is whether or not the two regularization techniques, exponential and algebraic, can be combined to even further enhance the quality of our computations. The answer is unconditionally affirmative. Thus the combined exponential and algebraic regularization techniques enable ultra precise calculations of the near-fields in EM simulations while permitting the construction of Universal Functions. Furthermore, it is worth emphasizing that both regularizations techniques apply to closed-form Green's functions as well Green's functions which can be calculated only numerically. The latter property is crucially important: it enables the simulation of nanoscale devices involving complex media.

On the Accuracy of Method of Moments for Solution of Full 3D Vectorial Electromagnetic Forward Scattering Problem

O. Güren[1], **M. N. Akıncı**[2], **and M. Çayören**[2]

[1]Electromagnetic Research Lab., Istanbul Technical University, Turkey
[2]Department of Electronics and Communication Engineering, Istanbul Technical University, Turkey

Abstract— In this communication, an analysis on the accuracy of the method of moments solution of full 3D vectorial electromagnetic forward scattering problem is presented. Although different mathematical techniques are developed for determination of the error rate of method of moments [1–6], this paper presents a numerical approach to this problem. In contrast to weak formulations of method of moments as in [7], we use a dyadic Green function based approach. We adopted the pulse functions as basis functions and obtained equations are weighted by the dirac-delta functions. In fact such a choice obliges us to calculate the hypersingular integrals of the components of the well known dyadic Green function. We utilize from [8] for the Cauchy principal value of these singular integrals. If the scatterer is divided into N many cells and a direct Gauss-Jordan inversion scheme is employed for the solution, then the resultant equation system requires a memory allocation of on the order of $O(N^2)$ and has a computational complexity of on the order of $O(N^3)$. To be able to decrease memory requirement to on the order of $O(N)$ and computational complexity to on the order of $O(N\log(N))$, bi-conjugate gradient method is applied instead of direct Gauss-Jordan inversion. Furthermore, the matrix multiplications are converted to spatial convolutions, which can be evaluated by the fast Fourier transform procedure. An accuracy analysis is made by comparing the simulated fields with the analytical expressions of the scattering field from a dielectric sphere. In particular, the accuracy analysis includes the following parts:

- Accuracy rate vs. the dielectric contrast between sphere and medium (Here the frequency of illumination and the size of the sphere are constant).
- Accuracy rate vs. the frequency of illumination (Here the dielectric contrast between sphere and medium and the size of the sphere are constant).
- Accuracy rate vs. the size of the sphere (Here the dielectric contrast between sphere and medium, the frequency of illumination are constant).

The results show that such an dyadic Green function based implementation of the method of moments works sufficiently well for a wide range of various parameters.

Accurate Determination of Surface Electric Fields for 2D Conformal Finite Difference Time Domain Simulations

M. C. Lin[1] and C. D. Zhou[2]

[1]Department of Electrical and Biomedical Engineering
Hanyang University, Seoul 133-791, Korea

Abstract— Modeling an electromagnetic (EM) structure with curved boundaries using a conformal finite-difference time-domain (CFDTD) method retains a second order accuracy while using a staircased FDTD one only gives a first order accuracy. Although the frequencies and EM fields residing inside the spatial domain determined in the CFDTD simulation are very accurate, the calculation of surface electric fields is performed by interpolation methods, and therefore usually gives unsatisfied results. In this work, a new algorithm possibly being able to accurately determine surface electric fields near a curved surface has been developed and tested. The preliminary benchmark results show a convergence that the surface electric fields can be calculated as accurately as higher than 99% using a medium size grid in 2D. A more rigorous benchmark is used for the validation of this approach and an extension to 3D counterpart is under consideration. Accurate determination of surface electric fields in CFDTD simulations is important for a lot of research studies such as surface breakdown, field emission, plasma wall interaction and ohmic heating, etc.. Detailed algorithm and benchmark results will be presented.

Fast Model Order Reduction Approach to Uncertainty Quantification in Electrokinetics

Lorenzo Codecasa and Luca Di Rienzo
Politecnico di Milano, Milan, Italy

Abstract— Electromagnetic computations rely on the perfect knowledge of material parameters. However, for a wide range of examples in electrical engineering, some uncertainty should be associated with that knowledge in the modeling process. In order to quantify the uncertainty of the output quantities of interest coming from the lack of knowledge of the input material parameters, the spectral stochastic finite element method, based on Polynomial Chaos Expansion (PCE), can be applied. This method, in both the intrusive and non-intrusive forms [1], allows to dramatically reduce computational time with respect to Monte Carlo (MC) method, in many electromagnetic problems. Nevertheless, in many situations, computational complexity can still be prohibitively large.

In this paper, uncertainty quantification problems due to random material parameters are considered in electrokinetics. For such problems a novel approach based on Model Order Reduction (MOR) is proposed. The starting point is an nonintrusive PCE method, in which the PCEs of variables are estimated from the solutions to the deterministic electrokinetic problems for all values of the random material parameters in a sparse grid. The main idea of the proposed algorithm is that of reducing the number of solutions of such deterministic electrokinetic problems by constructing a parametric reduced order model, which is used to approximate the solution to the deterministic electrokinetic problems. Such parametric reduced order model is tailored to approximating with chosen accuracy the deterministic elecrokinetics problems for the values of the random material parameters in the chosen sparse grid. The parametric reduced order model is generated in an efficient way by solving a reduced number of deterministic elecrokinetics problems with respect to that in the nonintrusive PCE approach. Moreover the computational cost for the solutions to the deterministic elecrokinetics problems required for constructing the parametric reduced order model is optimized by exploiting the relatedness among the solutions to the deterministic electrokinetics problems for different values of the random material parameters.

The proposed MOR approach has been validated by modeling a simplified geometry of a typical system for resistance welding [2]. In this situation the proposed MOR approach allowed to reduce the compuational time by about two orders of magnitutude with respect to that of standard nonintrusive PCE approach, maintaining the same level of accuracy. The storage requirement of the proposed approach is comparable to that for a single deterministic electrokinetics problem. The proposed approach thus seems a novel promising candidate for uncertainty quantification analysis in electrokinetics. The extension of the proposed approach to more general electromagnetic problems seems feasable and is currently under investigation.

Reduced Basis Model Reduction for Maxwell's Equations in Dispersive Media with Stochastic Coefficients

Martin Hess and Peter Benner
Max Planck Institute for Dynamics of Complex Technical Systems, Germany

Abstract— The simulation of the propagation of an electromagnetic pulse through linear, temporally dispersive media (like water) or systems (like a dielectric waveguide) is a typical problem of electromagnetics.

Consider the Maxwell-Debye model formulated in second-order form in the electric field E

$$\begin{aligned}\frac{1}{\mu_0}\nabla\times\nabla\times E+\epsilon_0\epsilon_\infty\partial_t^2 E &= f-\partial_t^2 P,\\ \partial_t P+\frac{1}{\tau}P &= \frac{\epsilon_0\left(\epsilon_s-\epsilon_\infty\right)}{\tau}E,\end{aligned}$$

with polarization P, relaxation time τ, relative permittivity at low-frequency limit ϵ_s and relative permittivity at high-frequency limit ϵ_∞, and a broadband input source f, which is modeled as a Gaussian pulse [1]. The equations are discretized with Nédélec finite elements of first order over a 2D unit square. Dirichlet zero boundary conditions (i.e., PEC, perfectly electric conducting) are imposed on all boundaries.

The model is parametrized by τ and $\Delta_\epsilon=\epsilon_s-\epsilon_\infty$, defining the 2-dimensional parameter domain D. Using a greedy sampling driven by an error indicator, we seek to generate a reduced model which accurately captures the dynamics in the parameter domain D [2]. We compare different greedy strategies and projection spaces to achieve an accurate low order model. Typically, the reduced basis model reduction reduces the model order by a factor of more than 100, while maintaining an approximation error of less than 1%. The error indicator evaluates the residual over all timesteps and finds the maximum over the parameter domain D. The maximum parameter location is then used to iteratively enrich the reduced basis space.

As an extension, we consider the parameters as random variables with an underlying distribution. We use stochastic collocation and Monte Carlo simulations to estimate the statistics of the system. This computationally expensive procedure becomes feasible by employing accurate reduced order models [3]. The statistical analysis will enable to simulate the behaviour of the electromagnetic system under uncertainties.

Uncertainty Quantification for Complex RF-structures Using the State-space Concatenation Approach

J. Heller, **T. Flisgen**, **C. Schmidt**, **and U. van Rienen**
Institute of General Electrical Engineering, University of Rostock
Albert-Einstein-Strasse 2, Rostock 18059, Germany

Abstract— In various applications of computational engineering and accelerator physics, the computation of the electromagnetic behavior of a structure is of crucial importance for the design and operation. The electromagnetic properties of the structure depend on its geometry, which, for real-life radio-frequency (RF) structures, generally deviates from their design values due to fabrication tolerances and operation. To make assessments about the effects of such deviations as well as to employ robust optimizations, a so-called uncertainty quantification (UQ) is applied. For large and complex structures such computations are heavily demanding and cannot be carried out using standard brute-force approaches. In this paper, we propose a combination of established techniques to perform UQ for long and complex structures, where the uncertainty is located only in parts of the structure. As exemplary structure, we investigate the third-harmonic cavity, which is being used at the FLASH accelerator at DESY, assuming an uncertain geometry of the left higher-order mode coupler. The investigation is carried out using the so-called polynomial chaos expansion (gPC). For that, the repeated numerical solution of Maxwell's equations is necessary. Usually, such investigations are carried out on supercomputers or small computer clusters with heavily parallelized code. Due to the fact that maximum-performance computational infrastructure is scarce and expensive, the electromagnetic properties are being computed on standard workstation computers using a newly proposed non-overlapping domain decomposition scheme named State-Space Concatenation (SSC) which is based on model-order reduction of the decomposed segments. Using the SSC scheme has the most important advantage that only the uncertain part of the structure, in our case the left coupler, needs to be recomputed when using a non-intrusive scheme like gPC. In comparison to the huge computational demand of a straightforward simulation, the combination of uncertainty quantification and model-order reduction allows for a reasonable improvement of the computational efficiency. Both schemes can be separately applied to structures related to accelerator physics. Yet, just their combination will enable the investigation of long and complex structures beyond the scope of standard approaches.

Application of Krylov-type Parametric Model Order Reduction in Efficient Uncertainty Quantification of Electro-thermal Circuit Models

Y. Yue[1], **L. Feng**[1], **P. Meuris**[2], **W. Schoenmaker**[2], **and P. Benner**[1]

[1]Max Planck Institute for Dynamics of Complex Technical Systems
Sandtorstr. 1, Magdeburg 39106, Germany
[2]MAGWEL NV, Martelarenplein 13, Leuven B-3000, Belgium

Abstract— Electro-thermal analysis is crucial in designing systems such as power-MOS devices used in energy harvesting and RF-circuitry in wireless communication. To design systems robust to device variations due to the fabrication process, uncertainty quantification plays an important role to quantify the uncertainties of the system output propagated from the process variations. However, simulation analysis of electro-thermal systems is already computationally demanding because the mathematical model is derived from a fine 3D mesh of a multi-layered structure consisting of dielectric, vias, contacts, and metal interconnection. The computational cost of uncertainty quantification is even higher since it requires simulating the model at many parameter samples, or simulating a coupled system with a much higher dimension. To reduce the high computational cost, we use parametric model order reduction techniques, which proves to be efficient in many application fields such as circuit simulation, acoustics, and structural vibrations. A parametric model order reduction method builds a reduced model that can capture the system dynamics regardless of parameter changes within a certain range. In this work, we use a Krylov-type parametric model reduction method, whose goal is to match the (cross-)moments of the state vector, because of its modest requirements on system properties and low computational complexity. For our test case, which is a nonlinear electro-thermal system with one-way coupling from the electrical part to the thermal part, a parametric reduced model of a low order exhibits high accuracy over a very large parameter range in approximating the original high-order model. We use the parametric reduced model to accelerate two methods for uncertainty quantification, namely a Latin hypercube sampling method and a stochastic collocation method. Numerical results show that for both methods, uncertainty quantification based on a reduced model reproduces the results of that based on the original model, while leading to significant speedup compared to the latter.

Meshing Technique for Efficient Macromodel Cloning in FEM Analysis of 3D Structures

G. Fotyga, J. Grzybek, W. Dembinski, P. Bielski, and K. Nyka
Faculty of Electronics, Telecommunications and Informatics, Gdansk University of Technology, Poland

Abstract— The finite element method (FEM) is regarded as one of the most powerful and flexible numerical techniques in computational electromagnetics. However, it becomes time and memory consuming, while analyzing complex multiscale problems. We present a novel method of mesh generation, which is dedicated to analysis of microwave and photonic structures, that contain many identical elements (in terms of the geometry and the electric properties), such as: vias in SIW circuits, holes in PBG structures, tuning elements in waveguide filters, etc.. The influence of each of these elements on the electromagnetic field in the entire domain (structure) can be represented by means of the small dense FEM matrices, called macromodels (macroelements), which are obtained using the model order reduction (MOR). The proposed approach takes advantage of the fact that in the structures which contain many identical elements, one macromodel can be used to capture the electromagnetic behavior of many identical subregions. This operation is called a macromodel cloning. It requires creating an algorithm that allows for embedding one macromodel in multiple locations within the structure. The difficulty is associated with potentially nonconforming 2-D meshes on the boundaries of subregions, in which the clone of the macromodel is embedded. To overcome this problem, we developed a special tetrahedral meshing procedure, which allows one to establish an identical surface mesh on the boundaries of selected subdomains. The combination of these three techniques (3D-FEM, MOR with cloning, meshing technique) reduces the computation time and memory requirements significantly and makes it a promising method to incorporate into a CAD optimization tool.

Circuit Understanding for Electromagnetics via the Reduced-basis Method

Valentín de la Rubia
Departamento de Matemática Aplicada, Universidad Politécnica de Madrid, Spain

Abstract— Finite Element Methods (FEM) have proven to be robust in solving the time-harmonic Maxwell's equations for the analysis of microwave filters and diplexers. Nowadays, microwave engineering relies on full-wave analysis not only to accurately predict the electrical behaviour prior to construction of microwave circuits, but also to actually design their electrical response. However, still we have little knowledge on how electromagnetics actually behaves, and only rather experienced microwave engineers are able to develop high-demanding specification designs. If only a link between electromagnetic phenomena and circuit behaviour were established, all our expertise in circuit theory could be used for electromagnetics. This is how microwave engineering is working nowadays, but this link is only based on approximations.

In this work, the electromagnetic behaviour in microwave filters and diplexers is described in terms of circuit theory. A transversal coupling matrix gathering all electromagnetic phenomena within a frequency band is found. As a result, further insight from the microwave point of view arises. A Finite Element Method approach is carried out for the electromagnetic analysis and a reliable reduced-order model for fast frequency sweep is proposed. The ingredients of this methodology are: 1) the use of field solutions at given frequencies as basis functions to reduce the original system, 2) adaptively choosing the field solution frequency samples, 3) evaluation of the residual error of the reduced field solution to determine the convergence of the reduced-order model in the frequency band of interest and 4) change of basis in the reduced-order model to get a transversal coupling matrix description of electromagnetics.

Once the reduced-order model is obtained, which is a reliable surrogate of the original Maxwell problem in the frequency band of interest, further manipulations are carried out to get further insight in the Maxwell problem. It is known that output ports in microwave filters and diplexers do not see individual resonators in the microwave circuit, but global eigenresonances. For the sake of circuit understanding, it is then important to force this global eigenresonance representation of the Maxwell problem.

Several microwave filters and diplexers, made up of dieletric resonators or dual-mode resonances, will illustrate the capabilities of this approach.

Robust Shape Optimization of Accelerator Magnets

O. Lass[1], **U. Römer**[2], **and S. Schöps**[3]

Dolivostr. 15, Darmstadt 64293, Germany
[2]Institut für Theorie Elektromagnetischer Felder, Technische Universität Darmstadt
Schlossgartenstr. 8, Darmstadt 64289, Germany
[3]Graduate School of Computational Engineering, Technische Universität Darmstadt
Dolivostr. 15, Darmstadt 64293, Germany

Abstract— Bending and focusing magnets are among the most important and expensive equipment used in particle accelerators. Particle beam dynamics rely on a very high field homogeneity, that can be critically affected by uncertainties in both material and geometry. We discuss shape optimization to achieve a high field homogeneity, insensitive to stochastic influences.

In many cases the underlying field distribution can be accurately described using a magnetostatic formulation. Incorporating uncertainties results in a stochastic partial differential equation. Using the magnetic vector potential $\vec{A}$, the formulation reads as

$$\nabla \times \left(\bar{\bar{\nu}}(\omega,\vec{x})\nabla \times \vec{A}(\omega,\vec{x})\right) = \vec{J}(\vec{x}) - \nabla \times \vec{H}_c(\omega,\vec{x}), \quad \text{in } D, \tag{1}$$

$$\vec{n} \times \vec{A}(\omega,\vec{x}) = 0, \quad \text{on } \partial D. \tag{2}$$

In (1), modeling linearization, we allow for a tensor valued reluctivity $\bar{\bar{\nu}}$ and for a coercitive magnetic field strength $\vec{H}_c$. Also $\vec{J}$ refers to the source current density, $\vec{n}$ to the outer unit normal and $\omega \in \Omega$ to a random outcome. Geometric uncertainty refers to randomness in the shape of the *iron-air* interface. It is taken into account through the spatial dependency of the material. Using a truncated Karhunen-Loève or polynomial chaos expansion we obtain a finite dimensional noise representation. More precisely, for the reluctivity, we have $\bar{\bar{\nu}}(\omega,\vec{x}) \approx \bar{\bar{\nu}}_M(\vec{Y}(\omega),\vec{x})$, where $\vec{Y} \in \Gamma$ refers to an M-dimensional random vector.

The physical quantity of interest is given by the harmonic distortion factor [1]

$$Q = \sum_{i=1, i\neq N}^{K} a_i^2 + b_i^2, \tag{3}$$

where a_i and b_i refer to the skew and normal multipole coefficients, respectively, and N denotes the pole-pair number of the magnet. The multipole coefficients in turn can be seen as linear functionals of the solution.

Let $\vec{c}$ denote a set of shape parameters, e.g., the control points in a spline representation of the interface. The robust optimization problem reads

$$\vec{c}^* = \arg\min_{\vec{c}} \max_{\vec{y}\in u} Q(\vec{c},\vec{y}), \tag{4}$$

where u refers to a convex uncertainty set as given, e.g., in [2]. Solving (4) numerically can be very challenging. However, the complexity can be reduced using perturbation techniques as well as polynomial surrogate and reduced models in the stochastic and deterministic variable, respectively. These issues will be discussed and illustrated by means of numerical examples.

Analysis of Inhomogeneous Plane Wave Scattering from Periodic Metamaterials

S. Tooni, **T. F. Eibert**, **and L. Vietzorreck**
Lehrstuhl für Hochfrequenztechnik, Technische Universität München
Arcisstr. 21, Munich 80333, Germany

Abstract— The spectral domain analysis of periodic open metamaterial unit cells is performed by inhomogeneous plane wave excitation. The hybrid finite element boundary integral method is employed to compute the scattered field, the reflection and the transmission coefficients from unit cells. Discrete surface and complex leaky modes of the unit cells are computed from the singularities of the scattered field. The robustness of the method is demonstrated by comparing the computed results with the results from other methods.

For Sturm-Liouville problems, the Green's functions can be expanded based on constructing discrete and continuum modes [1]. Depending on the excitation methods, several procedures can be introduced to compute the eigenmodes and corresponding eigenvalues. Most of the conventional approaches are employing the singular value decomposition (SVD) of a system matrix, which is obtained from the discretization of the system operator. In open problems, usually the system matrix has a non-linear dependence on the eigenvalues. Therefore, utilizing SVD methods is not practical and non-linear optimization procedures have to be assessed. An alternative to obtain the eigenvalues and eigenmodes are excitation based methods. These methods, mathematically model the physical response of the system for excitation over a spectrum [2].

In the current paper, the method of excitation of eigensolutions in periodic structures by plane waves is investigated. Some new properties of periodic media, such as impedance boundary conditions, absorption and near-field imaging are explored based on the modal behavior of the constructing unit cells.

Green's functions of layered media are combinations of reflected and transmitted plane waves in different layers. The generalized reflection and transmission coefficients can, therefore, be considered as the desired Green's functions of these media. In periodic stratified media, while the operation frequency is enough below the cutoff of the higher order Floquet modes, the medium can be approximated as a homogeneous layered medium. However, the scattering of the field must still be computed by expansion of the scattered field based on Floquet modes. The coefficients of the fundamental Floquet mode over the open boundaries can be considered as the describing parameters of the physical properties [3].

On the one hand, complex leaky modes can be either in the fast or in the slow wave region. On the other hand, in loss less structures, complex eigenvalues exist always in conjugate pairs. In the slow wave region, all the computed eigenvalues are proper while in the fast wave region one of the poles is improper. By consideration of the radiation condition, the undesired pole can be removed from the response [4].

Broadband Analysis Including Beam Steering of Phased Array Antennas by Order Reduction

O. Floch, **A. Sommer**, **O. Farle**, **and R. Dyczij-Edlinger**
Chair for Electromagnetic Theory, Saarland University, Saarbrücken D-66123, Germany

Abstract— In applications such as radar, phased antenna arrays are to be characterized over broad frequency bands and wide ranges of steering and look angles. When numerical methods, specifically the finite-element (FE) method, are used, the determination of the far-fields tends to be very time-consuming, for the following reasons: Typical antenna arrays are electrically large and consist of high numbers of radiators. Hence the resulting FE systems are of very large dimension. Furthermore, broad variations in frequency (f) and steering angles (θ_s, ϕ_s) requires the FE solution for large numbers of operating points (f, θ_s, ϕ_s), each of which has to be computed by solving the large-scale FE system. When direct solvers are no longer applicable because of their high computational complexity, one must resort to iterative techniques. In this regard, the availability of efficient preconditioners is of utmost importance. For electrically large structures, domain decomposition (DD) methods have proven to be highly effective. However, even with the aid of these techniques, solving the large-scale FE system remains a time-consuming procedure. Finally, wide variations in look angles (θ, ϕ) call for large numbers of sampling points (θ, ϕ). Each of them requires a separate near-field-to-far-field (NF-FF) transformation, for each considered operating point (f, θ_s, ϕ_s).

To reduce computational efforts, we here propose a two-step model order reduction (MOR) approach, similarly to [1, 2], but with the focus on electrically large structures: We fist construct a reduced-order model (ROM) for the near fields of the phased antenna array which is very cheap to solve at any value of the parameter triple (f, θ_s, ϕ_s). For this purpose, a multi-point MOR method with self-adaptive expansion point selection [1, 2] is employed. The second step utilizes the empirical interpolation method (EIM) [3] to construct an affine approximation to the NF-FF operator as a function of frequency and look angles. Since the EIM-based NF-FF operator is also fast to evaluate at any value of the parameter triple (f, θ, ϕ), the combination of both methods results in a highly efficient numerical model for computing the far-fields as a function of the five parameters (f, θ_s, ϕ_s, θ, ϕ). The accuracy and efficiency of the suggested two-step MOR approach is demonstrated by means of an electrically large real-world example.

SC1: Electromagnetic Field Transformations for Measurements and Simulations

Spherical-multipole Based Near-to-near and Near-to-far Field Transformations

L. Klinkenbusch
Kiel University, Germany

Abstract— Spherical-multipole expansions have been employed in the context of near-to-far field transformations from antenna near-field measurements in the frequency domain [1] and (less often) in the time domain [2]. Since these approaches (among others) exploit the orthogonality of the spherical modes the scanning process has to be performed on a spherical surface. Spherical-multipole expansions can also be used for conveniently describing the electromagnetic field outside of the solution domain for numerical methods via a spherical-multipole interface [3]. In that case the radiating structure is replaced by a certain number of elementary (Hertz and Fitzgerald) dipoles located on a Huygens surface which completely encloses all radiating elements but otherwise can have an arbitrary form. The multipole expansion of the field of a dipole is known analytically in the frequency domain, and a linear superposition (summation) leads to the total frequency-domain spherical-multipole expansion of the electromagnetic field valid outside of a minimum sphere containing all sources. By means of the analytically known Fourier Transform of the spherical Bessel function of the first kind,the far-field approximation of that spherical-multipole expansion can be transformed into the time domain [4]. Furthermore a finite expansion of the spherical Hankel function yields the opportunity to recursively derive the time-domain spherical-multipole expansion in the near-field from that one valid in the far field, and hence to perform a systematic time-domain near-to-near field transformation [5]. Finally, the field information is non-redundantly stored in a discrete set of time-domain spherical-multipole amplitudes and ready for an arbitrary post-processing.

Besides a brief review of these methods and corresponding new numerical results the paper focuses on the validity of the reconstructed electromagnetic fields in the near of the Huygens surface.

Comparison and Application of Different Echo Reduction Techniques in Antenna Measurement

Manuel Sierra Castañer[1], **Javier García-Gasco Trujillo**[2], **Pilar González Blanco**[1], **Manuel López Morales**[1], **Francesco Saccardi**[3], **and Lars J. Foged**[3]

[1]Universidad Politécnica de Madrid, Spain
[2]SES Engineering, Spain
[3]Microwave Vision, Italy

Abstract— During the last years, different methods for improving the quality of the antenna measurements results have been developed, in particular for echo reduction. This paper is a common research work between Universidad Politécnica de Madrid and Microwave Vision Group whose objective is the comparison of different echo reduction techniques in order to be able to explore the advantages of each one in antenna measurements applications. In particular, these techniques are specially important for outdoor antenna measurement systems, for systems as the StarLab (where the measurement equipment is placed without full coverage of absorbing material) or for measurements at lower frequencies where the performance of the absorbing material is not good enough. These techniques are based on spatial filtering, modal filtering and time gating techniques. The paper analyzes different approaches: in particular for spatial filtering, holographic techniques [1] and source reconstruction based on integral equations [2] are analyzed. In the first case, the field is back propagated to a large planar surface containing the antenna under test, and the fields out of the antenna area are filtered out. The main advantage is the very small time required for the transformation, while the disadvantages are focused on the specific applications for planar antennas and the need of geometrical information to improve the results. The second algorithm, based on source reconstruction using integral equation (in particular the authors analyzed MVG INSIGHT© algorithm). The main disadvantage is the time consumption, although the results are better accurate than the previous one. In the case of modal filtering, there are different approaches, with similar theoretical basis. This paper uses the approach included in MV-Echo© [3] for the cancellation of the echos based on the spherical modes decomposition of the radiated field. The last group of algorithms are based on time filtering. In particular FFT [4], Matrix Pencil method [5] and non uniform DFT are used. In all the cases, the results are similar. The first algortihm requires uniformly frequency spaced samples (not always available) but it is faster. In these three cases, the main disadvantage is the number of frequencies (and step) required for having a good echo reduction. The different algorithms have been applied to the measurement of a dipole antenna (SD1900) in the MVI StarLab System. Results show that depending on the angular range of the pattern the improvements are better or worst using any of the methods. Results will be shown in the final paper or presentation.

Electromagnetic Field Transformations with Spectral Field Representations on the Ewald Sphere

T. F. Eibert, **E. Kılıç**, **C. Lopez**,
R. A. M. Mauermayer, **O. Neitz**, **and G. Schnattinger**
Lehrstuhl für Hochfrequenztechnik, Technische Universität München, Munich, Germany

Abstract— Electromagnetic field transformations are of increasing importance for achieving improved insight into field measurements and into simulations. Spectral field representations utilizing propagating plane wave expansions on the Ewald sphere provide for extremely flexible field transformations without compromising the efficiency of a fast transformation approach. The transformations can be set up with various equivalent sources representations and for arbitrary measurement locations, where the measurements can be collected with arbitrary measurement probes. The paper presents an overview of hierarchical propagating plane wave based field transformations and discusses various transformation results from the fields of near-field far-field transformations for antennas, antenna diagnostics and imaging as well as from the solution of nonlinear inverse problems.

Electromagnetic field transformations have been developed to high sophistication in the field of near-field antenna measurements [1], where focus is, however, mostly on the common measurement configurations (spherical, planar, cylindrical) with regular sampling. Inspired from the new possibilities achieved in the numerical solution of integral equations, a series of propagating plane wave based field transformation algorithms have been designed and realized over the past years [2, 3], which provide for excellent flexibility without compromising the efficiency known from so-called fast algorithms. With this flexibility, there is also a chance to establish novel measurement approaches and it will become possible to seamlessly merge simulated and measured field data in a common framework. The hierarchical propagating plane wave based algorithms have become very mature over the past years and many of their properties have been investigated [4–7]. In this contribution, we review important properties of the hierarchical propagating plane wave based algorithms and we will discuss novel achievements and applications in the fields of near-field far-field transformations, antenna diagnostics and broadband imaging, as well as of the solution of nonlinear inverse problems, e.g., nonlinear inverse medium problems or phaseless near-field far-field transformations.

Full-sphere Radiation Pattern Measurement of 3D Antennas Using a Compact Planar Very-near-field Scanner

Kasra Payandehjoo and Ruska Patton
EMSCAN Corp., Calgary, AB, Canada

Abstract— Far-field test facilities for antenna pattern measurements are often very large, costly, and slow. An alternative to direct far-field measurement exists based on near-field scanning and near-field to far-field transformations. The compact size of these near-field measurement systems allows for integration of measurement probes in planar [1], circular [2], and other array configurations to reduce the required movements of the antenna-under-test (AUT) and hence the measurement time. Planar very-near-field scanning has already been successfully commercialized for small antennas with an array of 1600 H-field probes printed on a 45 cm by 45 cm printed circuit board [1]. Radiation pattern in a hemisphere is predicted in a matter of a few seconds using plane wave spectrum expansions. The accuracy of these far-field patterns however, degrades as the "apparent antenna dimension"-to-"scanner aperture" ratio increases. Hence, a single planar scan fails to accurately predict the pattern of 3D antennas that have high profiles relative to the dimensions of the scanner. Alternatively, multiple planar scans that close the measurement surface around the antenna can improve pattern accuracy [3]. As suggested in [3], a cubic measurement surface composed of 6 planar scans is considered herein. Phase coherence between the six measurements is crucial and is ensured by feeding a sample of the input signal to the scanner via a power divider. For fast far-field predictions, measured fields on each face are independently transformed to far-field in a matter of a few seconds. Subsequently, the far-field contributions of different faces are superimposed after proper coordinate translation/rotation.

This works investigates the optimum setup required for accurate radiation pattern measurement of high profile antennas. It is concluded that different box dimensions are required at different frequency bands. A 40 cm × 40 cm × 40 cm box provides good far-field results below 1GHz whereas a smaller 20 cm × 20 cm × 20 cm box is required at higher frequencies. Two test fixtures are prototyped to facilitate movements of the AUT for all 6 measurements. The rather large height-to-scan-area ratio in these setups leads to two spurious artifacts; first, the consequent large truncation error results in ripples in the radiation pattern. A raised cosine window with a quadratic phase window is optimized for elimination of these pattern ripples. Secondly, the large separation of the AUT above the scanner results in inaccurate far-field phase of a single scan beyond the solid angle formed between AUT and the corresponding face [4]. At each point in the far-field, before superimposing the contributing fields, the phase of the fields are corrected according to the phase of the field that is most accurate at that point. Figure 1(a) depicts the near-fields of a 900 Hz antenna measured on faces of a 40 cm × 40 cm × 40 cm box. Only the magnitude of H_x is shown in Figure 1(a). The predicted far-field pattern of Figure 1(b) is in good agreement with chamber measurements.

Parametric Near-field-to-far-field Transformation by Precomputed Empirical-interpolation Patches

A. Sommer, **O. Floch**, **O. Farle**, **and R. Dyczij-Edlinger**
Chair for Electromagnetic Theory, Saarland University, Saarbrücken D-66123, Germany

Abstract— Using conventional finite-element (FE) methods, the broadband analysis of antenna arrays and the resulting farfields tends to be computationally demanding, because the FE systems are of large size and need to be solved at a high number of frequency points.

Methods of order-reduction provide an attractive alternative. They need some extra time to construct a reduced-order model (ROM), but the ROM itself is so cheap to solve that evaluation time is usually dominated by the costs of the nearfield-to-farfield (NF-FF) transformation. To improve runtimes even further, it was suggested in [1, 2] to replace the steps of field reconstruction on the Huygens surface and subsequent NF-FF transformation by a procedure that computes the farfields directly from the ROM. For this purpose, an affine approximation to the NF-FF operator is constructed by the empirical interpolation method (EIM) [3]. The suggested approach greatly accelerates the *online* computation of antenna patterns, at the price of increased *offline* time, for constructing the model.

In a previous paper, the authors proposed a subdomain approach on the Huygens surface that allows to restict the EIM domain to a small number of reference surfaces. Since the subface areas are much smaller than that the entire Huygens surface, the offline part of the EIM is performed much more efficiently. Still, the EIM offline step is not cheap and needs to be done for every antenna structure anew.

The present work shows that the offline part of the EIM may be computed upfront, without reference to a specific FE model. The resulting data structures are stored as templates which may be incorporated into ROMs later on, by cheap scaling and compression steps. The proposed method computes an affine approximation to the NF-FF operator for the Huygens surface similarly [4] and supports fast online computation of antenna patterns as a function of frequency and observation angles.

Electromagnetic Scattering-matrix Theories Based on Plane Waves and Complex-source Beams

T. B. Hansen
Seknion Inc., Boxford, Massachusetts, USA

Abstract— Plane waves and complex-source beams constitute complete sets of basis functions for electromagnetic fields in homogeneous source-free regions. From the completeness of these basis functions, one can derive exact scattering-matrix theories of antennas and antenna-antenna interactions, which lead to efficient computation schemes for electromagnetic field transformations in both near and far-field regions.

This presentation discusses two such theories for time-harmonic fields in three dimensions: (i) a plane-wave theory with a directional spectrum that is obtained through a complex-source point substitution procedure, and (ii) a complex-source beam theory based on a beam expansion of spherical multipole fields. The plane-wave basis functions have sources of infinite extent whereas the complex-source beams have sources of finite extent. Hence, the two types of expansions are distinctly different in many ways.

Scattering matrices for plane-wave expansions, which determine the plane-wave spectrum of the scattered field of an object due to an incoming plane wave, are readily available. The analogous scattering matrices based on complex-source beams will be derived from Waterman's T matrices. These scattering matrices determine the beam weights for the scattered field in terms of the output of elementary beam-receivers, which sample the incident field at complex points in space.

With the scattering matrices based on the complex-source beams, the scattering computation is performed by integrating over radiating and receiving-beam directions. Expansions based on plane waves and complex-source beams each have their advantages and disadvantages as will be illustrated through numerical examples involving near-field scanning and scattering. The two scattering-matrix formulations will also be compared with Kerns plane-wave theory.

Metamaterials for Microwave Radomes: An Overview

E. Özis[1], A. V. Osipov[1], and T. F. Eibert[2]

[1]German Aerospace Center (DLR), Microwaves and Radar Institute, Oberpfaffenhofen, Germany
[2]Lehrstuhl für Hochfrequenztechnik, Technische Universität München, Munich, Germany

Abstract— Metamaterials have a great potential for designing improved and novel antenna components and systems, including substrates, feed networks, phased array antennas and antenna radomes [1]. In radome applications, metamaterials can enable such features as improved transmission over a broader range of antenna scan angles, reconfigurable pass and reject frequency bands, polarization transformations, one-way transmission and switchability.

A radome is a cover protecting an antenna from a hostile environment (wind, rain, ice, heat, aerodynamic drag, electromagnetic interference, etc.). From the electromagnetic point of view the ideal radome should be fully transparent, non-refractive and lossless, in order not to distort the fields traveling from and to the covered antenna. In practice, however, the choice of the shape and material of the radome is typically determined by the application so that the radomes are often curved structures made from ceramics and composites with high values of permittivity, which results in a degraded performance of the antenna [2, 3].

Furthermore, in modern applications it is often desirable to make the radome impenetrable outside the operating frequency band to reduce interference with other antennas that can be maintained on the same platform. This and many other features are hardly possible with conventional materials, but can be achieved with metamaterials.

Metamaterials are artificial structures that involve variously shaped, typically metallic, inclusions placed in a substrate material and organized in periodic arrays, e.g., [4, 5]. In contrast to frequency selective surfaces, the size of the unit cells is much smaller than the wavelength so that metamaterial structures appear as effectively homogeneous with effective values of such electromagnetic parameters as permittivity, permeability, losses, reflection and transmission coefficients. By choosing the shape, orientation and size of the inclusions and the size of the unit cells, the effective parameters can be tailored to the desired values. A new kind of metamaterial structures, the so-called meta-sheets, which are quasi two-dimensional structures involving just a single layer of inclusions in an electrically thin substrate, is particularly promising for radome applications since meta-sheets permit eliminating reflection while controlling transmission [6–8]. Metamaterial layers can be added to existing radomes not only to correct the distortions but also to enable new features, like non-reciprocal transmission [9] or frequency- and polarization-selective behavior.

The purpose of this paper is to give an overview of applications of metamaterials to microwave radomes. This paper reviews the available literature, reports relevant applications and illustrates them by examples.

Abstract— The technologies incorporating optical fibers and smart optical fiber based devices are essential for future flexible all-optical network to enhance the transmission capacity and processing efficiency. We will demonstrate our works in this presentation about flex-grid tunable optical filter, flexible wavelength selective filter, space-wavelength division flexible optical transmission and all-optical fiber based signal processing in spectral or temporal domains.

Flow Aggregation and Migration Scheme Based on Real-time Monitoring for Time-varying Traffic in Optical Networks

Yuan Wen, Wei Guo, and Weisheng Hu
State Key Laboratory of Advanced Optical Communication Systems and Networks
Shanghai Jiao Tong University, China

Abstract— Nowadays, the transport network is experiencing a challenge of bulky data transfer for large-scale applications, such as E-science computing, data center data back-ups and cloud services [1]. When these applications require high transmission rate (e.g., 10 GE or more), a lightpath with guaranteed bandwidth provided by optical circuit-switched networks becomes an effective solution to meet application performance requirements, such as bit rate, packet loss and latency. However, the bandwidth of a lightpath is often underutilized. A major reason is that flows generated by applications may have a time-varying bandwidth demands, typically, higher traffic volume during daytime and lower traffic volume at night. If a lightpath is dedicatedly used by a flow, this may lead to bandwidth resource waste when flow rate becomes low.

In order to make better utilization of bandwidth resources, we proposed a flow aggregation method implemented by an extended SDN controller [2]. This method is to aggregate multiple fine-granularity flows into a lightpath, whose bandwidth resources have not been fully utilized. In this way, these flows can share the same lightpath and lightpath bandwidth utilization increases. However, the transmission rates of flows vary frequently over time. If the total transmission rate of the flows exceeds the bandwidth of the lightpath, packet loss will occur and transmission quality of flows will degrade.

In this paper, we propose a flow aggregation and migration scheme (AM) based on real-time monitoring to improve bandwidth utilization while guaranteeing transmission performance of the entire network. Our method is to aggregate some fine-granularity flows (with low-priority) into a lightpath with spare bandwidth resources. To guarantee transmission performance, the low-priority flows will be migrated into another lightpath when bandwidth resources of the original lightpath are used up. Since flow migration needs time, we set a threshold to control the maximal load in the lightpath. Once the overall flow rate exceeds the threshold (but still less than the bandwidth of the lightpath), flow migration will be executed to reduce packet loss. Due to the flexible programmability of SDN controller to flow, we can easily complete the flow aggregation and ow migration. We have tested the performance of our extended controller on our testbed. Experimental results show that our extended controller can migrate a flow from one lightpath into another in 2 seconds, with no influence on data transmission delay and packet loss of the original flow (with high-priority). In addition, we can reduce the packet loss of low-priority flows by reducing the threshold. We also conduct simulations, which illustrate that our AM scheme improves the lightpath bandwidth utilization and reduces the blocking rate.

Experimental Demonstration of 100-Gb/s TWDM-PON

Lilin Yi, **Zhengxuan Li**, **Xiaodong Wang**, **and Weisheng Hu**
The State Key Lab of Advanced Optical Communication Systems and Networks
Shanghai Jiao Tong University, Shanghai 200240, China

Abstract— With the wide spreading of internet-based services such as online video, cloud computing, etc., demands on the capacity of optical access network is growing continuously. Time and wavelength division multiplexed passive optical network (TWDM-PON) based solution for next generation PON stage 2 (NG-PON2) is being discussed and will come to a conclusion in the near future. A lot of 40-Gb/s TWDM-PON system demonstrations have been reported, providing a variety of technical candidates for practical applications [1–3]. However, for further capacity upgrade, e.g., 100-Gb/s TWDM-PON, the technical proposal is still open for discussion, where cost-effective transmitter with 25-Gb/s capacity is a key component. Some research institutions are making efforts to increase the modulation bandwidth of both external modulators [4] and directly modulated distributed-feedback lasers (DFBs) [5]. On the other side, advanced modulation formats with high spectral efficiency have been proposed to realize high data rate modulation on bandwidth-limited transmitters. A 4×25 Gb/s four-level pulse amplitude (4-PAM) modulation using 10-GHz devices have been demonstrated [6]. Besides, a symmetric 100-Gb/s TWDM-PON, where double sideband (DSB) orthogonal frequency division multiplexing (OFDM) was used in both upstream and downstream directions has been presented [7]. However, high sampling rate ADC/DAC are required in these systems which increases the difficulty and cost for real-time signal processing.

In this paper, we present 25-Gb/s operation of a commercial 10-GHz directly modulated DFB laser (DML) and PIN. Non-return to zero on-off-keying (NRZ-OOK) instead of advanced modulation format is used, which significantly simplifies the digital signal processing (DSP) module. In order to increase the modulation bandwidth, we employ a delay interferometer (DI) following the DML to equalize the modulation response. Simultaneously, the DI narrows the optical spectrum of the directly modulated signal and realizes chirp and dispersion management during fiber transmission. As a result, 40-km standard single mode fiber (SSMF) transmission is demonstrated with bit error ratio (BER) lower than 1×10^{-3}, which provides a cost-effective solution for 4×25-Gb/s TWDM-PON systems.

Advancements in Next Generation Broadband Optical Access Networks

Cedric F. Lam
Google, USA

Abstract— The Internet has become an indispensible part of our modern society. Development in broadband access networks are directly connected with economic growth and prosperity of societies. Companies are foraying into new technologies for next generation broadband systems. In this talk, we review the challenges and advancements in next generation broadband optical access network developments.

Impact of Protection to Converged Access Networks Planning in Rural Areas

Carmen Mas Machuca[1] **and Ana Muñoz Díaz**[1, 2]

[1]Technical University of Munich, Germany
[2]Technical University of Madrid, Spain

Abstract— Network operators are reluctant to offer broadband access in rural areas due to the high investments and limited revenues. Protection in those areas is even more critical and hence, not yet considered by operators. One alternative to decrease costs in rural areas is the use of new architectures such as Hybrid Passive Optical Network (HPON). These architectures offer several advantages not only from the longer reach and higher client count, but for the possibility of offering different bandwidth per end point. The recently proposed HPON architecture could be used to offer more bandwidth to the base stations (10 Gbps) and less bandwidth to residential users (300–500 Mbps). Recent work has presented a detailed framework that using real building and street data provided by OpenStreetMap allows computing the fiber layout for different access architectures and splitting ratios. The approach aims at minimizing the duct length, since costs associated to ducts and trenching have been shown to be cost drivers in access deployment. This framework has been applied in rural areas to compare the infrastructure required for a disjoint versus a joint planning. Savings depend on the building density, area size and the interBS distance. The new contribution of this paper is focused on the analysis of the cost impact of BS protection. The required availability is obtained when protection of feeder fiber and distribution fiber is guaranteed. The investment and extra fiber and duct infrastructure required for two protection schemes are compared with the unprotected scenario. The cost increase is shown to be relatively low compared with the unprotected solution.

Experimental Evaluation of Noise Impairments in Unrepeated Distributed Raman Amplified DP-16QAM SSMF Links

Abstract— Unrepeated fiber transmissions over hundreds of kilometers span with advanced modulation formats and DSP-based coherent detection schemes are considered as a potential candidate to meet the distance and capacity requirements in certain application scenarios where render amplification sites between terminals are impractical due to geographic, commercial or security constrains [1]. Distributed Raman fiber amplifier (DFRA) ensuring a relatively constant power distribution of the optical signals along links can effectively improve the system OSNR and fiber nonlinearity tolerance, therefore is widely adopted in unrepeated transmission solutions. To date, unrepeated transmissions of 30 Gbaud DP-QPSK over 444 km [2], single and dual carrier 28 Gbaud DP-16QAM over 240 km [3, 4] have been demonstrated by using Raman amplification with large effective area fibers (LEAF). In this paper we report on a systematic experimental characterization of both the amplitude and phase impairments of the received signal induced by a bidirectional Raman pump at 1455 nm with an evaluation of the coherent transmission performances of a 28 Gbaud DP-16QAM signal in a standard single mode fiber (SSMF). The Raman induced amplitude and phase noise on the received 1550 nm signal is directly measured and the discussions around the operational rules and limitations are presented considering the inter-relation between pump power, signal OSNR and induced noise. Furthermore, performances of different carrier phase recovery algorithms, including decision-directed phase-locked-loop (DDPLL) [5], blind phase search (BPS) [6] and a two-stage QPSK partitioning [7] with variable filtering implementations in the DSP routine are investigated taking into account the specific noise profile of the received signal.

Abstract— Today's Internet data traffic has exceeded 1 Zettabyte and continues to grow exponentially. By 2016, 90% of the global Internet/IP wide area network (WAN) traffic passes through data centers. This requires big data centers to handle the massive data traffic based on high speed optical data links. Considering the high volume of such short haul data links and optical transceivers in data centers, cost- and energy-efficiency is the critical consideration for implementations. As a response, the IEEE 802.3 created the IEEE P802.3bs 400 GbE Task Force on May 2014 and agreed objectives for both single-mode fiber (SMF) and multimode fiber (MMF) links. The distances considered include 100 m over MMF, 500 m, 2 km and 10 km over SMF. For such applications, conventional non-return-to-zero (NRZ) becomes very demanding on the transceiver bandwidth. Alternatively, advanced modulation formats with high spectral efficiency are promising solutions to achieve high data rate by using relatively less advanced components. The 400 GbE Task Force is still open to the choice of modulation format and number of wavelengths per fibre, four-level pulse amplitude modulation (PAM4) with eight wavelengths at 50 Gb/s as well as PAM4 and orthogonal frequency division multiplexing (OFDM) with four wavelengths at 100 Gb/s per wavelength dominate the debate. I addition to PAM and OFDM, there have been high speed short reach optical links demonstrated by using other advanced modulation formats such as duobinary, carrierless amplitude and phase (CAP) modulation, and quadrature amplitude modulation (QAM). This paper aims to review a wide range of implementation options for 400 Gigabit Ethernet using advanced modulation formats that have arisen in recent years. Simulations are provided to compare the system optical link power budget over both directly modulated laser and externally modulated laser based SMF links.

Programmable Photonics in Data Centers: Architectures and Algorithms

Carla Raffaelli
DEI, University of Bologna, Italy

Abstract— The recent evolution of the Internet is characterized by the need to dynamically share physical resources like storage, computing capacity and networks themselves, thus enabling modern applications, like social networking, cloud computing, video streaming and others to efficiently perform their service.

Data centers are emerging as aggregates of increasingly powerful physical facilities which generate high amount of traffic and consume high power, accordingly. In spite of the continue increase of peak performance, the allowable power consumption is required to increase at a much slower rate [1].

As a consequence, data center interconnection design will result one of the most challenging networking problem in the next future which can be solved in a massive adoption of new technological solutions, possibly based on silicon integrated photonics.

On the network service side, the evolving characteristics of content providers call for enhanced dynamic network reconfiguration capability. Emerging photonic technology can provide interconnection at extremely high rates with enhanced flexibility in spectrum sharing [2]. At the same time network control and management technologies should be able to exploit this flexibility in relation to cloud-based application dynamics.

Solutions based on combinations of Network Function Virtualization (NFV) and Software Defined Networking (SDN) can achieve the extreme flexibility required to support current and future development of cloud computing paradigms. Programmable features of emerging photonic technology can be fruitfully exploited in this context thus defining new roles and chances for optical interconnection both in capacity exploitation and energy efficiency perspective [3]. In any case the joint deployment of photonics and SDN to fulfill future dynamic network requirements, needs algorithms and architectures to harmonize and optimize several functionalities [4], which are addressed in this presentation.

The application of standard protocols like Open Flow must be studied to map network management functionalities on programmable photonics. Different approaches can be adopted based on protocol extensions or on protocol compliance. Architectures and algorithms to support the management of flexible grid channels are here considered through possible virtualization of photonic network elements based on emerging SDN protocols. Solutions to optimize the usage of wavelength channels will be also discussed in terms of procedures and performance.

Abstract— Near-field radiative heat transfer (NFRHT) has attracted considerable attention recently, with orders-of-magnitude heat transfer enhancement already demonstrated between bulk materials. Using custom-built experimental platforms we conducted experimental studies in the sphere-plate configuration and tip-plate configuration to probe NFRHT in the 30 nm–10 micron range and 1 nm–10 nm ranges, respectively. In our sphere-plate study, we systematically investigated the effect of film thickness on NFRHT. By studying thermal radiation between a hot silica microsphere and thin silica films of varying thicknesses (50 nm to 3 microns) as a function of gap size (30 nm to 10 microns), we found substantial enhancements in heat transport properties due to near-field effects, even for the thinnest films when the gaps size was comparable to the film thickness [1]. Further, we find that at larger separations (∼1 micron), the thicker films show substantially larger near-field enhancement than thinner films. These results provide first direct evidence of a distance-dependent penetration depth in thin films. In our experiments leveraging the tip-plate configuration we sought to understand NFRHT in the extreme near-field regime (gaps of 1–10 nm) using atomic force microscope (AFM)-based scanning probes with integrated nanoscale thermocouples, which were coated with dielectrics (SiO_2 or SiN_x) and metals (Au, Pt). Our measurements [2] of heat transport between the scanning probes and a flat substrate coated with dielectrics/metals, performed in an ultra-high vacuum environment, suggest that heat transport is dramatically enhanced in the near-field. This measured enhancement in heat flows was found to be in good agreement with computational predictions — thus establishing the validity of using fluctuational electrodynamics in modeling near-field heat transport even at single-digit nanometer separations.

Abstract— Radiative heat transfer between objects at different temperatures is of fundamental importance in applications such as energy conversion, thermal management, lithography, data storage, and thermal microscopy [1, 2]. It was predicted long ago that when the separation between objects is smaller than the thermal wavelength, which is of the order of 10 µm at room temperature, the radiative heat transfer can be greatly enhanced due to the contribution of evanescent waves (or photon tunneling) [3]. In recent years, different experimental studies have confirmed this long-standing theoretical prediction. However, in spite of this progress, there are still many basic open questions in the context of near-field radiative heat transfer (NFRHT). Thus for instance, recent experiments exploring the radiative thermal transport in nanometric gaps have seriously questioned the validity of fluctuational electrodynamics [4], which is presently the standard theory for the description of NFRHT. In this talk, I will review our recent theoretical and experiment efforts to shed new light on this fundamental problem. In particular, I will discuss the following two basic issues. The first one concerns the NFRHT using polar dielectric thin films. In this case, I will show how fluctuational electrodynamics naturally accounts for the enhancement of NFRHT reported in very recent experiments, where it has been shown that polar dielectric films as thin as 50 nm can exhibit NFRHT enhancements comparable to those of bulk samples when the gaps are smaller than the film thickness [5]. In the second part of the talk, I will address the issue of radiative heat transfer in the extreme near-field regime when objects are separated by nanometer-size distances. In particular, I will present a very detailed comparison of novel NFRHT experiments performed with scanning thermal probes with state-of-the-art simulations based on the fluctuating-surface-current formulation of the heat transfer problem [6]. The ensemble of our results clearly show that fluctuational electrodynamics provides an adequate description of the NFRHT between both metals and dielectrics all the way down to nanometer-size gaps [7].

Abstract— The control of electric current in solids is at the origin of the modern electronics which has revolutionized our daily lifes. The concept of diodes, transistors and memories respectively introduced by Braun [1] in 1846, Williams and Kilburn [2] in 1946 and by Bardeen and Brattain [3] in 1948 are undoubtedly the corner stones of almost all modern systems of information treatment. Such elementary devices allow for rectifying, switching, modulating and even amplifying the electric current and allow for storing bits of information. Thermal analogs of such devices which make possible the control of heat flow are not as widespread today. In 2000s Baowen Li et al. have proposed thermal counterparts of transistors [4] and memories [5] using phononic circuits made with interconnected solid segments. However, this technology suffers from some weakness (slow operating speed, presence of Kapitza resistance which strongly reduced the magnitude of heat flux) of fundamental nature which intrinsically limit its performances. In this work we discuss the feasability for a contactless technology [6–8] for the thermal management based on photonics analogs of classical diodes, transistors and volatile memories.

Radiative Heat Transfer in 2D Dirac Materials

D. A. R. Dalvit[1], **P. Rodriguez-López**[2], **and W.-K. Tse**[1]

[1]Theoretical Division, MS B213, Los Alamos National Laboratory, Los Alamos, NM 87545, USA
[2]Laboratoire de Physique Théorique et Modèles Statistiques
CNRS UMR 8626, Bât. 100, Université Paris-Sud, Orsay Cedex 91405, France

Abstract— We compute the radiative heat transfer between two sheets of 2D Dirac materials, including topological Chern insulators and graphene, within the local optics approximation. We derive both numerically and analytically the short-distance asymptotics of the near-field heat transfer in these systems, and show that it scales as the inverse of the distance between the two sheets. We discuss the limitations to the validity of this scaling law imposed by spatial dispersion in 2D Dirac materials.

Probing the Casimir Force with Optical Tweezers

Abstract— Optical tweezers (OT) are single-beam laser traps for neutral particles, usually applied to dielectric microspheres immersed in a fluid. The stiffness is proportional to the trapping beam power, and hence can be tuned to very small values, allowing one to measure femtonewton forces, once the device is carefully calibrated [1, 2]. In this work, we employ OT to measure the Casimir (or retarded van der Waals) force between polystyrene beads in a fluid, for distances between 50 and 500 nanometers. The spherical beads have diameters ranging from 3 to 7 micrometers. This configuration is well beyond the validity of the commonly employed [3, 4] Proximity Force (or Derjaguin) approximation (PFA), thus revealing unprecedented features of the Casimir interaction. For the comparison with experimental data, we compute the Casimir force using the scattering approach [5] applied to the spherical geometry [6]. We also present experimental results for the total force between a mercury microdroplet and a polystyrene bead immersed in ethanol, with similar distances and diameters.

Experimental Determination of the Thermal Dependence of the Casimir Interaction

Ricardo S. Decca
Department of Physics, Indiana University-Purdue University Indianapolis
Bldg LD154, 402 N. Blackford St., Indianapolis, IN 46202, USA

Abstract— In this talk we will present recent developments using a rotating engineered sample made out of Au and Ni sectors buried under a thin Au layer of thickness t. This approach follows the proposal made by G. Bimonte [1]. The rotating disc is placed in close proximity to either a Ni or Au covered sapphire sphere, which in turn is glued to a highly sensitive MEMS force transducer. The thermal noise of the apparatus is $\sim 3\,\mathrm{fN/Hz^{1/2}}$. Measurements with a sensitivity of 0.3 fN with integration times of the order of 1000 s have been performed. The collection of measurements for different configurations, different values of t and measurements with separations between the sphere and the disc between 200 to 1000 nm allows to distinguish between different potential explanations for the thermal effect of the Casimir interaction. A Drude model where thermal fluctuations in the magnetic contribution from Ni is taken into account is excluded. The plasma model, however, still appears to be consistent with the data.

Systematic effects arising from the experimental implementation, as well as a description of the sample characterization that was performed will be presented.

Abstract— In this talk I will consider the importance of tailoring the Casimir-Polder potential in order to develop atom chips that use quantum electronic components to control nearby ultracold atom clouds. In particular, I will consider the potential advantages of using quantum electronic components to trap, manipulate, and electrically image the ultracold atom clouds. Conversely, I will also consider how the cold atom clouds can be used to provide functional imaging of the electronic systems.

I will present calculations which predict that current through quantum electronic components fabricated within a two-dimensional electron gas (2DEG) in semiconductor heterostructures [1, 2] can trap ultracold atoms $\sim 200\,\mathrm{nm}$ away, with orders of magnitude less spatial and temporal noise than for metal trapping wires. This noise reduction, combined with low Casimir-Polder attraction [2], may enable the creation of hybrid atom chip structures, which exploit small changes in the conductance of quantum electronic devices to control the trapped atoms. For example, activating a single quantized conductance channel in a quantum point contact can split a Bose-Einstein (BEC) for atom interferometry [1, 3]. In turn, the BEC offers unique imaging of quantum devices and transport in heterostructures.

Abstract— Matter-wave interferometry has become an essential tool for precision measurements of physical constants and phenomena like for instance the fine structure constant, and gravity and its curvature [1, 2]. Modern atom interferometers achieve this feat by making use of near-resonant light gratings to realize large angle beam splitters [3]. However, these schemes often necessitate closed optical transitions, which are not available in complex molecules.

Material gratings have the advantage that they are universally applicable, as the diffraction mechanism is independent of the particles' properties. They have been demonstrated for atoms [4], molecules [5] and clusters [6]. However, they may also imprint substantial van der Waals phase shifts upon the polarizable particle during the diffraction process. For large masses this attractive interaction may even prevent the molecules from traversing the grating.

We have addressed this problem by reducing the grating's width to its ultimate natural limit: A single sheet of atoms. Single-layer and bilayer graphene, carbon nanoscrolls as well as $a1$ nm thin carbonaceous biphenyl membrane are compared with regard to their suitability for diffracting large organic molecules. The population of different diffraction allows us characterize the electrical interaction between the polarizable molecules and the nanomasks We observe a minimal van der Waals interaction for single layer graphene. This paves the way for new quantum experiments with material gratings.

Weak Thermal Contact is Not Universal for Work Extraction

H. Wilming, R. Gallego, and J. Eisert
Dahlem Center for Complex Quantum Systems, Freie Universität Berlin, Berlin 14195, Germany

Abstract— The free energy difference limits the amount of work that can be extracted on average using heat baths of fixed temperature from a system out of thermal equilibrium. This bound can be saturated by protocols putting the system and a bath into weak thermal contact (WTC), i.e., bringing the system into a Gibbs state at the bath's temperature. In this sense, WTC is universal for work extraction — a notion that can be made precise in a variety of operational frameworks. In this work, we introduce the study of work-extraction protocols under restrictions encountered in realistic devices at the nano-scale. We consider limitations on the maximum energies in the system and on the local structure of many-body Hamiltonians. Remarkably, we find that WTC then loses its universality. We do so by proving a general bound for the extractable work in such restricted scenarios. This is used to prove a gap between the work the can be extracted with WTC and with more general operations. Our work highlights the relevance of operational frameworks such as those of thermal operations and Gibbs preserving maps, as they can improve the performance of thermal machines. Furthermore, it provides a unifying framework of incorporating natural restrictions in quantum thermodynamics.

Thermodynamics with Superconducting Circuits

B. Huard
Ecole Normale Supérieure, CNRS, Paris, France

Abstract— In this talk, we will discuss an elementary thermal machine able to cool down or heat up a superconducting quantum bit. We have realized such a machine using superconducting circuits in two protocols. First, by measurement based feedback, a macroscopic observer acquires information about the quantum system and reacts on it. Second, by reservoir engineering, the entropy of the qubit is transferred to a cavity mode and towards a cold reservoir. We will discuss how these protocols relate to Maxwell demons.

Abstract— The shape and dimensions of semiconductor nanowires are responsible for the strong polarization anisotropy in their emission and absorption. The diameter of nanowires (comparable to the wavelength of visible light) leads to optical resonances, which can be described by Mie scattering theory or by coupling to guided modes in a cylindrical geometry. Based on this behavior, it is also expected a strong angular dependence of the emission and absorption by individual nanowires. The directional optical response of nanowires is a fundamental property that depends on the material, geometry and dimensions of the nanostructures and that needs to be considered in the design of nanowire LEDs and solar cells [1, 2].

In this contribution, we investigate photoluminescence and absorption from finite semiconductor NWs, theoretically and experimentally (Fourier microscopy) demonstrating their behavior as efficient optical nanoantennas [3–5]. Directional emission of polarized light is governed by the material and also by the NW geometry and dimensions, which determine the Fabry-Perot-like guided/leaky mode resonances [3]. We have indeed developed a simple model based on 1D line currents induced by leaky/guide modes that fully describes the physical mechanisms underlying nanowire photoluminescence [4]. Conversely, light absorption at finite semiconductor NWs has been also addressed, showing that, apart from the expected impact on absorption of Mie resonances at normal incidence, leaky/guided modes play a relevant role at grazing incidence [5]. Our results demonstrate that semiconductor nanowires can be described as linear nanoantennas which can efficiently emit and absorb electromagnetic radiation in defined directions, shedding light onto the nano-optics underlying NW photon sources and photodetectors.

Plasmonic Core-shell Nanoparticles Boosting the Power Conversion Efficiency of Dye-sensitized Solar Cells

Dang Yuan Lei[1, 2]

[1]Department of Applied Physics, the Hong Kong Polytechnic University, Hong Kong, China
[2]Shenzhen Research Institute, the Hong Kong Polytechnic University, Shenzhen, China

Abstract— Plasmonics has been widely demonstrated to be an efficient means to improve the power conversion efficiency of dye-sensitized solar cells (DSSCs). The proposed enhancement mechanisms mainly include nanoparticle scattering-induced increased light absorption path, plasmonic near-field-enhanced absorption of both semiconductors and dyes, and transfer of plasmonic hot electrons from metals to semiconductors at the metal-semiconductor Schottky junction. However, a decreased efficiency has also been observed in other studies with inclusion of metal nanoparticles, and attributed to the reduced surface area of the underlying semiconductor in direct contact with the absorbing dyes, Forster-type energy transfer from the semiconductor or from the dyes to the metallic nanoparticles, and the electron trapping at the metal surface. These controversial results have made plasmon-enhanced DSSCs an open study. To clarify these disagreements, we will present a systematic study on the plasmonic effects in the power conversion efficiency of DSSCs by using metallic core-dielectric shell nanoparticles with adjustable shell thickness. This is because the respective contribution from each of the aforementioned mechanisms strongly depends on the distance between the metal nanoparticle and the semiconductor. For example, since the plasmonic near-field amplitude exponentially decays from the nanoparticle surface, it is expected that the plasmon-enhanced absorption of both semiconductors and dyes will decrease with increasing the dielectric shell thickness. On the other hand, the dielectric shell on the metal nanoparticle can also rule out the possibility of electron trapping at the metal surface, thus clarifying the negative contribution by inclusion of metal nanoparticles in DSSCs. Specifically, we will investigate the power conversion efficiency as a function of the shell thickness varying from 0 to 20 nm, aiming at providing a complete scenario of the contribution channels and their respective dominant ranges.

Theoretical Description of Novel Applications of Nano-plasmonics in Super-resolution Microscopy

Y. Sivan
Unit of Electro-optics Engineering, Ben-Gurion University, Israel

Abstract— We study various applications of metal nanoparticles and metal patterned surfaces in microscopy, including super-resolution techniques in live-cell imaging as well as in inorganic systems.

The field of nanoplasmonics has attracted a lot of interest over the last few decades due to a wide variety of applications in many fields. Here we focus on the theoretical description of various novel applications of metal nanoparticles in super-resolution microscopy, including Stimulated emission depletion (STED) microscopy and saturated excitation (SAX) microscopy. We show the importance of a detailed account of the temporal and temperature dependence of the optical and thermodynamic properties of the medium in order to interpret correctly the images; in live-cell imaging, this is also necessary in order to avoid damage to the cells.

We further discuss the relevance of these considerations to photothermal imaging, where the generated heat modifies the optical properties of the medium, hence, is detectable with a variety of interferometric techniques and the extension of these ideas to 2D imaging, namely, to imaging in a close proximity to a metal patterned surface, a configuration which is very popular among bio-chemists and cell biologists. This is done partially in order to allow for effective removal of the generated heat in the metal. We describe the challenges on the way to achieve super-resolution in these two configurations.

Finally, we establish links to the novel application of refractory (high temperature) plasmonics.

Optical and Electrical Design of Novel Photodetectors Based on Hot-electron Collection

Yaohui Zhan, Xiaofeng Li, Shaolong Wu, and Kai Wu
School of Optoelectronic Information Science and Engineering, Soochow University, China

Abstract— Conventional photodetectors are mostly propelled by p-n junctions, where the detection wavelength is constrained by the band-gap width. Here we present some novel designs on metal/insulator/metal, which shows strong detection tunability without such a material constraint. The proposed hot-electron devices exhibits superior optical and electrical advantages, i.e., optically the proposed design leads to a strong asymmetrical photoabsorption and results in a high unidirectional photocurrent, as desired by the hot-electron collection; electrically the hot-electrons are generated in the region very close to the barrier, facilitating the electrical transport.

Plasmonic Properties of Ion-shaped Nanoparticles

Giancarlo Rizza
Laboratoire des Solides Irradiés (LSI) , Ecole Polytechnique
UMR 7642 CEA/DSM/IRAMIS, CNRS, Palaiseau Cedex 91128, France

Abstract— In the last years, ion-shaping technique has been proposed as an innovative and powerful tool to sculpt the matter at the nanometer scale [1–3]. Its importance relays in its unique capability to control both the morphology and the spatial orientation of metallic nanoparticles embedded within an amorphous host matrix. For example, spherical nanoparticles embedded within a dielectric matrix can be shaped into a nanowires along the ion-beam, Fig. 1(a). However, more complex shapes can also be obtained, e.g., a solid sphere with two arms. or onion-like NPs (prolate hollow NPs and prolate silica@metal nanoshell), Fig. 1(b). Consequently, ion-shaping technique can be seen as a novel route for downscaling the engineering of embedded NPs with a precision that is barely reachable with standard techniques, Fig. 1(c).

In the first part of this talk the fabrication of a model system and the potentialities offered by the ion-shaping technique will be reviewed. In particular, a model system is composed of nearly monodisperse metallic nanoparticles (NPs) (8–100 nm) confined between two silica. We show that the ion-shaping is not limited to the transformation into prolate nanorods and/or nanowires, but that depending on the initial size of the NPs, several new classes of ion-shaped NPs can also be obtained: i) facetted-like NPs, ii) nanowires growing from a facetted core or iii) chromosome-like NPs. In parallel, the evolution of the temperature profile within the nanoparticle is simulated by implementing the thermal-spike model for three-dimensional anisotropic and composite media [4]. In this way, a clear correlation is found between the fraction of the nanoparticle that is molten (vaporized) and the deformation path followed by the nanoparticles during the irradiation. This allows the construction of a size-vs-shape diagram relating the initial nanoparticle size to its final morphology. This diagram is used to give a rational description of the ion-beam shaping process for all the nanoparticle dimensions [5].

Besides the fundamental aspects related to the ion-matter interaction, ion-shaping can also be used to give new insights into the plasmonic properties of metallic nanorods and nanowires. Here, Electron Energy Loss Spectroscopy (EELS) is used to study Localized Surface Plasmon Resonances (LPSR) in ion-shaped metallic nanoparticles with a nanometer-scale spatial resolution [6]. LSPR are generated through electron excitation is a Scanning Transmission Electron Microscope (STEM), equipped with a High Angle Annular Dark Field (HAADF) detector. As the NPs are continuously deformed under irradiation, we investigate the LPSRs dependance on

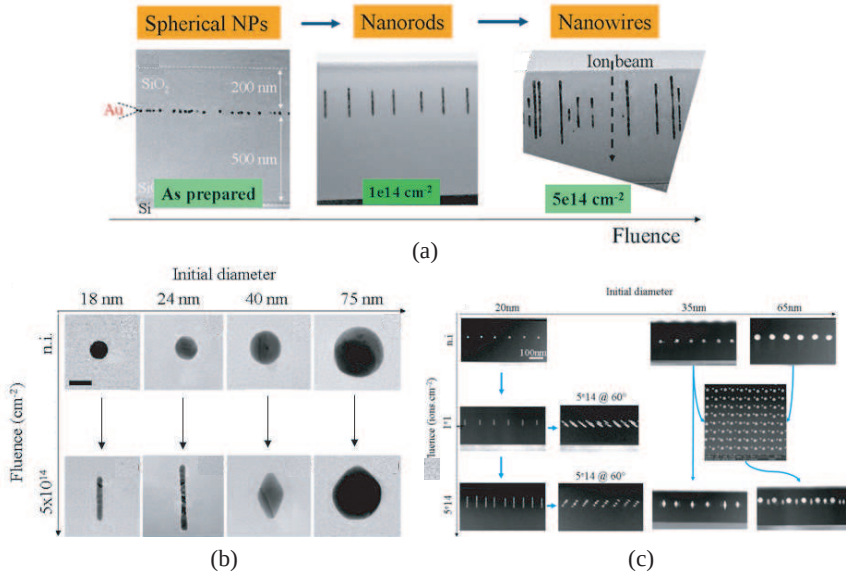

Figure 1: (a) irradiation-induced ion-shaping of Au NPs embedded within a SiO_2 matrix. (b) Relationship between initial NP size and final morphology. (c) Ion-shaped plasmonic crystals.

both the geometry and aspect ratio of the nanostructure. Finally, optical spectra are simulated using a specifically developed Auxiliary Differential Equations-Finite Difference Time Domain (ADE-FTDT) code [7], whereas EELS spectra and maps are simulated using the MNPBEM toolbox [8].

This work demonstrates the possibility to use ion irradiation as tool for the controllable fabrication of a whole family of plasmonic nanostructures with topologically tunable optical properties. These ion-beam shaped composite media have potential applications spanning from plasmonic photovoltaics, to bio-sensing, SERS and SEIRA spectroscopies.

Magnetic Field Modification of Optical Magnetic Dipoles

G. Armelles, B. Caballero, A. Cebollada, A. Garcia-Martin, and D. Meneses-Rodríguez
IMM — Instituto de Microelectrónica de Madrid (CNM-CSIC)

Abstract— Exploring and acting on the magnetic component of the electromagnetic field (optical magnetic field) in plasmonic nanostructures and metamaterials allows extending the control of light matter interaction, not only via the excitation of electric dipoles, but also through magnetic dipoles [1]. Many of the systems considered to study these effects make use of Babinet's principle, which deals with the complementarity of the optical response of structurally complementary systems. An archetype of complementary systems is that which relates metallic disks (electric dipole) with holes (magnetic dipole) in a metallic film [2, 3].

Here we demonstrate magnetic field modulation of the magnetic dipolar moment characteristic of resonant nanoholes in a thin metallic magnetoplasmonic film [4]. This effect is due to the magnetic field action on the electric currents induced around the hole and responsible for the existence of the magnetic dipole. This is experimentally shown by determining the contribution of holes to the Magneto Optical activity of a perforated magnetoplasmonic film, and comparing it with its Babinet inverted system: the contribution of disks to the MO activity of a layer of magnetoplasmonic disks on a substrate. Both, holes and disks, have mirror imaged MO spectral dependencies. This complementarity of the MO activity in structurally complementary systems may be considered as the equivalent to Babinet's principle in magnetooptics and proofs magnetic field effects on optical magnetic dipoles in the visible.

Abstract— Single semiconductor nanowires enable a diverse range of applications in sensing, photodetection, and photovoltaics. Such devices allow versatile designs on the cross-sectional configuration for controlling and optimizing the optical and electrical response. Although antenna effect is present in these devices, contributing improved absorption, a convincingly high absorption in a broad spectral band has seldom been realized.

We performed a series of numerical studies on properly design of the cross-sectional morphology for the photovoltaic single nanowires, with considering both optical absorption as well as the detailed carrier transport in the compact cells. Circular, square and crescent-deformed single nanowires are studied by examining the absorption spectra, internal cavity resonances, external quantum efficiency, current-voltage characteristics, etc., enabling a complete performance evaluation on the the designed single nanowire solar cells. For example, our study shows that the photocurrent density of the crescent-deformed single-nanowire solar cell can be improved by over 45%; under assistance of a metallic back reflector the photocurrent enhancement ratio can be up to 66.2% without taking into account the material reduction. We have also performed an extensive electrical investigation on the electrical optimization of single-nanowire solar cells.

Nanomolecular Mechanisms for Enhancing Light Capture in Silicon

Tom Markvart[1], **Nick Alderman**[1, 2], **Lefteris Danos**[3], **Liping Fang**[1], **and Thomas Parel**[1]

[1]Solar Energy Laboratory, University of Southampton, Highfield, Southampton SO17 1BJ, UK

[3]Department of Chemistry, University of Lancaster, Lancaster, UK

Abstract— Efficient capture of sunlight remains one of the great challenges to photovoltaics today. This is particularly so for the dominant photovoltaic material — crystalline silicon — which, as an indirect gap semiconductor, needs several hundred micrometers thickness for efficient operation. This paper will review the principal concepts that are currently being considered to enhance light capture by the solar cell. We shall, in particular, compare and contrast two main lines of thought that underpin the current status of the field. The first, based on thermodynamics, makes use of light trapping where photon path within a structure is extended by virtue of a stochastic photons distribution inside a dielectric/weakly absorbing semiconductor. The second approach rests on the use of sub-wavelength or nano-scale structures which allow the possibility of electromagnetic energy injection into very thin semiconductor layers, by direct interaction with the trapped modes or via the near field of an intermediate dipole absorber or scatterer.

The use of light trapping to enhance current generation in silicon solar cells can be traced to the COMSAT "black cell" in the 1970's, with a surface texture in the form of etched pyramids [1]. A theoretical explanation which gives the limit to light trapping in thermodynamic terms soon followed [2] but the origins of the fundamental ideas are much older, and date back to Planck's celebrated papers that marked the beginning of the quantum theory [3]. This approach has more recently been revisited and combined with the frequency management of light, more usually encountered in the so-called fluorescent concentrators/collectors [4, 5]. If combined with simple photonics this thermodynamic "squeezing" of light can produce devices which can concentrate diffuse light and operate with photon collection efficiency in excess of 90%. A similar structure (the "photonic bandgap solar cell") can be optimised for light trapping, and the resulting energy conversion efficiency can match (or even slightly exceed) the efficiency of an ideal (thick) crystalline silicon solar cell.

We shall then take a look at photon management at the "nanoscale". Particular attention will be paid to two principal mechanisms for the generation of electron-hole pairs in a very thin layer of weakly-absorbing semiconductor such as silicon, via the excitation of molecules near the surface:

(i) Photon tunnelling between an excited molecular state and the trapped modes inside the semiconductor layer, mediated by the evanescent field;
(ii) Interaction between the near field of the molecular dipole and the transition dipole moment of the electron transition between the valence and conduction band of the semiconductor. Similar to Förster's resonance dipole interaction between molecules [6], this mechanism parallels the energy collection by light harvesting in the photosynthetic unit [7–9].

Research and Design of Photonic Devices Based on Optical Tamm Plasmon

Wei-Li Zhang, Fen Wang, and Yun-Jiang Rao
Key Laboratory of Optical Fiber Sensing & Communications (Education Ministry of China)
University of Electronic Science & Technology of China, China

Abstract— As a special type of surface plasmon (SP), optical Tamm plasmon (OTP) can be excited directly by TE or TM polarized light without any additional operations, even at the status of normal incidence. Usually, OTP can be observed at the interface of metal and distributed Bragg reflector (DBR), showing stronger light-trapping ability than SP. Taking advantages of all these characteristics, many photonic devices based on OTP have been reported, such as optical switch, laser, and perfect absorber, which opens a new way for the realization of all-optical integrated photonic circuits.

Firstly, an all-optical bistable switching is proposed through sandwiching a Kerr medium in the metal-DBR structure. We realize the clockwise (anticlockwise) bistability by varying the intensity (angle) of the external optical injection. This structure is also proved to be polarization sensitive, showing lower switching threshold in TM-polarized injection than TE.

Based on the above bistable structure, we add an additional DBR in the metal side and realized low-threshold all-optical bistable logic control. Control (i.e., pump) and controlled (i.e., probe) light are chosen near two OTP, respectively. Intensity and injection angle of pump light can induce bistable effect with low threshold because of the enhanced Kerr nonlinearity. Meanwhile, the probe changes correspondingly with the pump.

Besides the above-mentioned applications, optical sensing using OTP is also supposed to be a promising way to enhance sensing performance. We use a high-refractive-index-contrast optical Tamm plasmon (OTP) structure, i.e., an air/dielectric alternate-layered DBR coated with metal. In the reflection spectrum of the structure, a dip related to the formation of OTP appears. Wavelength and reflectivity of this dip are sensitive to variation of ambient refractive index. Thus refractive index sensing can be achieved by wavelength or intensity interrogation. In addition, metal thickness, injection angle and polarization can be adjusted according to the detailed sensing requirement.

Proximity Effect Assisted Absorption Enhancement in Thin Film with Locally Clustered Nanoholes

Shaolong Wu, Xiaofeng Li, Yaohui Zhan, and Cheng Zhang
College of Physics, Optoelectronics and Energy & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China

Abstract— Periodically structuring the photoactive material in micro/nano-scale has been extensively employed for high-efficiency light harvesting; however, the clustering effect is usually encountered in fabrication process and thus believed to be harmful. This study indicates that the controlled clustering effect can be useful for substantially improving the light-trapping characteristics of a thin film. For a 100-nm-thick amorphous silicon film, the optimal nanohole-clustering design is able to double the integrated optical absorption over solar spectrum, compared to the planar counterpart, as well as shows much improved optical performance than that of the unclustered setup. The behind physical reasons are intensively explored/discussed in terms of mode analysis, dispersion relation, power and electric profiles. As a conclusion, the improved and wide-angle light-trapping capability of NH-clustered thin film relative to the periodic counterpart is ascribed to a combination of more available modes, higher input coupling efficiency, and higher density of photon states. We believe that the information contained would attract a wide interest in nanotechnology and solar energy utilizations (e.g., photovoltaic and photocatalytic devices) since it enables efficient photo-conversion devices based on semiconductors with low optical-absorption coefficients and short minority-carrier diffusion lengths.

Optical Resonance Analysis in Dielectric-film Supporting Metallic Gratings and the Infrared Perfect Optical Absorption Design

Zhiqiang Guan and Hongxing Xu
Center for Nanoscience and Nanotechnology, School of Physics and Technology
Wuhan University, Wuhan 430072, China

Abstract— Optical responses of dielectric-film supporting metallic grating structures are analyzed by coupled-mode analysis within single-mode approximation. Two kinds of resonances are found in the optical spectra. One is reflection deep which is also well known as extraordinary optical transmission (EOT). The other resonance is transmission null which is a new resonance and is introduced by the dielectric film. The two resonance conditions are analyzed by multiple interface scattering coefficients and their direct relation with two different phase matching conditions are revealed. The waveguide modes in dielectric films, surface plasmon polaritons on interfaces, and metal slit Fabry-Parot modes are shown to contribute to these resonances, as seen from the dispersion plots and electromagnetic field distributions. By simultaneously satisfying reflection deep and transmission null, perfect optical absorption (POA) in infrared wavelength is predicted. The POA devices show a wide range tunable POA wavelength together with very high quality factors. Benefit from phase matching analysis, three simple analytical formulas are derived for POA device design. A practical device fabrication scheme is also proposed. Thus our findings will find important applications for enhanced light-matter interactions, such as nonlinear optics, optical cavities and optoelectronics.

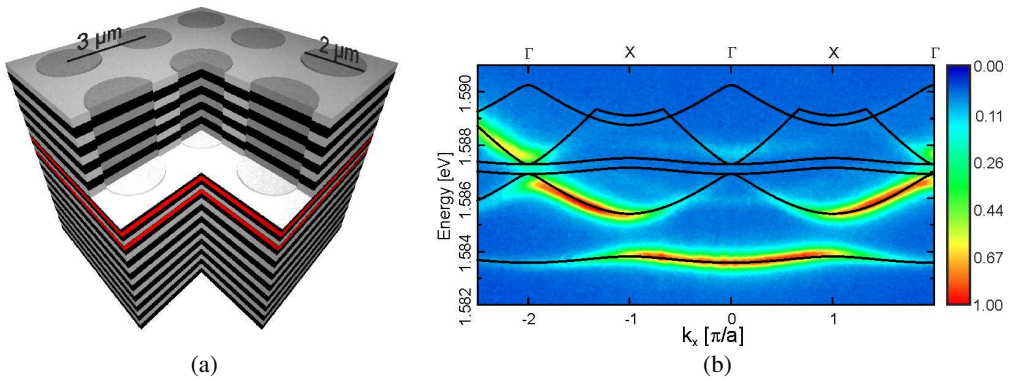
Abstract— Exciton polaritons are an ideal system to study collective behavior of macroscopic coherent quantum states in a solid state environment as they facilitate condensation into a single energy state at rather high temperatures, even under non-equilibrium conditions [1]. The properties of polaritons can be engineered by manipulating either the excitonic or photonic part of the composite particles. Nanotechnology allows defining potentials which can be arranged in almost arbitrary landscapes. This triggered the effort to engineer polaritonic integrated circuits by tailoring their flow on a chip, and furthermore makes polaritons promising candidates for solid state quantum emulation [2]. An ideal trapping technique for the implementation of polariton quantum emulation architectures should combine the following features: (i) deep and tunable confinement on a single site; (ii) controllable inter-site coupling; (iii) surface recombination effects from etching the active medium should be fully avoided.

Deep and flexible confinement of polaritons has been demonstrated in locally elongated microcavity structures [3, 4], however the technological difficulties have prevented the observation of polariton condensation phenomena under non-resonant pumping in such devices.

Here, we exploit this technology that enables deep tunable trapping in any 2D geometry without compromising any of the favorable polariton characteristics. Attractive polariton potentials are generated by local elongations of the microcavity that can be defined by standard lithography (Fig. 1(a)). The optical confinement in such buried traps indeed can exceed several meVs, facilitating strong localization of polaritons in single sites. We observe condensation of polaritons in such mesas, study the directed flow of polaritons into such traps and furthermore demonstrate the successful formation of polariton bands separated by well-defined energy gaps in a square lattice geometry (Fig. 1(b)). Under high power injection, we observe the formation of a polariton condensate in the energy gap at the M-Point of the Brillouin zone, which indicates the existence of a localized gap state.



(a) (b)

Figure 1: (a) Layer sequence of our polariton lattice. Confinement is accomplished by the locally elongated cavity. (b) Polariton band structure in the square lattice (experiment and theory).

Light-matter Interaction of a Many-body System in Solid State: Resonance Fluorescence of the Two Dimensional Electron Gas

Nathan Shammah and Simone de Liberato
School of Physics and Astronomy, University of Southampton, Southampton SO17 1BJ, UK

Abstract— In 1969 Mollow predicted that when a two level quantum system is strongly pumped near its resonance, it reemits light not only at the resonance frequency but also at two satellite frequencies. The prediction of this nonlinear phenomenon is a major result of quantum optics theory. Part of its beauty resides in the fact that it could be tested in very different solid-state systems that fit into the two-level-system and dipole-interaction approximation.

From this premise, we extend the description of resonance fluorescence to a solid-state system in which the electron gas is confined in two dimensions. This system can be implemented in a doped semiconductor quantum well, in which the electronic excitations are intersubband transitions. This is an attractive system for the generation of terahertz radiation, which currently poses a technological challenge. As transitions occur between parallel subbands, their bare absorption line is very thin (down to a few meV). When the system is strongly pumped, each electron cycles between the two subbands, similarly to what occurs in a collection of independent two level systems. For this reason driven intersubband transitions have been described in terms of dressed states of artificial atoms in solid state.

We show that this picture, while useful to describe the collective Rabi oscillations, is broken when the system couples with the free electromagnetic field. The unbound nature of intersubband transitions allows processes between different electron states. We develop a general many-body theory that can be used to describe the resonance fluorescence of this and similar systems. Due to the many-body nature of this system, several interaction processes must be accounted for, notably also electron interference effects that lead to the enhancement of the central peak of photon emission. This mechanism is controlled by the coherence of the two-dimensional electron gas, as explored analytically and numerically. This mechanism thus hints at the intriguing possibilities of mapping the coherence of the two-dimensional electron gas onto photon emission profile. Constraints on the characteristics of a suitable realization in solid state will be discussed.

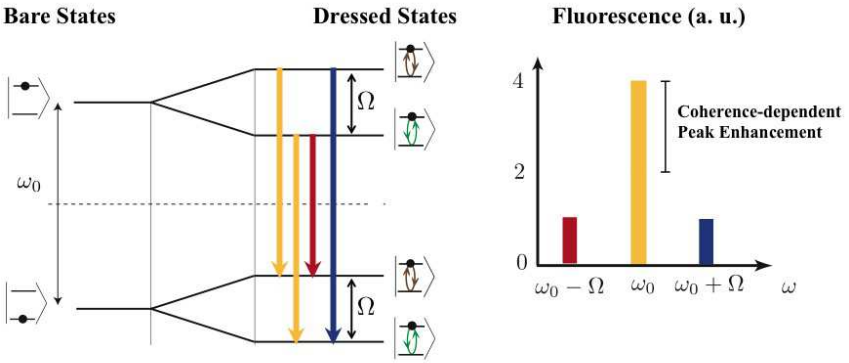

Figure 1: Energy levels and transitions leading to the Mollow triplet explained in terms of dressed states. In this system many-body effects lead to a different fluorescence profile.

Abstract— In this talk I shall show that emitter-cavity dressed states may be probed through interactions with a thermal environment in solid-state cavity QED systems. This is true even in regimes that can be described semiclassically in the absence of such an environment, for example when the emitter-cavity coupling strength is dominated by cavity losses. For this experimentally relevant case, I shall outline how bath-induced dressed state transitions lead to asymmetries in the cavity emission properties, which are absent otherwise. This behaviour is attributed to the quantum nature of the environment and its resulting sensitivity to the joint eigenstructure of the cavity and emitter. This heralds a failure of the semiclassical approach, and challenges the notion that coupling to a thermal bath supports a more classical description of the system. Bath-induced asymmetries also persist over wider regions of parameter space, including the Fano and quantum strong coupling regimes.

Two-color Second-order Correlations and Pulsed Resonance Fluorescence Spectrum of the Light Scattered by a Quantum Dot

K. Konthasinghe, **M. Peiris**, **B. Petrak**, **and A. Muller**
University of South Florida, Tampa, FL, USA

Abstract— The theoretical prediction and experimental measurement of the spectrum of the light resonantly scattered by a two-level atom remains one of the major achievements in quantum optics. Under monochromatic excitation, the resonance fluorescence spectrum evolves from a sharply peaked line (coherently scattered light) into the characteristic Mollow triplet (incoherently scattered light) as the magnitude of the external field is increased [1]. Today, this evolution is also well-documented in other two-level quantum systems, such as quantum dots (QDs). Within the monolithic support of a semiconductor chip, a resonantly driven two-level QD may be used for emerging applications in quantum information science, for example as a source of single photons with tailored properties. However, despite much progress in recent years in this direction, the conventional approach to investigating this system still typically resorts to ordinary first or second order correlations of light scattered under monochromatic excitation.

Here we report recent measurements that go beyond basic photon correlation spectroscopy of a quantum dot under monochromatic laser excitation. First, we report the measurement of the resonance fluorescence spectrum under pulsed excitation. Although one might expect pulsed excitation to simply give rise to a broadened version of the Mollow triplet, our measurements reveal a rich spectrum with a shape strongly dependent upon the laser pulse width and laser intensity. Secondary sidebands emerge as the light-matter interaction evolves beyond saturation, i.e., when the Rabi frequency exceeds the decoherence rate. At the same time, pulsed-area dependent Rabi oscillations develop, with a different evolution for coherently and incoherently scattered light [2]. Second, we describe experiments in which the light scattered by the QD under resonant excitation is being spectrally filtered. Using tunable spectral filters in front of the detectors of a Hanbury-Brown-Twiss type arrangement provides access to a color-resolved two-photon spectroscopy of the scattered light. By scanning the filter frequencies and recording the detector coincidence rate, a two-photon spectrum (TPS) — recently introduced theoretically by del Valle et al. [3] — can be reconstructed experimentally for the first time. The TPS captures previously obscured features of the cascaded emission involved in the scattering process, such as "leapfrog" transitions proceeding via virtual intermediate states. Our measurements further reveal that the underlying correlated photon pair-emission violates classical inequalities such as the Cauchy-Schwartz criterium [4].

Decoherence of Semiconductor Quantum Dots Coupled to Micro and Nanocavities

Jesper Mork, **Dara McCutcheon**, **Anders Nysteen**, **and Niels Gregersen**
DTU Fotonik, Department of Photonics Engineering
Technical University of Denmark, Kgs. Lyngby DK-2800, Denmark

Abstract— A semiconductor quantum dot embedded in a micropillar or photonic crystal cavity is a promising system for realizing solid-state sources that emit on-demand indistinguishable single-photons. Such sources are considered important for the development of quantum computers. However, phonons in the solid-state environment perturb the quantum dot energy levels, leading to decoherence and jeopardizing the indistinguishability of subsequently emitted photons. In the talk we will discuss how the characteristic parameters characterizing the coupled system, like cavity quality factor and cavity-dot coupling strength, affect the rate of decoherence and the indistinguishability. It turns out that differences between phonon emission and phonon absorption probabilities lead to a "coloured" reservoir, where non-Markovian effects are important. Thus, simple approaches, where the dephasing is described by the common Lindblad-approach, fail in predicting how the indistinguishability depends on the characteristic parameters of the coupled system. Possibilities for reducing the rate of decoherence will be discussed.

Nanophotonic Design for Bright Single-photon Sources Based on Single Quantum Dots

[4]Department of Physics and Astronomy, University of Rochester, Rochester, NY 14627, USA

Abstract— Nanophotonic design can be effectively employed to engineer the radiative properties of single solid-state quantum emitters, allowing significant modification of the spontaneous emission rate, as well as spatial emission patterns. Such characteristics can be harnessed to create a variety of important devices for photonic quantum information, ranging from strongly coupled cavity quantum-electrodynamic systems to bright single-photon sources, with optimized efficiency and performance. In particular, single photon source brightness is crucial in many proposed applications, and for that single InAs quantum dots (QDs) grown epitaxially in GaAs constitute a particularly promising technology: the short QD radiative lifetimes and narrow linewidths allow for bright and pure emission, and the availability of mature device fabrication technology allows the creation of scalable nanophotonic structures with maximized efficiency.

Here, we describe design and performance of bright single-photon sources based on individual epitaxially grown InAs quantum dots embedded in GaAs-based nanophotonic geometries which can be produced via standard III-V fabrication processes. Two different types of geometries will be covered (Fig. 1), predicted and verified to provide a moderate enhancement of spontaneous emission rate and allow spectrally broad and efficient single-photon extraction and coupling respectively into free-space or guided collection optics. Our design process involves extensive use of finite-difference time domain and frequency-domain finite element-based simulations and allows optimization and assessment of Purcell enhancement factor, mode volume, and, importantly, the efficiency with which the emitted radiation can be funnelled into collection optics. The importance of dipole location within the nanophotonic structure will be illustrated. Lastly, the potential for the incorporation of nanophotonic structures with embedded single quantum dots within hybrid, III-V/silicon photonic circuits will also be discussed.

Abstract— Epitaxially-grown InAs/GaAs quantum dots are promising semiconductor quantum emitters for a variety of photonic quantum information processing applications. Their usefulness for applications such as single-photon sources is significantly increased when they are embedded in a controlled photonic environment that enables, for example, strong radiative rate enhancement (the Purcell effect) and near-unity collection into a desirable optical channel, such as a single mode optical fiber. However, the self-assembly process by which InAs/GaAs quantum dots are commonly grown results in an essentially random spatial distribution of quantum dots within the plane of the wafer, presenting a challenge in the creation of such high performance quantum nanophotonic devices. In particular, the desired photonic environments are often creating using nanophotonic geometries in which confined optical fields significantly vary over length scales of $\approx 100\,\mathrm{nm}$. Therefore, optimally performing geometries will often require knowledge of the quantum dot location prior to device fabrication.

Here, we present one approach to quantum dot location, utilizing a novel two-color photoluminescence imaging technique. We locate single InAs/GaAs quantum dots with respect to alignment features with an average (minimum) positioning uncertainty of $< 30\,\mathrm{nm}$ ($< 10\,\mathrm{nm}$). We combine this position data with spectroscopic information provided by the same microscopy setup and use calibrated device fabrication processes to create quantum-dot single-photon sources based on optimally located quantum dots. These sources are simultaneously bright (collection efficiency as high as 48.5% $\pm$5% into a 0.4 numerical aperture lens), pure (multiphoton probability $< 1\%$ at the highest collection efficiency), and Purcell-enhanced ($\approx 3\times$ Purcell factor). We will conclude our presentation by discussing new developments on the positioning technique and its application to various device geometries.

Advances in Quantum Dot Cavity Quantum Electrodynamics Using Photonic Crystal Structures

Abstract— Photonic crystal (PhC) structures embedding semiconductor quantum dots (QDs) form a fascinating platform for investigating solid-state cavity quantum electrodynamics (CQED) and its applications. Various CQED phenomena including vacuum Rabi splitting, Purcell enhancement of spontaneous emission rate, single photon tunneling and so on, have been observed in PhC nanocavities coupled with a single QD. However, some interesting aspects, which could deepen our understanding and be applicable to various nanophtonic devices, has not been revealed yet. QD-PhC coupled systems with higher quality and novel techniques/structures enable to tackle such unexplored physics in QD-CQED systems.

In this presentation, we will discuss our resent experimental progresses on QD-CQED systems with PhC structures. We first discuss the figure of merit of QD-CQED systems, g/κ, where g is the QDcavity coupling strength and κ is the cavity decay rate. Using a high-Q H0-type PhC nancavity, we achieved the largest g/κ ever reported in QD-CQED systems. This is an important step for diving into deeper strong coupling regime, where more quantum characteristics of the systems are available. We will also report a novel spectroscopic study measuring the direct spontaneous emission form a QD strongly coupled with a PhC nanocavity.

In addition to PhC nanocavities, engineered electromagnetic vacuum field in defectless PhCs provides another tool to tailor the light emission properties of QDs in the structures. In the presentation, we will briefly touch the possibility to enhance the circularly polarized light emission from QDs due to the increased density of states of circularly polarized photons in chiral 3D PhCs.

Engineering Collective Quantum Effects with Solid-state Nanostructures in Cavities

E. M. Gauger
Institute of Photonics and Quantum Sciences, Heriot-Watt University, UK

Abstract— Placing multiple optically active quantum systems in a common light field can give rise to profound non-classical phenomena. A signature example of such an effect is superradiance, where constructive interference leads to a pulse of light that is being emitted faster and more intense than is possible classically [1]. Combining this well-studied many-body effect with advances in cavity QED, super- (and subradiant) behaviour has recently been observed for pairs of superconducting qubits [2], atoms [3], and ions [4] interacting with a common cavity mode.

In this theoretical presentation, we will consider systems comprising several quantum nanostructures, which are not only collectively coupled to a structured electromagnetic environment, but which in addition also experience mutual pairwise interactions as well as the influence of their condensed matter host environment. Their mutual interactions may be — but do not need to be — naturally present (e.g., mediated by the vacuum light field or a common cavity mode), or they could be engineered in a different fashion.

Traditionally considered detrimental, we will show that when harnessed in the right way, these additional interactions become an asset for unlocking light absorption beyond what is possible classically. Suitably engineered systems can support one or more of several distinct effects contributing to enhanced photon absorption efficiencies: inverting superradiance, breaking detailed balance, und optical ratcheting. Potential practical applications of these effects include improved photon detectors [5] and light harvesting devices [6].

Interestingly — and unlike for observing superradiance — for these purposes, small numbers of quantum absorbers may be sufficient or even advantageous. Since the required levels of control over the geometrical arrangement of the nanostructures and their dissipative processes are within the current state-of-the-art, near future experimental verification of these effects may be possible.

Abstract— I will report our experiments on unconventional control of light flow in high-quality whisperinggallery-mode (WGM) resonators around an exceptional point (EP), which is characterized by the coalescence of the eigenvalues and eigenstates of a system. The presence of an EP affects the system significantly, leading to nontrivial physics with interesting counterintuitive features. In the experiment, we show that when the resonator system is operated in the vicinity of an EP, the effect of loss could be reversed. Specifically, we demonstrate that the lasing power increases with increasing the loss introduced to the system.

Wave Propagation in the Presence of Parity-Time Symmetry: Examples from Integrated Optics and Electronics

T. Kottos
Department of Physics, Wesleyan University, CT-06457, USA

Abstract— In recent years, research have focused their efforts in manipulating absorption, and via a judicious design that involves the combination of delicately balanced amplification and absorption mechanisms, to achieve new classes of synthetic structures with altogether new physical behavior and novel functionality. This idea can potentially have a vast range of applicability to wave systems, ranging from optical structured materials, to electronics and antenna arrays. In fact, optical and electronic synthetic structures, which incorporate gain and loss mechanisms such that they are invariant under space-time reflection, have been reported over the last years, showing intriguing functionality. These systems are currently known as Parity-Time symmetric systems.

In this talk we will review our recent efforts on PT-symmetric wave propagation. Using integrated photonics and electronics as a playfields we show how one can construct new circuitry designs that allow for asymmetric wave transport due to interplay of the novel properties of PT-symmetry and non-linearity or gyrotropic elements. Finally we will demonstrate a non-reciprocal dynamics occurring in a new type of PT-symmetric lattices that emerges in the presence of periodic driving.

Constant-intensity Waves in Non-hermitian Optical Systems

[4]CREOL, University of Central Florida, Orlando, FL 32816, USA

Abstract— Recent years have witnessed an intense research activity in theoretical and experimental studies of non-hermitian effects in photonics. This activity was partially initiated by the recent introduction of the concept of PT-symmetry [1] in the framework of optics [2], and its subsequent experimental observation [3]. In this context of open photonic systems, we now demonstrate for the first time the existence of so-called "constant-intensity waves" (or CI-waves) [4], which can evolve with constant intensity in the presence of inhomogeneous gain-loss media — a property known so far only for plane waves in free space. We show here that quite in contrast to the conventional paradigm of hermitian optics, such CI-waves can even exist in strongly scattering cavities and resonators when these are composed of components with gain or loss that satisfy certain relationships in terms of the real and imaginary part of the underlying refractive index. We derive these relationships analytically for such CI-states in one-dimensional Fabry-Perot cavities and in the particularly counter-intuitive case of disordered resonators. The existence of such novel waves allows us also to study for the first time the modulation instability of constant wave solutions in optical complex potentials. In particular, for a general class of non-Hermitian potentials we can derive analytical constant intensity solutions valid for any sign of the Kerr nonlinearity. In the self-focusing regime, these waves are always unstable, while in the defocusing case the instability appears for specific perturbation Bloch momenta values. In both regimes, the CI-waves break up into filaments following a complex nonlinear evolution pattern.

Non-Hermitian Supersymmetric Photonic Structures

R. El-Ganainy
Department of Physics, Michigan Technological University, Houghton, Michigan 49931, USA

Abstract— Parity time reversal (PT) symmetry has been a subject of intense investigations for the last few years [1]. PT symmetric photonic structures represent a sub-class of non-Hermitian photonic arrangements and they exhibit a wealth of intriguing effects such as power oscillations, asymmetric transport dynamics and spontaneous symmetry breaking [2]. On the other hand, the notion of discrete supersymmetry (SUSY) has been only recently introduced to the research field of optics [3, 4].

Here we show that combining non-Hermiticity and supersymmetry can be employed to engineer the complex spectrum of photonic structures and we discuss how to utilize this concept to solve a long standing problem, namely that of building single mode laser arrays that exhibit a regular temporal behavior [5].

In particular, starting from a cavity array that contains N lasing elements, we construct its partner array by using discrete supersymmetry. By introducing an evanescent coupling between the two arrays, we show how the quality factors of the supermodes can be tuned at will through a precise control of the optical loss of the superpartner structure.

We investigate the lasing onset of these configurations under different conditions and we show that single-transverse mode operation can be achieved either by introducing nonuniform optical losses to the superpartner array or by applying selective pumping to the main structure [6].

We discuss the robustness of these arrangements against disorder and nonlinear effects and we show that the laser array can function in the single mode regime within a wide range of physical parameters. Finally, methods to extend these design concepts for two dimensional planar structures are also presented.

Local Symmetry Induced Structures in Wave Scattering Systems

P. A. Kalozoumis[1], **C. Morfonios**[2], **F. K. Diakonos**[1], **and P. Schmelcher**[2]

[1]Department of Physics, University of Athens, Athens GR-15771, Greece
[2]Zentrum für Optische Quantentechnologien, Universität Hamburg
Luruper Chaussee 149, Hamburg 22761, Germany

Abstract— Symmetries constitute one of Physics' corner stones as they possess a central role in the theoretical treatment of physical systems. The usual pathway, which is based on the global validity of a symmetry transformation is an idealized scenario, not adequate in most cases for the description of realistic physical systems. On the other hand, in a multitude of complex systems, like large molecules [1] and quasicrystals [2], these symmetries appear broken and manifest locally in restricted spatial domains. Moreover, technological advances often require such symmetries to be present by design in application-oriented, tailored structures as photonic multilayered devices [3], quantum superlattices [4] or acoustic waveguides [5]. Focusing on broken global symmetries — namely, inversion, translation and PT-symmetry — locally retained in one-dimensional scattering setups, we find a class of symmetry-induced, invariant currents which provide a systematic pathway towards discrete symmetry breaking. In a fundamental level, these currents, viewed as remnants of the corresponding broken global symmetry, allow for the generalization of the well-known Bloch and parity theorems through an appurtenant mapping relation [6].

Additionally, we develop a local symmetry-based construction scheme which utilizes the simultaneous decomposition of a setup in non-overlapping reflection symmetric parts for the design of complex wave mechanical devices with intriguing wave control properties [7, 8]. Setups with such decomposition properties constitute a new class of materials referent as *completely locally symmetric* (CLS) [6]. The fact that this scheme lies on very general symmetry arguments, combined with the Helmholtz-Schrödinger isomorphism, provide a unified framework applicable to quantum, optical and acoustic systems, notwithstanding their essential differences. Employing aperiodic photonic multilayers, we implement the aforementioned design technique and we find how local reflection symmetries are utilized for the manifestation of perfect transmission resonances at preselected frequencies [8]. Subsequently, by considering optical systems with PT-symmetry we show that the symmetry-induced invariant indicates the broken PT-symmetric phase and acts as the natural order parameter for the system, permitting the full determination of the corresponding phase diagram for any incoming scattering state [9]. Finally, recent and successful experimental results performed in acoustic waveguides [10] pave the way towards the design of specialized filtering devices with possible control of wave localization.

Dissipation-induced Super Scattering from PT-synthetic Plasmonic Metafilms

Simin Feng
Naval Surface Warfare Center Dahlgren Division, Virginia, USA

Abstract— Parity-time (PT) synthetic materials represent a new class of metamaterials with novel electromagnetic properties arising from a delicate balance between loss and gain elements. Interaction between loss and gain media can lead to surprising electromagnetic properties which cannot be fund in nature. Except for compensating loss with gain, active plasmonic materials offer an ideal platform for studying non-Hermitian Hamiltonian in the electromagnetic domain at the subwavelength scale. Currently, most studies on the PT-symmetric structures use analytical models based on either one dimensional scalar Helmholtz equation or two dimensional scalar paraxial wave equation. For plasmonic metamaterials having subwavelength "meta-atom" as resonators, above analytical descriptions are not applicable. In this paper, by recasting Maxwell's equations in a Schrödinger-type form, we numerically investigate electromagnetic properties of a PT-synthetic plasmonic metafilm composed of a planar array of coupled PT-symmetric dimers embedded in a metallic substrate. We found that the extraordinary transmission and reflection of a finite bandwidth can occur at the same wavelength when the electromagnetic wave is incident on the PT-synthetic metafilm. Remarkably, this phenomenon disappears if the metallic substrate is lossless while keeping other parameters unchanged. When the metafilm is adjusted to the vicinity of a spectral singularity, tuning the substrate dissipation to a critical value can lead to supper scattering in stark contrast to what would be expected in conventional systems. This phenomenon implies that strong coherent radiation may be able to generate from a cavity having gain elements by tuning cavity dissipation to a critical value.

PT and RT Symmetries in Non-reciprocal Periodic Photonic Systems

Jin Wang[1], **Hui Yuan Dong**[2], **C. W. Ling**[3], **C. T. Chan**[4], **and Kin Hung Fung**[3]

[1]Department of Physics, Southeast University, Nanjing, China
[2]School of Science, Nanjing University of Posts and Telecommunications, Nanjing, China

[4]Department of Physics, Hong Kong University of Science and Technology, Hong Kong, China

Abstract— We use simple examples to illustrate the roles of PT symmetry and RT symmetry in phenomena associated with non-reciprocal dispersion. In the first example, we present a one-way surface mode in a PT symmetric magnetized photonic system at "effective" mu close to zero. The new mode is non-propagating and purely magnetic when the system is infinite while it becomes propagating in the finite case. One-way optical tunneling is supported in oblique-incidence configuration. In the finite-slab case, the radiative mode supports non-reciprocal unidirectional beam shift at normal incidence. The PT symmetry provides exceptional point and high transmission. In the second example, we show that a magnetized diatomic chain of plasmonic nanoparticles can support a non-reciprocal dispersion, only when the RT symmetry is broken. Plasmonic optical isolation can be achieved in such a simple non-chiral and translationally periodic structure.

Electromagnetic Scattering Properties of Topological Insulators

Lixin Ge[1], **Dezhuan Han**[2], **and Jian Zi**[1]

[1]Key Laboratory of Micro and Nano Photonic Structures (MOE)
Key Laboratory of Surface Physics, Department of Physics, Fudan University, Shanghai 200433, China
[2]Department of Applied Physics, Chongqing University, Chongqing 400044, China

Abstract— Topological insulators (TIs) exhibit many exotic properties. In particular, a topological magneto-electric (TME) effect, quantized in units of the fine structure constant α, exists in TIs. As is known, the constitutive relations for bi-isotropic media are:

$$\begin{aligned}\mathbf{D} &= \varepsilon_0\varepsilon\mathbf{E} + (\chi + i\kappa)\sqrt{\varepsilon_0\mu_0}\,\mathbf{H} \\ \mathbf{B} &= \mu_0\mu\mathbf{H} + (\chi - i\kappa)\sqrt{\varepsilon_0\mu_0}\,\mathbf{E},\end{aligned}$$

where κ and χ are the chirality and magneto-electric parameters, respectively. The medium with $\chi \neq 0$ is non-reciprocal and named Tellegen medium. TIs are a kind of Tellegen medium in which χ is contributed from surface Hall currents and quantized in units of α. We theoretically study the scattering properties of electromagnetic waves by TI cylinders and spheres. Compared with ordinary dielectrics, the electromagnetic scattering of TIs shows many unusual features due to the TME effect. For TI cylinders, the topological quantization can be determined simply by measuring the electric-field components of scattered waves in the far field at two scattering angles. This could also offer a way to measure the fine structure constant. Moreover, in certain configurations, the bulk scattering can be suppressed leading to strong backward scattering in both Rayleigh and Mie scattering regimes due to the TME effect. At anti-resonance frequencies, an interesting filed trapping phenomenon is found which is absent in conventional dielectric cylinders. For TI spheres, enhanced backward scattering and field trapping effect at anti-resonances are also investigated.

Four-port THz Circulator Based on One-way Magnetoplasmonic Cavity

Kexin Liu[1, 2] **and Sailing He**[1, 2]

[1]Department of Electromagnetic Engineering, School of Electrical Engineering
Royal Institute of Technology, Stockholm S-100 44, Sweden

State Key Laboratory of Modern Optical Instrumentation
Zhejiang University, Hangzhou, China

Abstract— In recent years, research on plasmonics in THz spectral range has progressed rapidly due to its important potential in spectroscopy, imaging and integrated circuits. Many THz plasmonic components and waveguides are based on surface plasmons or spoof surface plasmons on semiconductor or metal surface. When the metals and semiconductors are under external static magnetic field in the Voigt configuration, the surface plasmons could only propagate in one direction in a certain frequency regime, which is called one-way surface magnetoplasmons [1, 2]. This effect could be used to design nonreciprocal devices such as isolators (to prevent unwanted reverse propagation of wave) and circulators in THz frequencies.

Here we introduce a one-way magnetoplasmonic cavity to construct a Four-port THz circulator. The cavity is a semiconductor disk which supports magnetoplasmons at the boundary. The magnetoplasmons circulate around the cavity in one-direction, clockwise or anticlockwise, depending on the direction of the applied magnetic field. The cavity couples with two parallel waveguides. Because of the unidirectional property of the magnetoplasmons, the coupling efficiency is different for the guiding wave from different ports. As shown in the following figure, assuming that the magnetoplasmons circulate around the cavity anticlockwise (blue line), the guiding wave from Port 1 cannot couple with the one-way magnetoplasmonic cavity, as direction of their wave vectors are opposite, and thus the wave exports at Port 2 (red line). While, the guiding wave from Port 2 can couple with the cavity and export at Port 3 (green line). For the same reason, the wave from Port 3 exports at Port 4 and the wave from Port 4 couples out at Port 1. The above four-port circulator is analyzed by the coupled-mode theory and demonstrated by numerical simulation.

Abstract— We propose a scheme of creating a tunable highly nonlinear defect in a one-dimensional photonic crystal. The defect consists of an atomic cell filled in with two isotopes of three-level atoms. The probe-field refractive index of the defect can be made parity-time (PT) symmetric, which is achieved by proper combination of a control field and of Stark shifts induced by a far-off-resonance field. In the PT-symmetric system, families of stable nonlinear defect modes can be formed by the probe field.

Theoretical Study of Infinite-lifetime Guided Modes inside the Light Cone

Xingwei Gao[1], **Chia Wei Hsu**[2], **Marin Soljacic**[2], **and Hongsheng Chen**[1, 2]

[1]The Electromagnetics Academy at Zhejiang University, Zhejiang University, Hangzhou 310027, China
[2]Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Abstract— Normally, guided modes only exist below the light line, where fields are confined in the higher-index region due to total internal reflection. However, a photonic-crystal waveguide allows for guided modes above the light line [1]. These modes, instead of being leaky, can have infinite lifetimes. By using mode expansion method with structural symmetry, we theoretically studied this phenomenon in a 2D layered waveguide. The absence of radiation loss is explained by an edge cancellation among transmitted fields from multiple eigenmodes inside the photonic crystal waveguide.

Mode Suppression for Microdisk Laser with Cylindrical Metallic Nanoparticle

J. Y. Hsing, T. E. Tzeng, and T. S. Lay
Department of Electrical Engineering, Graduate Institute of Optoelectronic Engineering
National Chung Hsing University, Taichung, Taiwan

Abstract— We have fabricated microdisk laser with a cylindrical gold-germanium (AuGe) nanoparticle on the microdisk cavity, and measured the lasing spectra at 80 K. The microdisk cavity has a diameter near at 3.5 μm. The cylindrical metallic nanoparticle is placed close to the rim of the microdisk. The diameter and thickness of cylindrical AuGe nanoparticle are 230 nm and 50 nm, respectively. The gain material is InGaAs quantum dots (QDs) grown on (001) n^+-GaAs substrate by molecular beam epitaxy. The wafer structure consists of 1 μm AlGaAs sacrifice layer and InGaAs QDs active layer. The emission properties for the microdisk lasers were investigated at $T = 80$ K by optical pumping under pulse condition with duty cycle 1.5% and pulse width 30 ns. Fig. 1(a) illustrate the top view of SEM image for microdisk cavity without cylindrical AuGe nanoparticle, and the lasing spectrum. The lasing peaks are designated to whisper gallery modes (WGMs) obtained by simulation, as shown in Fig. 1(b). Fig. 2(a) shows the SEM image for the microdisk cavity with cylindrical AuGe nanoparticle, and the corresponding lasing spectrum which exhibits a blue-shift emission to a strong 1st-order WGM with $m = 24$ of wavelength near 1000 nm. Fig. 2(b) shows the simulated lasing spectrum of the microdisk with AuGe nanoparticle. The adding of AuGe nanoparticle to the microdisk eliminates the $M_{1,22}$, $M_{1,21}$ WGMs at longer wavelength, and enhance the $M_{1,24}$.

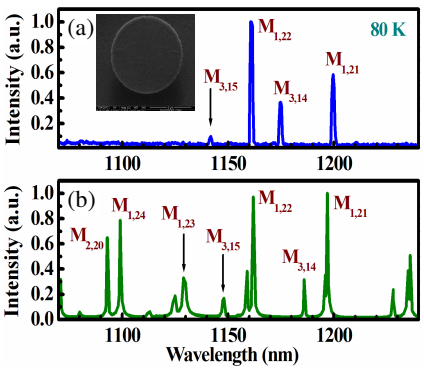

Figure 1: Microdisk laser without cylindrical AuGe nanoparticle.

LTE Baseband DSP/FPGA for Beamspace MIMO RF Antenna

Uooyeol Yoon and Dang-Oh Kim
Wireless Power Transfer Research Center
KAIST (Korea Advanced Institute of Science and Technology), Daejeon, Republic of Korea

Abstract— As the MIMO processing gets popular in LTE wireless mobile communication, the number of RF chains of eNodeB for MIMO processing gets increased, which results in the increase of cost and the volume of eNodeB base-station. In order to solve this problem, the Beam-space MIMO RF Antenna has been proposed. The advantage of Beam-space MIMO RF Antenna is to reduce the RF chain which results in the cost reduction of LTE RF module. In order to support Beam-space MIMO RF Antenna, the LTE baseband signal from LTE modem should be modified. This modification includes the matrix computation which is hard to be performed by FPGA. From this observation, authors have implemented baseband algorithm in DSP processor which enables the complex matrix computation efficiently. The requirement of DSP processing is 300 Mbps in 33 MHz band which supports 4 streams. While DSP processor is very efficient for the matrix computation, there should be interface module between baseband DSP and the impedance loading module for Beam-space MIMO RF Antenna. Authors have implemented this interface module with FPGA. The interface between DSP processor and FPGA has been implemented PCIe (PCI Express) to support high-speed serial IO. The integration system has been designed with LTE modem that supports 4×4 MIMO. The testing of full integration system consists of baseband DSP, FPGA, LTE modem and Beam-space MIMO RF Antenna module. Various spectrum analyzers have been used to validate the design of Beam-space MIMO RF baseband system during the test procedure.

Dynamical and Stochastic Approach to Non-linear Polarization Optics

Satoshi Tuchida and Hiroshi Kuratsuji
Department of Physics, Ritsumeikan University-BKC, Kusatsu City 525-8577, Shiga, Japan

Abstract— The polarization characterizes the light propagation in anisotropic materials. The polarized state is orthogonal to traveling direction and is described by two component (complex) wave function. What we are going to develop is concerning the dynamical as well as stochastic aspect for the polarized light transmitting the non-linear media. The central concept of our attempt is the non-linear birefringence (NLBR). The NLBR is realized for the two component non-linear Schrödinger equation (NLSE). Let $\psi(\mathbf{x}, z)$ be the polarized wave. The variable z is the coordinate of propagation direction, and the $\mathbf{x}$ is that of polarized plane. We put ansatz: $\psi = (\psi_1\ \psi_2) = (a(z)\ b(z))\, F(\mathbf{x})$, where $F(\mathbf{x})$ is the single component scalar wave which is given as the "soliton" solution of NLSE, and $(a(z), b(z))$ may be called *profile* function. We define the action function as : $S = \int \psi^* \left(i\lambda \frac{\partial}{\partial z} - \mathcal{H}\right) \psi d\mathbf{x} dz$, where λ is the wave length for traveling wave, and $\mathcal{H}$ is the Hamiltonian which includes effect of NLBR, and is written by 2×2 matrix. By using the action principle, we derive the coupled equation for profile function, which can be reduced to the equation of motion for the Stokes parameter. The next problem takes into account of randomness contained in the birefringence media, together with the effect of dissipation. Then we get the Langevin equation for the Stokes parameter. From this equation, we can derive the Fokker-Planck (FP) equation for the probability distribution with respect to the Stokes parameter. In order to get the FP equation, we employ the technique of functional path integral. We analyze the FP equation, for some specific cases.

Calculations of Inductance and Induced EMF in a Planar Pickup Coil

G. A. Topasna and D. M. Topasna
Department of Physics and Astronomy, Virginia Military Institute, Lexington, VA, USA

Abstract— We present derivations of the equations and numerical solutions for the inductance and induced EMF in a rectangular pickup loop in the presence of a current-carrying short straight wire. We explore three orientations of the loop with respect to the wire: in the plane of the wire with one edge of the loop parallel to the wire, in the plane of the wire with one edge of the loop at an arbitrary angle to the wire, and with the loop at an arbitrary angle in three-space with respect to the wire. Solutions in closed-form are presented for the simple cases. This work has applications related to pickup coils in general.

Time Delay Module Design, Simulation and Synthesis Based on FPGA for Dielectric Dispersion Logging

Changqi Yang, **Simin Liu**, **Liuyi Yang**, **and Cheng Yang**
School of Science, Xi'an Shiyou University, Xi'an 710065, China

Abstract— A few years ago, a kind of dielectric scanning imaging logging instrument emerged in the foreign markets. That instrument scanned the earth at different frequency electromagnetic wave. It can measure the dielectric constant at different frequencies of the layer. There is not any similar instrument developed at home. Xi'an Shiyou University has launched a project to develop a comparable instrument. This paper introduces the basic principle of dielectric dispersion logging. A general layout is given for the dielectric dispersion logging. The time delay module is simulated and synthesized based on FPGA. This laid the foundation for the development of comparable instruments gradually.

Geometry and Its Physical Meaning

S. L. Vesely[1] and A. A. Vesely[2]

[1]I.T.B. — C.N.R., Italy
[2]Via L. Anelli 13, Milano, Italy

Abstract— The physical meaning of geometry has been evolving during several centuries, bringing about salient epistemological changes. Maxwell developed his theory based on Faraday's experiments, so as to overcome the concept of action-at-a-distance while also attributing a physical meaning to space.[1] At a time when it was generally agreed that geometry can depict objective relations in the physical space, Klein conceived a mathematically rigorous *geometric model* of Maxwell's equations in a vacuum. He showed that those equations are invariant under projective transformations of the linear complex of lines,[2] where a line is represented by six Cartesian coordinates E_x, E_y, E_z, B_x, B_y, B_z. That model complies with the principle of relativity, according to the Erlangen program.[3] Unlike vector spaces, the *null system* requires neither a definition of orthogonality nor one of volume, thus, as a model, it is more general. Einstein discarded Klein's proposal because one of the invariant transformations of the projective group — the inversion — is not compatible with the convention of using measuring-rods and clocks.[4] He considered that operational convention irrefutable because Mach, in his influential critical account of the science of mechanics, stressed that mathematical idealizations should manifest the role of physical experiences in the development of a geometry for technical and scientific purposes. Mach criticized two of Newton's assertions in particular, 1) the existence of the extent,[5] and 2) the identification of physical space and Euclidean geometry.[6] To overcome those problems, he tried to imbue geometry with experimental contents by establishing statics anew, on the basis of *geometric constructions*, and then deriving mechanics from statics.

From Mach's critics, Einstein inferred geometrical properties have to be independent of a coordinate system in order to bear a physical meaning. Subsequently,[7] he conceived the extent as an effect of geometrizable forces. However, the purpose of having the whole of physics agree on a shared conception of geometry[8] met some difficulties. While Einstein requires to unambiguously identify geometric quantities with their corresponding "elements of reality", quantum mechanics must ascribe a physical meaning to the square of the wave function, which supplants the single outcome.[9] There are two main interpretations, the ontic one, which ascribes to objects the properties measured by the wave function, and the epistemic one, which focuses on the physically relevant information that that function conveys. In either case, the implied geometrical space is strikingly different from Minkowski's. At that point, the best option was Hilbert's suggestion to discriminate between the validity of logical deductions and their truth, and to treat in the same manner as geometry — by means of axioms — those physical sciences in which mathematics plays an important part. After that move, geometry turns back into just a logical development, deprived of any intuitive association with physical space. The ontic interpretation of quantum mechanics deals with the truth of the undefined elements and relations. Information theories applied to telecommunications and information-based complexity theories draw rather from the epistemic interpretation.

[1]Maxwell considered aether accessible to physical testing. At his time, geometrical space was considered homogeneous and isotropic.

[2]A complex of lines is an aggregate of lines of the projective space, defined by a single relation. Möbius' null system, which represents forces and momenta equated to zero, is an example of a linear complex of lines (because the defining relation is linear). To define one ruled quadric three relations are necessary.

[3]For both Einstein and Klein, the *transformations of space* are associated to physical laws. The principle of relativity is the first postulate of special relativity, whereby physical laws must be the same in every inertial frame of reference. The second postulate states the invariance of speed of light. In order to satisfy the second postulate, Klein introduced a metrical hypercone in addition to the null system.

[4]Framing physics in space and time is traced back to Aristotle.

[5]Newton calls Aristotle's absolute space *Sensorium Dei*, meaning that the extent is an attribute of God.

[6]Euclid set geometry apart from the cosmology of his time.

[7]In general relativity, the operational definition of rods-and-clock measure is replaced with the hypothesis that dynamics determines the intrinsic space-time curvature. Thus, space-time, rather than being "empty", is endowed with a geometric structure. The original formulation of that hypothesis is due to Helmholtz, according to whom potential results from kinetic energy of cyclic motions.

[8]The shared conception is Hamiltonian geometry. It can account also for non-homogeneous/anisotropic coordinates, needed for quantum magnitudes such as spin.

[9]The single-outcome expectation would interpret a prediction like "A half of these students will pass the exam" as a half of each student, unless 1/2 is interpreted as the likelihood that a student passes.

After recalling the above, the full paper endeavors to illustrate the scope of projective geometry as a hypothetical-deductive system. Our goal is to also use it to model the extent and compare on a common basis graphic constructions, optical perception, and image reconstruction techniques in other frequency ranges. For modeling the extent, the use of construction tools is inherent in synthetic geometry. Straightedge-and-compass figures of Euclidean geometry are conceptually different from straightedge-only constructions of projective geometry, and cannot be reduced to one another in general. We'll restrict ourselves to showing the impact that a switch from analytic to synthetic geometry may imply on the means used to relate geometrically based pictorial display and mathematical analysis. In particular, the points that are to be tackled in order to have Klein's geometric model of Maxwell equations also cover sampling, transforming and interpreting received signals that can be presented as images.

Efficient Analysis of EM Scattering from Rotating Structures Using a Fast Iterative Physical Optics Method

E. Pascual, G. Gutierrez, and F. J. Jimenez
EMC & MW Department, AIRBUS DS, Spain

Abstract— Analysis of the electromagnetic fields scattering from rotating structures such as aerogenerators, aircraft propellers, turbojets and turbofans, helicopter rotors, etc. has an increased interest due to the influence in civil and military radars efficiency and in radiation characteristics of on-board antennas. Doppler effects and spatial modulations can degrade the performances of radars and antennas. To predict accurately the scattering is necessary to compute the interaction of EM fields with the rotating and fixed parts and the interaction of scattered fields from one part with the others for each relative position between them taking into account also the different electromagnetic material properties. In the case of complex rotating structures such as turbofans or turbojets with hundreds of blades rotating at different speeds and directions, it is necessary to analyze efficiently thousands of relative positions in order to obtain useful results. An Iterative Physical Optics method (IPO) [1, 2] accelerated by a fast Far Field Approximation (FFA) [3] has been developed in such a way that the computation time is reduced by means of a multilevel FFA, a preprocessing of the parameters that are invariant with the rotations, a fast calculation of the rotation transformations of the parameters affected by the movement and a parallelization schema based on FORTRAN co-arrays. Cross comparison with Multilevel Fast Multipole Method results of several test cases shows an excellent agreement at a much lower computational cost. Complex cases such as time-variant radar cross section of an aircraft with four rotating propellers have also been computed in affordable time.

On the Impact of Dissipation on Dispersion Interactions between Two Atoms

P. Barcellona and S. Y. Buhmann
University of Freiburg, Germany

Abstract— We consider the interaction between two neutral, ground-state atoms in the presence of an arbitrary arrangement of dispersing and absorbing magnetodielectric bodies by means of a dynamical approach. Our result differs from the previous ones obtained with time-independent perturbation theory because it accounts for the influence of dissipation via the atomic decay rates. Modern measurements of Casimir force seems to indicate an agreement with plasma model instead of Drude model [1]. This has lead to heated debates, because the latter is more a more realistic description of matter. Our new result can explain the agreement with the plasma model for the zero-temperature case. Further investigations will be needed in order to include finite temperature and many-body interactions.

We also consider the interaction between a ground-state atom and an excited atom. There are discordant results in the literature for the retarded potential: one oscillating [2–4] and one monotonous [5–7]. Our dynamical result uniquely leads to the oscillating result when taking into account the decay rates. The result seems go into the same line with recent measurements of the Casimir force between an excited barium ion and a mirror [8, 9].

Modeling the Scattering by Small Holes

R. Solimene, **P. Piccolo**, **and R. Pierri**
Dipartimento di Ingegneria Industriale e dell'Informazione, Seconda Università degli studi di Napoli, Italy

Abstract— The scattering by a hole within a perfect electric conducing (PEC) plane is a classical electromagnetic problem.

As is well known, the scattering by an aperture can be formulated as the solution of an integral equation where the unknown aperture electric field (or equivalently the magnetic source) once the incident field is known.

When the aperture becomes a hole, which is small in terms of the wavelength the Bethe diffraction theory [1] or the low frequency approximation (Stevenson's series first term) [2] can be invoked to approximate the mentioned integral equation. This allows getting analytical results for simple hole's shape, for example, in the case of circular hole. For such a case the analytical results are compared with numerical simulation obtained by a commercial FDTD forward solver. It is shown that the low-frequency approximation fits numerical simulations better than the Bethe theory does in near zone. However, Bethe theory works fairly well in predicting the radiated field (far-zone) and allows to more easily considering the role of the incident field polarization and the hole's shape. To this end, the case of an elliptical shaped hole with incident field having different polarizations is considered and compared with simulations.

Finally, also the case of a hole made over the faces of a rectangular waveguide in different point is analyzed.

Compact Circularly Polarized RFID Tag Antenna with an Embedded L-shaped Feedline for Metallic Objects

Cheng Liu, **Zhibin He**, **Hui Liu**, **Yoichi Okuno**, **and Sailing He**
Centre for Optical and Electromagnetic Research, Academy of Advanced Optoelectronics
South China Normal University, Guangzhou, China

Abstract— An ultra-high frequency (UHF) passive radio frequency identification (RFID) tag antenna with circular polarization for metallic objects is proposed. Using a novel and embedded L shape microstrip line to feed, a good performance of impedance matching is achieved. The proposed antenna can cover the whole operating frequency of UHF RFID system from 860 MHz to 960 MHz. The 3-dB circular polarization bandwidth is 7 MHz (from 916 to 923 MHz). The optimized antenna has a high gain of −5.5 dBi in 0 degree direction. The main parameters of the antenna are also discussed.

Microwave Dielectric Properties of $BiNbO_4$ Ceramics

C. S. Ferreira, **M. P. F. Graça**, **T. Santos**, **and L. C. Costa**
I3N and Physics Department, University of Aveiro, Aveiro 3810-193, Portugal

Abstract— $BiNbO_4$ is a dielectric material that presents high dielectric constant,at microwave frequencies. In this work, $BiNbO_4$ ceramics were prepared by the solid state reaction, and the as-prepared samples were treated at temperatures between 600 and 1200°C. The samples structure was analyzed by X-Ray Diffraction and the morphology was studied using Scanning Electron Microscopy.

For the microwave dielectric measurements, a resonant cavity operating at 2.7 GHz, in the TE_{105} mode, was used. The electromagnetic fields, inside the cavity, without and with the cylindrical sample were simulated using the COMSOL Multiphysics software.

The low-perturbation resonance cavity method has been used in order to calculate the dielectric properties of the ceramic material. In this technique, we measured the shift in the cavity resonant frequency, Δf, caused by the insertion of the sample inside the cavity, which can be related to the real part of the complex permittivity, ε', and the change in the inverse of the quality factor of the cavity, $\Delta(1/Q)$, which is related with the imaginary part, ε''. The relations are simple when we consider only the first-order perturbation in the electric field caused by the sample.

The samples heat treated at temperatures above 800°C present the $BiNbO_4$ crystal phase, being also the predominant phase on the samples treated above 950°C. The samples treated below 900°C present the $Bi_5Nb_3O_{15}$ phase, which seems to be responsible for the highest dielectric constant values observed at room temperature. The dielectric losses of all samples are always lower than 10^{-4}.

Measurement and Uncertainty Analysis of Free-space Antenna Factors of a Log-periodic Antenna with Bow-tie Element Using Time-domain and Pulse Compression Technique

Satoru Kurokawa, **Masanobu Hirose**, **and Michitaka Ameya**
National Metrology Institute of Japan
National Institute of Advanced Industrial Science and Technology of Japan, Japan

Abstract— We propose a method for evaluating the free-space antenna factor of a log-periodic dipole antenna with bow-tie element (Bi-log antenna) using a time-domain and pulse compression technique. The proposed method enables the direct wave to be isolated from reflected waves on the ground plane of an open-area test site (OATS) and evaluation of the free-space antenna factor.

In a measurement, two antennas are held on masts at a height of 8 m above the ground and are separated by 10 m. The direct wave is separated using a Wiener filter obtained from frequency-domain data at 3 m antenna separation. The proposed method can completely separate the direct wave from other waves from the ground plane of an OATS. The expanded uncertainty ($k = 2$) of Bi-log antenna was estimated to be 0.4 dB over the frequency range from 30 MHz to 1000 MHz.

Chaos Generation Utilizing Optically Square-wave-injected Semiconductor Lasers

Chen-Wei Fu, **Shao-Wei Peng**, **and Yu-Shan Juan**
Department of Photonics Engineering, Yuan Ze University
No. 135, Yuandong Rd., Zhongli Dist., Taoyuan City 32003, Taiwan

Abstract— Benefiting from a non-zero value of the linewidth enhancement factor which leads to a variety of dynamics different from any other lasers, the broad bandwidth of chaos can be easily generated. There are several applications in chaotic laser, such as broadband random-bit generation, ranging, and secured communications. In the past two decays, most studies of the chaos generations focused on the nonlinear dynamics of the traditional continuous wave (cw) injection and dynamical pulse and sine wave injection. In this work, we study chaos generation utilizing an optically square-wave-injected semiconductor laser with tunable duty cycle. By injecting a slave laser with periodic optical square-wave at specific parameters, chaos oscillation and chaos pulsing can be generated individually. Compared with continuous wave injection with the same injected conditions, the chaos oscillation generated by square-wave injection shows larger bandwidth and more complex behaviors. Furthermore, if the operating variables are adjusted to the center of the chaos area in the dynamical mapping, the waveforms of power spectra of the generated chaos are much smoother and broader. In this paper, the distribution map of chaos oscillation and pulsing oscillation are investigated. When the duty cycle is operated at high level, chaos oscillation is observed. On the other hand, if we operate the condition at high repetition rate and strong injection strength, the nonlinear dynamics is driven into the chaos pulsing states and the bandwidth of chaos pulsing is two times larger than chaos oscillation which is operated in week injection strength. The three parameters, duty cycle, repetition rate and injection strength, all play important roles in chaos generation utilizing optical square-wave injection system.

Coupling between Double Split Ring Resonators and Complementary Split Ring Resonators

Yu-Zhan Lin and Watson Kuo
Department of Physics, National Chung Hsing University, Taichung 402, Taiwan

Abstract— In this work we study the coupling between double split ring resonators (DSRRs) and complementary split ring resonators (CSRRs) by experiment and simulation. As a planar resonator, DSRR is frequently used in building most planar left-handed material. For our study, the resonators have resonance frequency between 3 GHz and 4 GHz. We study inter-resonator coupling in two ways: For the first study, two DSRRs were placed on the same plane with various center-to-center distance and different orientations. We found that the difference of their resonance frequencies increases when center-to-center distance decreases, featuring the coupling between two resonators. When the gaps of outer ring are face-to-face, the coupling is stronger. The difference can vary as large as 0.11 GHz. Secondly, we studied the coupling of a DSRR and a CSRR when they are respectively placed on upper and lower planes of a printed circuit board. Their resonance frequencies f_D (DSRR) and f_C (CSRR) were monitored when center-to-center distance were continuously changed by using a home-made moving stage. We found that shift of f_D is greatest when center-to-center distance is roughly the resonator's radius, $R = 3.9$ mm. Moreover, frequency difference of two resonators f_D-f_C decreases when center-to-center distance reduces, with a maximum change of 0.1 GHz, a phenomenon opposite to coupled DSRR case.

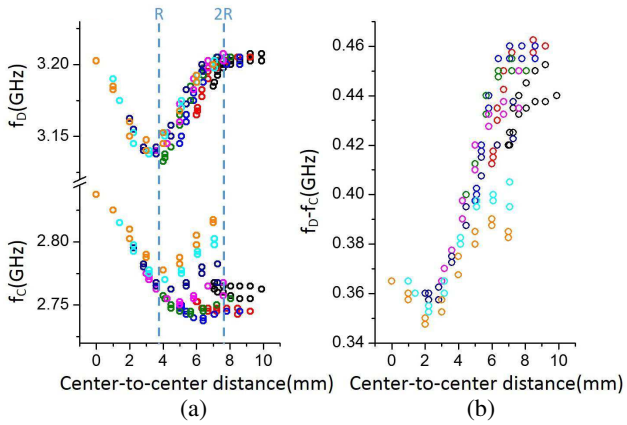

Figure 1: The measurement of inter-resonator coupling between DSRR and CSRR. (a) Resonance frequency of DSRR and CSRR as a function of center-to-center distance. (b) Frequency difference, f_D-f_C reduces as center-to-center distance reduces.

Photonic Band Structure and Field Distribution for TE Polarization. High Plasmon Concentration in the Corners of Metallic Rods of a 2D Photonic Crystal

D. M. Calvo-Velasco and N. Porras-Montenegro
Departamento de Física, Universidad del Valle, A. A. 25.360, Cali, Colombia

Abstract— In recent years the study of photonic crystals (PCs) and their optical properties, aroused the interest of the scientific community, thanks to the discovery of the photonic band gaps present in these structures, that is, frequency ranges where the propagation of the electromagnetic field is prohibited, allowing the development of new technologies. PCs are an arrangement of materials with different refraction index, which allow light behaviors not present in the bulk materials. The photonic band structure (PBS) and the band gaps in the PCs depend on the difference between the refractive index of the components of the PC, their geometry disposition, and the filling fraction. The different studies on this structures rangs from multiple slabs of different materials for 1D systems up to 3D structures, including fractal disposition of a dielectric material in air in a limited region of the space. Also, some studies are related to defects which modify the translation symmetry of the PC allowing the existence of high localized modes used in the construction of wave guides.

In this work we calculated the photonic band structure (PBS) of a square 2D photonic crystal (PC) made of square metallic rods embedded in air, considering a Drude type dielectric function without loss for different values of the rod plasma frequency, ω_p. The PBS was calculated for TE polarization in the Γ-X direction using the revised plane wave method (RPWM), considering the Li's rules for the product of two periodic functions. We found that the PBS presents at bands below and above the frequency value $\omega_p/\sqrt{2}$, and by calculating the distribution of $|H_z|^2$ in the crystal unit cell we found that these bands are related with the existence of plasmon-polaritons in the surface of the rods, as it has been discussed and published in previous works. Besides these findings, in this work we also present the distribution of $|E|^2$, but in this case the square shape of the metallic rods contributes to a high field concentration close to their corners. For frequencies around ω_p, we found that the magnetic field presents a distribution which does not change in passing from the metallic regime to the dielectric one, being not the case of the electric field, which is distributed only inside the rods for frequencies below ω_p and in the whole unit cell above this frequency.

Unidirectional Nanoantenna for Second-harmonic Generation

X. Y. Z. Xiong, L. J. Jiang, W. E. I. Sha, Y. H. Lo, and Yan Lin Li
Department of EEE, The University of Hong Kong, Hong Kong, China

Abstract— Due to symmetry breaking at surface and plasmonic enhancement, second-harmonic generation (SHG) from centro symmetric metal nanoparticles has a bright outlook for nanoscale sensing and detection applications. While SHG were greatly enhanced by well-engineered nanostructures, a directional (or angular) control of second harmonic (SH) radiation, which is highly important to far-field detection of nonlinear signals, has not been explored yet. In this work, a unidirectional nanoantenna is designed tore direct radiated SH wave and separate it from incident wave spectrally and spatially. To solve challenging issues in the modeling of the nanoantenna system, SH nonlinearity is described by equivalent nonlinear current sheets on the surface of metal nanoparticles. Then, the nanoantenna is simulated and optimized by the surface integral equation (or boundary element) method based on equivalent principles. A modified PMCHWT formulation is solved iteratively to capture the mutual coupling between fundamental and SH fields. As a result, the modeling of SHG is not restricted by the undepleted-pump approximation. Compared to other simulation approaches, the proposed method is efficient with a surface discretization; and could employ experimentally tabulated linear susceptibility and nonlinear surface susceptibility tensor of metals directly.

The SH radiation from a plasmonic small sphere with a plane wave excitation can be modeled by the emission from an induced electric dipole and an induced electric quadruple. According to the selection rule, the SH radiation is strictly zero along the incident direction. However, SH radiation always shows a double-side scattering feature due to mirror symmetry along the radiation directions. In the designed nanoantenna, two passive dielectric nanospheres functioned respectively as a director and reflector are employed to break the mirror symmetry. By tuning the size of dielectric spheres and sphere-sphere spacing, interference and retardation effects between multiple spheres could be fully controlled, which leads to the unidirectional scattering of SH waves at a desired wavelength. The work paves a new way to far-field detection and sensing of nonlinear signals.

The Dispersion Properties of Three-dimensional Magnetized Plasma Photonic Crystals as the Mixed Polarized Waves Considered

Hai-Feng Zhang[1, 2], **Yi-Bing Lin**[2], **Yu-Qing Chen**[2], **and Guo-Wen Ding**[1]

[1]College of Electronic and Information Engineering
Nanjing University of Aeronautics and Astronautics, Nanjing 210016, China
[2]Nanjing Artillery Academy, Nanjing 211132, China

Abstract— In this paper, the dispersion properties of three-dimensional (3D) magnetized plasma photonic crystals (MPPCs) with face-centered-cubic lattices are theoretically investigated based on the modified plane wave expansion method, in which the homogeneous magnetized plasma spheres are immersed in the homogeneous and isotropic dielectric background, as the mixed polarized waves and magneto-optical Faraday effects are considered. The more general case has been studied, and PBG of such MPPCs is not only for the left and right circular polarized waves but also for the mixed polarized waves. The equations for calculating the PBG for all of the electromagnetic waves in such 3D MPPCs also are theoretically deduced. Theoretical computing results show that one PBG and two flatbands regions can be observed. Compared to the conventional dielectric-air photonic crystals with similar structure, the larger PBG can be obtained in such 3D MPPCs. However, the narrower PBG can be achieved compared to the PBG for the right circular polarized (RCP) wave, but the larger upper edge frequency of flatbands region can be obtained.

Zn Concentration, Shape and Size Effects on the Band Structure of Photonic Crystals Based on Ferrofluids with ($Co_{1-x}Zn_xFe_2O_4$) Nanoparticles

Luz E. González and N. Porras-Montenegro
Departamento de Física, Universidad del Valle, A.A. 25360, Cali, Colombia

Abstract— In this work using the transfer matrix technique we study the Zn concentration and shape effects on the band structure of a 1D photonic crystal, made of alternating layers of air and a ferrofluid containing ($Co_{1-x}Zn_xFe_2O_4$) nanoparticles, coated by oleic acid suspended in ethanol. For the three-phase mixture we have based our study on the Maxwell-Garnett theory for two confocal inclusion phases contained in a background representing the third phase. We found that the photonic band structure (PBS) is shifted to higher frequencies with the increasing of the Zn concentration and with ferrofluids containing ellipsoidal instead of spherical nanoparticles. However, the difference in the shifting of the PBS due to oblate or prolate ellipsoidal nanoparticles, is negligible. The effects of the Zn concentration, the width of the ferrofluid and air layers, as well as their dielectric constant on the PBS, allow us to propose photonic quantum wells by means of which we can have very well defined frequency regions to transmit or reflect electromagnetic waves to be used in technological applications. Taking into account that there have been several experimental reports showing that an external magnetic field applied perpendicular to the plane of the ferrofluid organize the nanoparticles in parallel rods to form a hexagonal 2D photonic crystal, we also extended our study to these kind of photonic crystals considering the effect of dispersive dielectric response, dissipation effects, as well as the influence of the applied magnetic field by using the Finite-Difference Time Domain. We hope our results can be taken into account for future understanding of the optical response of these systems to be used in technological applications.

Porphyrinic Photosensitizers for Biology and Medicine

Sergey I. Gorelov[1], **Marina V. Dobrun**[1], **Antonina V. Dadeko**[2, 3], **Tatyana K. Krisko**[2], **Tatyana D. Muravieva**[2], **Andrey M. Starodubtsev**[2], **and Ivan M. Kislyakov**[3]

[1]Sokolov Clinical Hospital No. 122, Saint-Petersburg 194291, Russia
[2]S. I. Vavilov State Optical Institute, Saint-Petersburg 199053, Russia
[3]ITMO University, Saint-Petersburg 197101, Russia

Abstract— Porphyrin-based substances are modern materials applied in the design of preparations for for photodiagnosis and photodynamic therapy of cancer [1]. The wide interest to their study is drawn by its low toxicity and selectivity to accumulation in tumor tissues. At that, the photodiagnosis task requires pronounced photoluminescent property of porphyrins whereas the photodynamic therapy applications are based on their high efficiency as regards to photosensibilization of reactive oxygen species, and especially of singlet oxygen.

We report on study of three water-soluble forms of porphyrins as the photosensitizing objects: 1) chlorine E6 salt with N-methyl-D-glucamine as the dye composition of Photoditasin preparation; 2) coproporphyrin III tetrapotasssium salt, the base of preparation Coproporphyrin III; 3) 2, 4-di-(alpha-methoxyethyl)-deuteroporphyrin IX disodium salt, known as the Dimegin photosensitizer. The first preparation is already widely applied in clinical practice for photodiagnosis and photodynamic therapy. The second one was developed and manufactured by Elest JSC (Saint-Petersburg, Russia) and its optical properties were studied last few years [2].

Coproporphyrine III and Dimegin preparations can be promising drugs for medical purposes, due to their high solubility in water and low rat intravenous toxicity (240 ± 16 mg/kg for Dimegin as has been found in St. Petersburg Research Institute of Toxicology) and 2400 ± 120 mg/kg for Coproporphyrine III [3]).

Here, we experimentally show a high singlet oxygen photosensibilization ability of these species. The process of singlet oxygen generation and its quantum yield for each of the photosensitizers was studied in phosphate buffer. The singlet oxygen production was measured by two chemical trap methods. The first one was based on the simultaneous application of L-histidine and p-nitrosodimethylaniline, while another one used L-tryptophan.

Dimegin showed the greatest singlet oxygen quantum yield (ca. 0.8) compared to other dyes. The quantum yields for Photoditasin and Coproporphyrin III were found to be 0.6 and 0.37 correspondingly. It was note that biological media possess a significant effect on the singlet oxygen generation property. For example, 0.1% ovalbumin addition led to reduction of Photoditasin and Coproporphyrin III singlet oxygen photosensibilization efficiency in 3 and 2 times correspondingly.

The comparative study performed corroborates high perspectives of Dimegin preparation for photodynamic cure.

Analysis on the Aperture Averaging Weight Factor for Equidistant Dual-aperture Receiver

Changqi Yang and Simin Liu
School of Science, Xi'an Shiyou University, Xi'an 710065, China

Abstract— Free-space optical communication receiver aperture is usually a single circular aperture. When the aperture size is large, its cost will be high. This paper proposes a new receiver aperture structure: equidistant dual-aperture receiver. The authors analyze its performance. Aperture Averaging Weight Factors of the two kinds of receiver structures are compared. The analysis results show that: Equidistant dual-aperture receiver can obviously decrease the Aperture Averaging Weight Factor, and reduce the optical scintillation.

Trend Technology's Theory Model and Experiment Verification for Atmospheric Optical Scintillation

Changqi Yang
School of Science, Xi'an Shiyou University, Xi'an 710065, China

Abstract— Trend technology's theoretical model for atmospheric optical scintillation is establishes in this paper. For many years, people have always thought that atmospheric optics is completely random. In the previous paper, the author has used several experiments to overturn the traditional view. In this paper, the author will put forward a model to explain the author's point of view theoretically. It will demonstrate the process how does the optical scintillation evolve according to the trend. In this paper, the author will give the second batch of the experimental data to verify the theory model.

Zn-diffusion 850 nm VCSEL with Stable Single Mode Operation and 21 GHz Bandwidth

Fang-I. Lai[1], **Dan-Hua Hsieh**[2], **Jin-Wei Shi**[3], **and Hao-Chung Kuo**[2]

[3]Department of Electrical Engineering, National Central University, Taoyuan, Taiwan

Abstract— The vertical-cavity surface-emitting laser (VCSEL) had been an attractive light source for the fiber-optical communication due to its high bandwidth, low cost and high reliability. Until now, most VCSELs are used in short-haul optical link, which usually transfer data through multimode fiber and the distance is shorter than 2 km. To reach the longer transfer distance, significant effort had been paid on the development of high power single-transverse mode VCSELs. In this study, we demonstrate stable pure single-mode operation by using selective Zn-diffusion technique to suppress the lasing of high order mode. The effect of Zn-diffusion is also investigated via simulation. Here the commercial software of Photonic Integrated Circuit Simulator in 3D (PICS3D) is conducted to simulate the device character, which is developed by Crosslight corp. The simulator is based on the nonlinear Newton-Raphson method. All the equations involved in the calculation are discretized on the grids within target devices self-consistently. Because of the mutual interaction between optical, electrical and thermal occurs within VCSEL devices. All these effects are taken into consider during the simulation. To obtain a good result, the key factor to discretize the mesh distribution is based on the box method. The target VCSEL structure consist three GaAs/$Al_{0.3}Ga_{0.7}As$ MQWs sandwiched by 35-pair n-type and 22-pair p-type DBR. An oxide layer is placed above the MQWs for the current and optical confinement. Zn-diffused region is formed in p-DBR to provide a high order mode stopper. The calculation results show that, except for the fundamental mode, almost all high order modes are stopped by Zn-diffusion region due to the high free-carrier-absorption and the decreased reflectivity of p-DBR, the only observable high order mode is the first high order mode, which has a large overlap between the mode profile and Zn-diffusion region. Finally, the fabricated device shows stable single mode operation over all bias point ($1 \sim 5$ mA), which is consistent with the simulation result. And the maximum bandwidth exceeds 20 GHz as bias current over 2 mA.

Electromagnetic Simulation of Coupled Silicon and Diamond Microdisks and Slab Waveguides in the Mid-infrared

Abstract— Electromagnetic numerical studies of silicon and diamond microdisks coupled with silicon and diamond slab waveguides are performed in the CO_2 laser emission region in the mid-infrared. Microdisk is the 2D analog of the microsphere and the slab waveguide is the 2D analog of the rectangular optical waveguide. The evanescent coupling between the waveguide and the microdisk results in efficient pumping of the whispering gallery modes of the microdisk. On-resonant and off-resonant studies are performed by tuning the laser wavelength to the microdisk whispering gallery modes.

Global Simulation for Quantum Cascade Lasers Subjected to External Optical Injection

Abstract— Recently, the use of the terahertz (THz) frequency band for wireless communication has attracted considerable attention. In this context, the development of modulation schemes for solid-state THz sources such as THz-quantum cascades lasers (THz-QCLs) has become a very important technological issue. However, in contrast to the several investigations being carried out on radio-frequency (and thus electrical) modulation of THz-QCLs, the optical modulation of THz-QCLs is at an early stage of development. In the optical scheme, amplitude or spectral changes of the QCL arise from photon-generated electrons (holes) in the conduction (valence) band of the devices, which trigger on various modulation mechanisms, such as the change in the intersubband laser gain [1], additional mirror loss induced by free carrier plasma, or even heating of the device in the limit of high intensity excitation ($> \mu$J/pulse) [2]. Up to now, one obvious problem in the optical modulation is that these coexisting and interacting relaxation processes leads to a complexity in relating certain output behavior to the specific processes in a decomposed or integrated manner.

In this paper, we report a global simulation scheme for QCLs subjected to the optical pulse injection, allowing us to reproduce the optically induced amplitude change in the QCL over a wide range of injection power. Our scheme consists of the heat equation and the three-level rate equation. Here, the internal parameters (e.g., electron temperature, scattering times, and hence internal gain) are treated as spatiotemporal, evaluated on the basis of the temperature distribution of the device, and by substituting these parameters into the rate equation photon number is obtained, which is then converted into the output power using the reflectivity of the illuminated facet (time dependent). The simulation results are in good agreement with our previous measurements [2].

A Photonic QPSK Modulator Aimed at Space Applications

J. Panasiewicz[1, 2], D. M. S. Morais[2], and G. M. Pacheco[2]

[1]National Institute for Space Research, Brazil
[2]Aeronautics Technical Institute, Brazil

Abstract— This paper addresses the subject of the satellite payload signal transmission and the digital-microwave link. Usually, the carrier modulation data transmitter (DT) employs in-phase (I) and quadrature-phase (Q) processing to achieve phase shift keying (M-PSK). Typically, this I/Q processing is obtained by multiplying a low-frequency reference signal. Such systems usually have many stages of multipliers, amplifiers and filters. As a result, the microwave transmitter is complicated, bulky and costly. The results presented are based on a photonic circuit that achieves QPSK modulation directly at the microwave frequency carrier. The QPSK modulation was performed using a carrier frequency of 2 GHz and 2 Mbps I/Q signal from a pattern generator using a photonic circuit with a pair of Mach-Zehnder optical modulators arranged in a parallel configuration. The source of the photonic circuit is a DFB diode laser with a wavelength equal to 1550 nm. The modulated optical signal direct detection comes from an InGaAs photo detector. The optical modulator circuit output can be directly connected to the high power amplifier (HPA) and the transmission antenna. The resulting system enables one to achieve a microwave data transmitter with a reduced mass and volume, further lowering power consumption. These achievements are very important for spacecraft engineering teams during the conception of the satellite payloads when starting a new satellite project. Gamma radiation and thermal effects of the space environment are also discussed.

Ultra-porous Aluminium Oxides for GHz and THz Components

O. Stepanenko[1], **A. Tartari**[2], **M. Amamra**[3], **T. H. N. Nguyen**[3], **M. Piat**[2], **A. Kanaev**[3], **and G. Leo**[1]

[3]Université Paris 13, LSPM, CNRS UPR 3407, 99 Avenue J.-B. Clément, Villetaneuse 93430, France

Abstract— We report on the experimental study of ultra-porous alumina (UPA) [1], which is a promising low-κ dielectric material for GHz wideband antennas. The UPA samples are fabricated by oxidation of laminated metallic aluminium through a mercury film at room temperature [2], which leads to the formation of a nano-porous monolith of up to 99% porosity. Since the UPA monolith is extremely fragile at this stage, spectroscopic measurements were carried out after annealing at temperatures 870 and 1300°C, milling to a powder, and compaction under pressure to form rigid tablet samples. Some of UPA samples are also treated in trimethylethoxysilane (TMES) vapour. In this case, an additional annealing decomposes TMES molecules, resulting in a silica film covering the UPA nanofibres and mechanically reinforcing the samples.

The electromagnetic characterization consisted in the measurement of the S-matrix parameters of our ultra-low-ε UPAs substrates. Our setup relies on a Vector Network Analyzer (VNA) with 8–19 GHz generation and multiplication stages up to the THz range. Different fabrication conditions have been comparatively studied in the 150 GHz range, the VNA enabling us to retrieve the complex permittivity $\varepsilon(1 - j\tan\delta)$ of the material. While we measured an interestingly low refractive index $\sqrt{\varepsilon} \approx 1.1$, the loss tangent ($\tan\delta \approx 10^{-2}$) is still one-order-of-magnitude higher than the typical values of commercially available antenna substrates. However we are confident that such losses can be strongly reduced by the fabrication process optimization that is currently under way.

While we presently focus on the 110–170 GHz range because of its importance in the research on the cosmic microwave background, UPAs can also be interesting for higher frequencies in the THz range, once their hydrophilic nature will be properly dealt with. In this case, beyond their potential use in patch antennas, UPA might also become competitive with currently available THz optical components, whose spectral ranges are sometimes limited. In this respect, the potential of creating refractive index gradients through thermally induced UPA density gradients might also lead the way to fancy optical components like THz Luneburg lenses [3]. In the low-microwave range, an approximate version of these lenses (manufactured by assembling concentric, homogeneous dielectric shells with different ε) is widely used for radio communications in the X-band between 12 and 16 GHz, as well as in the military field. [4] UPA-based Luneburg lenses would of course be very interesting in the THz domain, where implementing the above piecewise-constant radial permittivity seems impractical.

Optoelectronic Applications of Sapphire Microspheres

Muhammad Zakwan, Muhammad Sohail Anwar,
Syed Sultan Shah Bukhari, Ulaş Sabahattin Gökay, and Ali Serpengüzel
Microphotonics Research Laboratory, Department of Physics, Koç University
Rumelifeneri Yolu, Sarıyer, Istanbul 34450, Turkey

Abstract— The sphere with its highly symmetric geometrical shape enhances the efficiency of optical effects with its high quality factor morphology dependent resonances (MDRs). We report here on numerical studies of elastic light scattering in a sapphire microdisk coupled to slab waveguides, i.e., the 2D analog of a microsphere coupled to the 2D analog of an optical waveguide. The numerical electromagnetic simulations for the surface electric field strength are performed at 800 nm. The experimental elastic light scattering measurements are also proposed in the near-infrared from sapphire microspheres. 800 nm operation with sapphire microspheres is suitable for local area networks (LANs) applications such as channel dropping, filtering, switching, modulation, and monitoring.

Silicon Microspheres in Metrology

Microphotonics Research Laboratory, Department of Physics, Koç University
Rumelifeneri Yolu, Sarıyer, Istanbul 34450, Turkey

Abstract— The Système International unit of mass is the kilogram. The present definition of the kg is based on a prototype dating back to 1880s. New approaches to define the unit of mass are being investigated. Avogadro Project uses 10 cm diameter single crystal silicon spheres. The technique commonly observed to measure the radius of the silicon sphere is optical interferometry. Here, we propose an alternate method of measuring the diameter of the single crystal silicon sphere using near-infrared spectroscopy. We demonstrate our approach by numerically simulating the electromagnetic coupling of a silicon microdisk of radius 5 μm to an optical waveguide of width 0.5 μm, thereby approximating the coupling of a microsphere to a rectangular optical waveguide. It might be possible to have a precise technique for determining the radius of the sphere, which can be used for the definition of the kilogram.

A 10 Gbps, Wide Dynamic Range CMOS Optical Receiver

Sheng-Hua Lai and Wei-Zen Chen
Department of Electronics Engineering, National Chiao-Tung University, Hsinchu, Taiwan

Abstract— This paper describes the design of a 10 Gbps, high sensitivity and wide dynamic range optical receiver is TSMC 40 nm CMOS technology. Typically, a high sensitivity optical receiver is achieved by utilizing a core voltage amplifier with a large shunt-shunt feedback resistor, so as to diminish the input referred noise current. The voltage amplifier's 3 dB bandwidth should be at least $\sqrt{2}$ times the overall TIA bandwidth (ω_{TIA}), while its gain should be sufficiently high (> 15 dB) to tolerate the parasitic capacitance of PD. Thus shunt-peaking inductors in general are required for bandwidth enhancement in the core amplifier design under the constraint of low supply voltage in the nano meter CMOS technology. On the other hand, the feedback resistor should be tunable to accommodate wide dynamic range input signal. However, it may suffer from phase margin degradation under the low gain mode, and results in significant gain peaking. To overcome the aforementioned issues, the proposed TIA is composed of dual path nested feedback loop architecture. In addition to an outer passive feedback loop that determines the TIA gain, an inner active feedback loop in the core amplifier is incorporated for bandwidth enhancement. Thus no peaking inductors are required for a small form factor. By monitoring TIA's output with an automatic gain controlled circuit, the core amplifiers voltage gain is adjusted in conjunction with the feedback resistor, so as to maintain a relatively constant damping factor and alleviate gain peaking. The TIA is integrated with a 2 stage post limiting amplifier, and the circuit performance is demonstrated by integrating a photo detector with a responsivity of 0.65 A/W. Experimental results show that it has a maximum conversion gain of 86 dBΩ while tolerating input power level from -15 dBm to 0 dBm. The measured bit error rate is less than 10^{-12}. The total power dissipation is 17.3 mW from 1.2 V supply. Chip area is 0.628 mm $\times$ 0.53 mm^2.

Light Out Coupling Efficiency of Top-emitting Organic Light Emitting Diode

Dong Bin Yeo, Woo Young Kim, Chang-Bum Moon, and Chul Gyu Jhun
School of Green Energy & Semiconductor Engineering
Hoseo University, Asan, Chungnam 336-795, Korea

Abstract— We theoretically study the light out coupling efficiency of the top-emitting OLED with inverted structure. The dipole mode is used analyzing the light out coupling efficiency of the top emitting OLED. With this process, we can analyze the out coupling efficiency with respect to the location of the emitting dipole from the cathode.

Organic light emitting diode (OLED) is considered as the next-generation display technology owing to its superior performance such as fast response, wide viewing angle, and high contrast ratio [1–4]. The response time is a few tens of microseconds. The viewing angle is over 170°. The contrast ratio is over 70,000 for all viewing angle. However, the out coupling efficiency is limited to about 20% due to the total reflection caused by the organic layer and glass. In this paper, we analyze the light out coupling efficiency of the OLED for the high efficiency.

The analysis of light out coupling efficiency must consider near field. The traditional approach for such device simulation is known as the dipole model [5]. Our simulations about the out coupling efficiency are also based on this model, in which, the dipole source takes the form of a forced damped harmonic oscillation. Using the dipole model and considering the surface plasmon resonance effects, the power dissipation of the top-emitting OLEDs was calculated. The light out coupling efficiency of the top-emitting OLED was analyzed with respect to the location of the emitting dipole from the cathode.

Abstract— In this work, we have demonstrated a monolithic integration of optoelectronic (LED) and electronic (MOSFET) devices in the GaN-based platform by using standard semiconductor-manufacturing technologies. The fabricated monolithically integrated LED/MOSFET device exhibits a maximum output current of $I_{DS} = 1050\,\mathrm{mA/mm}$ and a peak transconductance of $G_m = 368\,\mathrm{mS/mm}$. The LED exhibits a well rectifying behavior with a slightly high turn-on voltage of 5.32 V, mainly due to the un-optimized condition of p-contact metal. Most importantly, the monolithically integrated LED/MOSFET device exhibits good gate controllability in the LED's light output power, and hence is viable and highly promising for a broad range of applications.

Comparison of the Two Rapid Measurement Methods for Circular-cut Far-field Patterns of Elongated Base-station Antennas — Kim Method and Evans-Vilenko Method

Masanobu Hirose and Kurokawa Satoru
National Institute of Advanced Industrial Science and Technology, NMIJm, Japan

Abstract— For wireless mobile communications, the base-station antennas are indispensable equipment and the rapid as well as accurate measurements of the far-field patterns are one of the critical issues in the mass productions.

Many base-station antennas have elongated structures and the far-field patterns have narrow tilted beams along the longitudinal direction. To obtain the far-field patterns along the direction rapidly, 1-D linear near-field scanning methods and the Evans-Vilenko method (a circular scanning in the Fresnel region) are relatively well-known. Whereas the 1-D linear near-field scanning cannot make it possible to obtain the circular-cut far-field patterns in the narrow beam cut-plane, the Evans-Vilenko method can realize to obtain the circular-cut patterns from the measurement on a circle in the Fresnel region.

We show a superior candidate (Kim method) for the rapid as well as accurate measurement methods suitable to obtain the circular-cut patterns of the elongated base-station antennas. The Kim method is derived from the formula of the cylindrical near-field scanning method and the equation of the near-field to far-field transformation is the same as that of the cylindrical near-field scanning method except a factor. Therefore the same algorithm of the cylindrical near-field scanning method can be used without performing the Fourier transform along the z direction.

In the Kim method and the Evans-Vilenko method, we measure the s_{21} between two antennas (the base-station antenna and a probe) on a circle of a finite radius in the Fresnel region and calculate the far-field patterns in the plane including the circle.

For elongated base-station antennas, we show that the Kim method is superior to the Evans-Vilenko method with respect to the errors after the near-field to far-field transformation at the radius that is shorter than a few parts in a ten or a hundred of the well-known far-field distance.

Resonance in Rectangular Microstrip Structure Loaded with a Thin Omega Medium Layer in the Substrate

R. Lech, **A. Kusiek**, **W. Marynowski**, **and J. Mazur**

Abstract— The resonant frequency problem of a microstrip patch has been extensively studied. In literature one can find the configurations of microstrip patches located on planar substrate with superstrate layer [1], microstrip patches located on single [2] or multilayer substrate covering conducting circular cylinder and loaded with superstrate layers [3], or located on elliptic cylinder [4, 5]. For electrically small structures the analysis is commonly carried out by solving the electric field integral equation with the method of moments.

Electromagnetic properties of the complex, chiral or pseudochiral materials, have also gained considerable attention in the literature [6]. The chiral material consists of small wire helixes inserted into the host medium, whereas the pseudochiral material contains Ω-shaped microstructures in which both the loop and stamps lie in the same plane. The induced electric and magnetic field polarizations in Ω element of the pseudochiral medium are perpendicular to each other, while in chiral medium they are parallel. The chiral medium exhibits optical activity that refers to the rotation of the polarization plane, while in the Ω medium the field displacement phenomenon occurs. Introducing Ω particles into the substrate layer results in a notable field displacement due to the pseudochirality properties of the particles, which in turn affects the resonant frequency of the structure.

The complex resonant frequency of a rectangular microstrip structure with substrate layer containing a thin Ω medium layer is studied here. The investigation is performed by using a full-wave analysis and Galerkin's moment method. To simplify the analysis approximate continuity conditions modeling a thin Ω layer are introduced [6]. The numerical results for the effect of Ω medium layer location in the substrate on the complex resonant frequency of the rectangular microstrip structure are presented.

Abstract— Using a moment-method solution technique in an Electric-Field Integral Equation (EFIE) formulation approach, this presentation examines certain performance characteristics of the electrically thin-wire variety of the Chireix-coil antenna, whose geometry as defined by Kraus (1998) is given by $C_\lambda = \sqrt{1 + 2S_\lambda}$, where the parameters ($C_\lambda$, S_λ), respectively symbolize helix circumference and turn spacing, measured in units of wavelength at the operating frequency.

Computational results obtained for the Chirac coil with 4-, 6-, 8-, and 10-turns suggest that the maximum value of magnitude of current distributed along the axis of the antenna is more or less independent of number of antenna turns. And the results also indicate that when S_λ is less than 0.9 the radiation field (E_ϑ, E_φ) patterns on the azimuthal plane consist of two diametrically oppositely directed majors; which degenerate into four distinct lobes (with relative maxima along $\varphi = 0°$, $90°$, $180°$, and $270°$ axes) for values of S_λ in excess of 1.0.

A particularly remarkable feature of these radiation field pattern characteristics is that they appear to be independent of the number of coil turns.

A Frequency Reconfigurable PIFA Design for Wireless Communication Applications

S. C. Basaran and E. Dokuzlar
Department of Electrical-Electronics Engineering
Akdeniz University, Antalya 07058, Turkey

Abstract— In order to sustain the enormous bandwidth and multi-functionality requirements of modern wireless communication technologies, wideband reconfigurable antenna designs have attracted considerable attention in recent years. Compared to conventional wideband antennas that can cover multiple communications bands, reconfigurable antennas provide much needed agility to dynamically tune into sub-bands for improved noise, crosstalk, and jamming suppression without using external filters, thus also reducing the size, cost, and power requirements of wireless mobile devices.

In this paper, we propose a novel frequency reconfigurable PIFA design based on printed split-ring elements. The proposed design with novel configuration is depicted in Fig. 1. As seen, the antenna is fabricated on the Rogers RO3006(tm) substrate with 0.64 mm thickness and dielectric constant of $\varepsilon_r = 6.15$. The radiating top plate consists of two concentric split-ring elements and six metallic loadings (s_1–s_6) appropriately placed between the rings. The antenna height is 10 mm, and the space between the top plate and the substrate is filled with air. The shorting plate has dimensions of 3 mm, and the feed plate has dimensions of 7 mm. The shorting plate is placed under the top corner of the top plate. The horizontal distance between shorting and feed plates is 22 mm. The proposed antenna is fed by a current-probe placed in the feeding plate in the simulations. In addition, a conductive switch, implemented as a small metallic pad in the numerical design, is integrated into a straight patch and inner split-ring element. Computed return loss characteristic of the proposed antenna is shown in Fig. 1 for the two states of the switch (SW). When the switch is in OFF state, a dual band operation at 1.8 GHz and 3.5 GHz is achieved. On the other hand, when the switch is the ON state, the antenna provides a dual band performance at 1.7 GHz and 5.2 GHz, respectively. In the full paper, the details of design steps will be discussed, and also the related pattern/gain characteristics will be presented.

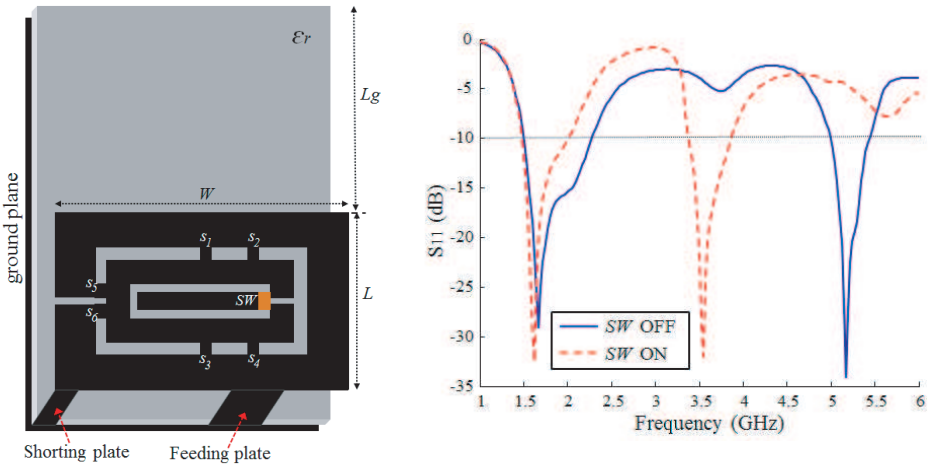

Figure 1: Proposed frequency reconfigurable PIFA design and its frequency response: ($W = 40$, $L = 20$, $L_g = 40$ (all in mm), $\varepsilon_r = 6.15$).

An Accurate Technique to Model the Substrate of Wearable Textile Antennas

Ghufran M. Hatem, **Ali J. Salim**, **and Jawad K. Ali**
Microwave Research Group, Department of Electrical Engineering, University of Technology, Iraq

Abstract— The utilization of wearable textiles in the antennas has shown a dramatic increase due to the recent challenges imposed on wireless devices to be miniaturized. For RFID purposes, a wearable antenna is meant to be a part of the clothing used. This includes tracking and navigation, mobile computing and public safety applications. Investigating the wearable textile antennas reported in the literature, it has been noted that when modeling the antenna using the commercially available EM simulators, the substrate (textile) has been dealt with as a solid homogenous material. This is fact is not the case, since the textile as a substrate is composed of woven threads (fibers). As a result, this adds some inaccuracy when comparing the simulated results with measured ones. In this paper, the textile antenna material, as a substrate, has been modeled in a way closer to the real practice. It has been modeled as horizontal and vertical fibers with different thread levels. A case study, representing a wearable textile antenna structure, has been investigated and the relevant textile material is being modeled using the proposed modeling technique. Simulation results of the antenna return loss responses using the proposed modeling technique; have shown to be more accurate than those obtained using the conventional modelling technique in that they are more close to measured results relevant to the antennas involved in the case study.

A CMOS I/Q Up-conversion Mixer and a Power Pre-amplifier for UHF RFID Reader Systems

Abstract— A high gain, high linearity, low noise I/Q up-conversion mixer and a programmable gain power pre-amplifier are designed in a standard 0.18 µm CMOS process, which are both the critical building blocks in a transmitter for UHF RFID reader systems. To comply with the system specifications, both low noise figure (NF) and high LO-IF isolation for the up-conversion mixer are required, so the I/Q mixer topology based on two coupled double-balanced Gilbert cells is applied. Besides, other techniques such as the pseudo-differential structure and the active load are also used to improve its linearity, gain, etc.. As for the power pre-amplifier, a programmable gain fully differential cascode configuration is employed to satisfy the emission spectrum requirements from various application environments. A 3-bit control word is used to switch the three parallel trans-conductance transistors in each side to change the output power flexibly. And the source inductance negative feedback technique is adopted to achieve a good trade-off among noise matching, impedance matching, linearity and gain. From a single 1.8 V power supply, simulation results show that the up-conversion mixer has a total conversion gain of 4 dB, an input 1 dB compression point ($IP_{1\,dB}$) of 4.84 dBm, and an input NF of less than 20.9 dB. The power pre-amplifier has an output 1 dB compression point ($OP_{1\,dB}$) of better than 2.8 dBm, a gain of above 7 dB, and a good input impedance matching.

A UHF RFID Reader Receiver SoC in 0.18 μm CMOS Technology

C. C. Zhang[1, 2], **Y. Q. Qian**[1, 2], **J. Zhao**[1, 2], **Y. Zhang**[1, 2], **D. B. Wang**[1, 2], **and Y. F. Guo**[1, 2]

Abstract— A fully-integrated single-chip receiver for an 860-960MHz UHF RFID reader is designed in 0.18 μm CMOS technology. It is mainly composed of an RF front-end, a DC offset cancellation (DCOC) block, and an analog baseband. The RF front-end consists of a double-mode low noise amplifier (LNA) and an I/Q mixer. The LNA can operate under two different modes, which correspond to the listen-before-talk (LBT) and the normal mode specified by UHF RFID protocols, respectively. The common-gate structure and the dynamic current injection technique are used for the mixer to achieve high linearity and low $1/f$ noise. The analog baseband comprises a programmable gain amplifier (PGA) and a low-pass filter (LPF). The opamp-based PGA is composed of a fine gain stage with a gain step of 1 dB, and a coarse gain stage with three fixed gain, corresponding to 6 dB, 12 dB and 24 dB, respectively. The LPF is a fourth-order Butterworth active RC one, whose bandwidth can be adjusted between 480 kHz and 1.68 MHz. Simulation results show that the receiver achieves $P_{1\,dB}$ of -2.1 dB in LBT mode and sensitivity of -88 dBm in normal mode, with power dissipation of 95.72 mW from a 1.8 V power supply.

Compact Substrate Integrated Waveguide BPF for Wideband Communication Applications

Aya N. Alkhafaji[1], **Ali J. Salim**[2], **and Jawad K. Ali**[2]

[1]Department of Electrical Engineering, University of Technology, Baghdad, Iraq

University of Technology, Baghdad, Iraq

Abstract— A new compact substrate integrated waveguide (SIW) bandpass filter (BPF) is presented in this paper as a candidate for use in wide bandwidth X-band applications. The proposed filter is constructed by embedding two semi-circular slots have been in the SIW structure from the input and the output sides. The simulation and performance evaluation of the proposed filter have been carried out using Microwave Studio Suite of Computer Simulation Technology CST. A parametric study reveals that the insertion of these slots has successfully led to the compact size and the wide bandwidth. The cavity dimensions are $13.6 \times 10.6\,\mathrm{mm}^2$ while the overall filter dimensions are $28.5 \times 16\,\mathrm{mm}^2$ using a substrate with relative permittivity of 2.2 and thickness of 0.245 mm. The resulting filter exhibits a return loss less than $-15\,\mathrm{dB}$ and insertion loss approaching to 0 dB over the passband. The proposed filter offers a $-3\,\mathrm{dB}$ fractional bandwidth of about 68.4% centered at 11.7 GHz. The compact size offered by this filter makes it a suitable for use in designing microwave and millimeter-wave circuits.

Investigations of Elliptical Ferrite Coupled Line Junction

A. Kusiek, W. Marynowski, and J. Mazur
Faculty of Electronics, Telecommunications and Informatics
Gdansk University of Technology, Gdansk 80-233, Poland

Abstract— Nonreciprocal devices have been extensively used in modern microwave and millimeter wave system. Recently, the longitudinally magnetized ferrite coupled strip- or slotlines [1, 2] are being developed and employed to realize integrated nonreciprocal devices. Significant interest in these devices results from their advantages, which are weak biasing magnetic field and wide operation bandwidth.

So far, studies concerning FCL devices have been focused mainly on structures realized in planar line technology. Such structures allow one to obtain fully integrated FCL devices. However, the main drawback is high level of insertion losses occurring in the ferrite material [3]. The promising results concerning losses reduction were obtained for cylindrical ferrite coupled line (CFCL) junction [4, 5]. In such configuration strong gyromagnetic coupling occurs which is a result of high magnetic field concentration in the ferrite medium. This makes possible to design shorter ferrite junctions ensuring lower insertion losses in comparison to planar ones. However, in the experiment the narrow operation bandwidth was observed for fabricated nonreciprocal devices utilizing such junctions [4, 5].

In this paper the elliptical ferrite coupled line (EFCL) junction is proposed. In the analysis the hybrid technique combining spectral-domain approach (SDA) with coupled-mode method (CMM) is applied. In this approach the SDA is applied to determine the propagation coefficients and field distributions of fundamental modes propagated in the dielectric basis guide. The basis guide has the same cross-section as EFCL where instead of ferrite the dielectric material with the same permittivity is utilized. Then utilizing CMM the gyromagnetic coefficient, dispersion characteristics of ferrite coupled lines and scattering matrix of EFCL junction are determined.

Wave Properties of the Rectangular Waveguide Loaded with Thin Pseudochiral Medium Layer

W. Marynowski, **A. Kusiek**, **R. Lech**, **and J. Mazur**
Faculty of Electronics, Telecommunications and Informatics
Gdansk University of Technology, Gdansk 80-233, Poland

Abstract— One of the artificial materials is a pseudochiral medium firstly introduced by Saadoun and Engheta [1]. Due to its interesting features it is still in the area of researchers' interest [2–8]. The possible applications of this medium in the novel devices operating at microwave and millimeter-wave frequency ranges have been recently published in literature. Both the waveguide devices and the planar integrated structures were proposed and studied [1, 4]. The typical pseudochiral material is composed of Omega shaped microstructures where loops and stamps lie in the same plane. In such structure the field displacement phenomenon occurs [3] which is similar to the one obtained for transversely magnetized ferrite materials, except nonreciprocity [9].

In this paper a rectangular waveguide loaded with thin pseudochiral medium layer is investigated. The considered waveguide structure is composed of dielectric layer with thin omega medium layer placed on one side and the metallic strips on the other side. Based on the mode-matching method the mathematical model of the electromagnetic wave propagation in the investigated guide is derived. To simplify the analysis the approximate continuity condition are used in the modeling of the Omega medium [5]. With the use of the derived model the wave parameters, such as propagation coefficients and field distributions, are obtained. The different configurations regarding material parameters, dimensions and Omega medium layer location are considered. In comparison to the isotropic guide (without the thin Omega medium layer) for the investigated structure only the small differences in the propagation coefficients are observed. However, due to the presence of omega medium, the strong field displacement phenomenon occurs in the structure.

A Diplexer with a Dual-mode Resonant Junction

Eugene Ogbodo, Yi Wang, and Predrag Rapajic
Department of Electronic, Electrical and Computer Engineering
University of Greenwich, Kent, ME4 4TB, UK

Abstract— Microwave diplexers are used in communication systems to connect two channels operating at different frequencies to a common antenna port. A conventional diplexer is made up of two channel filters which are connected to a signal distribution network. Such a network usually contains a transmission-line based junction or a circulator [1]. In the past few years, a new diplexing configuration based on resonant junctions has attracted a lot of attention. Different circuit techniques have been used. For instance, in [2] two novel multiplexer topologies based on all-resonator structures were reported at X-band using waveguide technology. In [3], an FDD diplexer that integrates a T-shaped resonator and two sets of square open-loop resonators was developed. In [4], a compact diplexer was proposed and designed using an SIR resonator which acted as a common resonator.

In this work, a miniaturised and novel diplexer has been proposed and designed using hairpin resonator filters of 3.39 GHz and 4.39 GHz with a 4% fractional bandwidth each, linked together using a perturbed patch resonator. Each of the filters was individually designed using a three-pole structure and fed using proximity coupling. In order to achieve a diplexer, the two filters were joined together and here the novelty behind this proposal comes to light. A patch resonator structure, resonating at the overall central frequency of the two filters were designed and perturbed into a dual-mode to resonate at the centre frequencies of the two individual filters. The perturbed patch resonator was then used to replace the first hairpin resonator and the input feed line of each filter. Here the patch resonator acts as a common resonator linking both filters as well as a frequency selective splitter. This idea used, led to the miniaturisation of the structure from a total of six resonators to five resonators and without using any transmission-line based signal distribution network for matching. The CST EM wave simulator was employed in this design. Rogers 3010 substrate was used with a thickness of 1.27 mm, relative permittivity of 10.8 and loss tangent of 0.0035.

A Compact Dual-band Bandstop Filter Based on Fractal Microstrip Resonators

Hayder S. Ahmed, **Ali J. Salim**, **and Jawad K. Ali**
Microwave Research Group, Department of Electrical Engineering, University of Technology, Iraq

Abstract— Fractal geometries are found attractive to designers seeking for compact size microwave circuits and antennas. In this paper, Peano fractal based open-loop resonators are adopted to design dual-band microstrip band-stop filters (PSFs). The suggested filter structure is essentially based on that of the conventional open-loop rectangular microstrip resonators. The resonators of the proposed PSF structure are made in the form of Peano fractal geometry with different iteration levels. Many filters have been modeled and their performances have been evaluated using a commercially available full-wave electromagnetic simulator. Each of the modeled filter structures contains two pairs of open loop fractal based resonators with different iteration levels. The lower frequency band-stop performance is attributed to the resonators with higher iteration level, while the higher frequency band-stop performance is due to the resonators with lower iteration level. Simulation results for the proposed microstrip filters are shown to confirm the validity to realize compact dual-band narrow-stopband microstrip filters. A comparative study implies that higher size reduction of the realized filter has taken place as the iteration level of the fractal microstrip open-loop resonators becomes higher. The results presented show that the fractal based resonators can be used to construct compact narrow-stopband filters suitable for a wide variety of the recently available communication applications.

Development of High Stretchable Devices Material for the Wearable Electronics

Se-Hoon Park, **Dong Su Kim**, **and Jong-In Ryu**
System Packaging Research Center, Korea Electronics Technology Institute
#68 Yatap-dong, Bundang-gu, Seongnam-si, Gyeonggi-do 463-816, Korea

Abstract— Recently, IoT (internet of things) technology has strong demands for the wearable devices for the communications between mans and machines. Thus, the needs for wireless rechargeable devices which has a high efficiency will be continuously increased due to a convenience. Because a part of human body is normally deformed up to approximately 30%, wearable material also should be elongated to at least 30% and the flexible devices should provide comfortable fits to human body. When we consider these things, flexible material must have a proper modulus, high elongation and function of 3D forming. In this work, new flexible material and stretchable antenna were developed for the near field data transaction and wireless recharge for wearable devices. Flexible epoxy film was fabricated by casting epoxy resin on coper foil. In order to increase flexibility and stretchability of the film, alkoxy silane modified epoxy, phenol-novolac epoxy and half-ester modified acid anhydride were synthesized. The elongation, tensile modulus and tensile stress of flexible film showed 110%, 1 Gpa, 16 MPa respectively (see Fig. 1). Furthermore the flexible film had elastic restoring force. After it was elongated to plastic deformation region, its length was restored to a degree of 101.5% by itself compared to original length at room temperature (see Fig. 2). After fabricating flexible film, a type of inductor antenna was realized and evaluated by embedding 32 μm thick Cu pattern into polymer layer to reduce total thickness and increase flexibility. The pre-formed thick Cu pattern was transferred to the flexible films for embedding patterns and inductor pattern was interconnected through vias. The new flexible antenna has 150% thicker Cu pattern, lower electrical resistance, 10% lower thickness and 1.5 times higher Q factors than commercialized products.

Department of Electronic Engineering, National Kaohsiung University of Applied Sciences
415 Chien Kung Road, Sanmin District, Kaohsiung 80778, Taiwan

Abstract— There are more and more internet applications, such as internet TV, multimedia network, online games, social networking sites and cloud computing. We need to decrease the time of the data processing and increase the quality of the data transmission. For higher data rate applications, the 40/100 Gigabit Ethernet (GbE) standards was proposed in 2010. The 100 GBase can use four parallel 25 Gb/s channels to achieve the transmission rate. Therefore, the performance of the high data rate products, modules, devices, or testing kits need be measured over 25 GHz frequency range. The time domain measurement of high-speed signal needs generally an expensive pattern generator to provide a pseudo-random binary sequence (PRBS) signal.

In this paper, an evaluation board with a built-in 25 Gb/s PRBS source was developed for testing high frequency probe in time domain. The high frequency probes in semiconducting testing field are one of convincing contact elements selections. A commercial clock-data-recovery (CDR) chip was used to design the PRBS source. Some printed circuit board (PCB) layout techniques were used to design the 25 Gb/s evaluation board. The differential traces were designed to reduce noise interference, and the length of signal traces was short as possible for improving the transmission bandwidth. The dielectric material of our PCB used Rogers 4350B with dielectric constant 3.66. Special K connectors with 40 GHz bandwidth were used in signal input and output interfaces. The advantages of our 25 Gb/s evaluation board for testing high frequency probe have low cost, small size, and light weight.

The Optimized Electrode between a SMPM Connector and a Microstrip for High Frequency Applications

Cheng-Ying Wu, **Hong-Lu Lin**, **Jau-Ji Jou**, **Yaw-Dong Wu**, **and Tien-Tsorng Shih**
Department of Electronic Engineering, National Kaohsiung University of Applied Sciences
Kaohsiung, No. 415 Chien Kung Road, Kaohsiung City, Taiwan

Abstract— Due to the advent of the cloud computing, a high data rate transmission is greatly demand. The data traffic between servers inside a data center becomes busy. According to the requirement of a 100 GBASE Ethernet, the transmitted data rate of a single channel is 25-Gb/s and the aggregated data rate is 100-Gb/s by adopting 4-channel transmission simultaneously. The testing setup and connection for a 100-Gb/s environment is very essential. Signal integrity and impedance match are key points in designing either the transmission line on a printed circuit board (PCB) and the connector. Usually, a k-type connector is generally adopting and soldering with PCB. However, the size for a k-type connector is large, and makes a difficulty in minimizing the length of a microstrip of a PCB. A long trace of microstripe limits the transmission bandwidth. In this research, a smaller and cheaper novel Subminiature Modular Plug-in Mini (SMPM) connector has been used to replace a K-type connector. The SMPM connector is installed on the top of PCB and soldering with an electrode to reduce the trace of a microstrip and to maintain the high frequency performance. Three designs of the PCB electrode have been simulated and verified experimentally. The optimized impedance mismatch of the soldering point between a SMPM connector and the PCB electrode is controlled within a range of ±2-Ohm. The 3-dB bandwidth of the whole setup including two SMPM connectors and a 2.5-cm long microstrip is above 25-GHz. This optimization can be used in designing high-speed PCB for the application of 100 GBASE Ethernet.

High Frequency Performance Comparison among Three Kinds of Board to Wire Connectors

Ruei-Nian Wang, **Li-Wei Chen**, **Jau-Ji Jou**, **Yaw-Dong Wu**, **and Tien-Tsorng Shih**
Department of Electronic Engineering, National Kaohsiung University of Applied Sciences
Kaohsiung No. 415 Chien Kung Road, Kaohsiung City, Taiwan

Abstract— In recent years, due to the vigorous develop of information and communication technology, it makes the popularization of the internet broadband applications, such as bandwidth internet games, online teaching platform, network conference, and cloud applications. The 100 Gigabit Ethernet can use four parallel 25 Gb/s channels to achieve the transmission rate. Therefore, the bandwidth of the related device, module, equipment, and network must increase to near 25 GHz. For the high-speed modules, the signal integrity and impedance match between the printed circuit board (PCB) and connector have to be investigated.

In this paper, we analyze and compare the properties of three kinds of high frequency board to wire connectors which are subminiature modular plug-in mini (SMPM) connector, vertical K-type connector, and horizontal K-type connector. The S-parameters of these connectors were simulated through the High Frequency Structure Simulator (HFSS) software. Using these connectors, three kinds of evaluation boards (EVB) were designed for measuring the high frequency performance of the connectors. The impedances of these EVBs were measured through the time domain reflector (TDR), and the S-parameters were also measured and verified through the network analyzer. The insertion loss from PCB sheet material or connector can be distinguished through the different length EVBs. The bandwidth of the SMPM connector is about 20 GHz, the bandwidth of the vertical K-type connector is about 24 GHz, and the bandwidth of the horizontal K-type connector is above 25 GHz. The board to wire horizontal K-type connector is more suitable than the other two connectors for 25 Gb/s transmission applications.

Seasonal and Temporal Variation of GPS Phase Fluctuations at High Latitude under Low Solar Activity

Chien-Chih Lee[1], **Wei-Sheng Chen**[1], **and Fang-Dar Chu**[2]

[1]General Education Center, Chien Hsin University of Science and Technology

[2]National Standard Time and Frequency Lab of Telecommunication Laboratories
Chunghwa Telecom Co. Ltd., No. 99, Dianyan Rd., Yangmei City, Taoyuan County 32601, Taiwan

Abstract— This study investigates GPS (Global Positioning System) phase fluctuations over the high latitude site, Tromsø, Norway (69.66°N, 18.94°E, MLAT 66.75°N) during the low solar activity year 2007. In this study, the phase-fluctuation index Fp is used to characterize GPS phase fluctuations. Investigations include the seasonal and the temporal variation of Fp, the correlation between Fp and Kp, and the comparisons between Fp and the ionospheric electron density. The objects are to show the general variation of GPS phase fluctuations and the variation of the ionospheric electron density when irregularities occur. The results are that the active GPS phase fluctuations (Fp $\geq$ 50) occur frequently in all months; the highly active GPS phase fluctuations (Fp $\geq$ 200) prefer to occur in the equinox months; the occurrence of Fp $\geq$ 50 and Fp $\geq$ 200 both concentrate in the 18–03 LT period. These indicate that the active GPS phase fluctuations results from particle precipitation. Moreover, the temporal variation of Fp consists with that of scintillations in published papers but the seasonal variation does not. Regarding Kp, it shows positive correlations to Fp, which links the intensity of GPS phase fluctuations to the geomagnetic activity. Finally, the comparisons show that Fp $\geq$ 50 occurs when the E region density is quickly increasing or the E region density structure is extending up. This implies that GPS phase fluctuations are activated when intense particle precipitation is proceeding. Moreover, irregularities distribute from the E to the F region. The results of this study demonstrate the effective application of GPS phase fluctuations to space weather.

An Investigation of Equatorial Ionospheric Irregularities under Solar Maximum in the 24th Solar Cycle in Middle and East Africa Using GPS

Fang-Dar Chu[1], **Wei-Sheng Chen**[2], **and Chien-Chih Lee**[2]

[1]National Standard Time and Frequency Laboratory, Chunghwa Telecom Co., Ltd., Taiwan
[2]General Education Center, Chien Hsin University of Science and Technology, Taiwan

Abstract— Ionospheric irregularities exert scintillations on electromagnetic waves when the waves pass through them. So they are interesting for satellite signal propagation in the ionosphere at the magnetic equator and low latitudes. The global navigation satellite system (GNSS) observations recorded at ground-based tracking sites have been a convenient database for investigating ionospheric irregularities. The irregularities over Africa during solar maximum years of 2013–2014 in the 24th solar cycle were investigated by employing the Global Positioning System (GPS), which is a GNSS system. Six African GPS tracking sites of the International GNSS Service (IGS) network were adopted in this study. First three sites were located at low latitudes close to the geomagnetic equator, in Middle and East Africa from the coast of Atlantic Ocean to that of Indian Ocean. The other three were located at midlatitudes and at about the same longitudes as the aforementioned low-latitude sites. Equatorial irregularities were characterized by hourly GPS phase-fluctuation index. This index categorized irregularities into three levels: they are background, moderate, and strong irregularities. The important climatological results have been obtained as followings. First: The equinoctial irregularity occurrence rates over the three low-latitude sites decreased slowly from Middle to East Africa (94%, 89%, 83% and 87%, 73%, 64% for moderate and strong irregularities, respectively). Likewise, the June solstitial rates also decreased similarly (90%, 88%, 74% and 67%, 58%, 37%). However, the December solstitial rates decreased faster (55%, 24%, 28% and 26%, 10%, 7%). Thus, the equinoctial and June solstitial occurrence rates were also high in East Africa (83% and 64%; 74% and 37%), while the December solstitial one was low (only 28% and 7%). Second: Although moderate and strong irregularities occurred very frequently over the low latitude sites (e.g., 94% and 87%), they over the three midlatitude sites all were nearly at the background level (i.e., nearly 0% and 0%). This indicates the irregularities did indeed come from the equator. Third: Although the equinoctial irregularities were dominant, the June solstitial irregularities also occurred frequently and their occurrence rates were comparable to the equinoctial ones, especially in Middle Africa. As for the December solstitial irregularities, they were obviously of minor importance compared to both the equinoctial and June solstitial ones. The prominent June solstitial rates in Middle Africa may be due to the northward shifted geomagnetic equator (located in the northern hemisphere) and small declination angles.

Assessment of the Forest Disturbances Rate Caused by Windthrow Using Remote Sensing Techniques

[1]Faculty of Geography, "Babes Bolyai" University, Cluj Napoca, Romania
[2]Laboratoire LOTERR, Université de Lorraine, France

Abstract— Change detection using multi-temporal satellite images data is an important domain with various applications in forestry and can allow an evaluation of areas extended to the same spatial temporal scale. The focus of the study is to assess the changes occurring after catastrophic wind events using Landsat time series data. Estimates of disturbance rates are derived using 8 sample selected across the Apuseni Mountains during 2000–2014 periods. Multi-temporal analysis on annual basis has detected the patterns of the changing forest ecosystem and the trends that are occurring and give more accurate results. The satellite images have been calibrated and the root mean square error has been made. The satellite images preprocessing is made in order to transform the DN values into the surface reflectance. The approach requires images during the peak growing season. Local knowledge and available ancillary data about windthrow occurrence are required in order to fully understand the nature of these trends. The statistical algorithms are applied to characterize the magnitude of the disturbance. We found evidence of systematic change in the forest ecosystem of the Apuseni Mountains by analyzing multi-temporal surface data. The accuracy of forest disturbance detection diminishes with the decrease of the temporal resolution. Therefore, the approach described in this paper demonstrates that the Landsat time series data can be used operationally for assessing forest cover changes analysis after a windthrow occurrence across a large area.

Monitoring Land Use Change in South-west Romania Using Multi-temporal Landsat Remote Sensing Imagery

Cristina Rosca[1], **I. Holobaca**[1], **M. Alexe**[1], **D. Petrea**[1], **Paula Furtuna**[1], **and I. Haidu**[2]

[1]Faculty of Geography, Babeş-Bolyai University, Cluj-Napoca, Romania
[2]Laboratoire LOTERR, Université de Lorraine, Ile du Saulcy, Metz 57000, France

Abstract— Early detection of changes in land use is especially important in environments with fragile ecological equilibrium, such as those affected by drought or soil with a sandy texture. In this article we use remote sensing techniques integrated into a surface analysis to identify areas of nuts plantation, that have been deforested. Nut plantation, with an area of 50 hectares is situated in the south-west of Romania, in the field of sand dunes Dabuleni. According to Research Development Center for Agricultural Plants on Sandsăbuleni, at locality level area occupied with sand is: Calarasi — 6.800 ha, Dăbuleni — 10.300 ha, Bechet — 5.900 ha. Deforestation the nuts plantation occured gradually, beginning in the fall of 2012 and ending in the fall of 2013. The six curtains (plots) have been cut gradually, but deforestation occurred by pruning of the tree branches, subsequently tree trunks. We have been used multitemporale satellite data, Landsat (TM and OLI) covering the period 1987–2014. In order to ensure comparability of data, was chosen July, because it was in full vegetation season , the crowning is very developed. Deforested areas were detected by calculating NDVI and the use of thresholds. The changes were highlighted using the Erdas change detection module. The surface analysis has indicated an increase of deforested areas, so if the area occupied in July 1987 with rare vegetation (low pixel) was 15.05 ha, in July 2014 the affected area amounts to 42.7 ha out of 50 ha. The results show that the method used has proved to be useful in detecting precise and rapid environmental changes.

Looking for a Biophysical Approach to Early Stages of Chronic Kidney Disease

Alberto Foletti[1, 2] **and Mario Cozzolino**[3]

[1]Institute of Translational Pharmacology, National Research Council-CNR, Rome, Italy
[2]Clinical Biophysics International Research Group, Lugano, Switzerland
[3]Department of Health Sciences, University of Milan, Italy

Abstract— Chronic Kidney Disease (CKD) and its subsequent complications and consequences are an increasing concern in general population. A biophysical integrated approach in early stages of CKD was investigated in 30 patients with a 12-month follow-up. A clinical approach based on the use of an electro medical device (Medselect 729) was employed following previous reports as well as the procedure of electromagnetic information transfer through aqueous systems. Interestingly, we observed a significant increase in the estimated glomerular filtration rate (eGFR) according to CKD-EPI formula (+11.57 ml/min; +18.43%, $p < 0.0001$). Beside further studies are certainly recommended, a biophysical integrated approach in the management of early stages of Chronic Kidney Disease seems feasible, effective, and promising.

Steps towards a Biophysical Approach to Refractory Gynecological Infections

Ida Ferrara[1] **and Alberto Foletti**[1, 2]

[1]Clinical Biophysics International Research Group, Lugano, Switzerland
[2]Institute of Translational Pharmacology, National Research Council-CNR, Rome, Italy

Abstract— Refractory gynecological infections are often very difficult to treat. The need for new strategies of their management is therefore continuously increasing. Some researchers have recently pointed up that microorganisms could emit specific electromagnetic signals. Moreover electromagnetic signals could be able to yield response from immune system. The aim of this study was to assess the possibility to employ electromagnetic signals from swabs of refractory gynecological infections to rise a response of the immune system able to erase them. Twenty-two consecutive patients with refractory gynecological infections, since at least 3 months, participate into this study employing an electro medical device(Med Matrix) to perform the electromagnetic information delivery procedure. Vaginal swab was picked up for microbiological assessment at baseline and after 7 days. Out of 22 swabs performed 15 were positive for microbiological assessment at baseline. Out of the 15 positive at baseline only 2 were still positive after one week of biophysical treatment ($p < 0.0031$). Biophysical treatment of refractory gynecological infections seems to be an useful and promising second line clinical tool.

The Characteristics of Current-gated Single Electron Transistors

W. C. Chien[1], C. Y. Hong[2], C. S. Wu[2], and Watson Kuo[1]

[1]Department of Physics, National Chung Hsing University, Taichung 402, Taiwan
[2]Department of Physics, National Changhua University of Education, Changhua 500, Taiwan

Abstract— Superconducting single-electron transistors (SETs) with a gating junction are experimentally studied. Because of its large impedance, a one-dimensional Josephson junction array on the same chip is used for constant current gating. We experimentally studied the current-voltage characteristics of SETs under the constant current gating via a tunnel junction. The results can be compared with those obtained by using constant voltage gating through a tunnel junction. The SET current varies when one changes gating current, giving a current on-off ratio more than 1000 near zero voltage bias. The highest current gain of our current-gated SET was 16 dB when biased at the threshold of quasi-particle tunneling process.

Reliability Verification of Printed Electronics Type FPCB Used in NFC Antenna

Soon-Mi Hwang[1], **Kwan-Hun Lee**[1], **and Jin-Sung Lee**[2]

[1]Korea Electronics Technology Institute (KETI), South Korea
[2]Dreamtech Co. Ltd., South Korea

Abstract— Printed circuit board (PCB) is the carrier of electronic components which is widely used in many fields such as airborne electronic equipment [1]. Among the several types of PCB, Flexible printed circuit boards (FPCB) is being used extensively in current electronics devices because of their excellent flexibility, light weight, and reduced thickness [2].

There are two types depending on the production process FPCB; etching type and printed electronics type. Printed electronics refer to the printing of electronic circuitry on a common media such as paper, plastic, or textile. The conductive materials are available in liquid and paste forms, and can be applied using ink jetting and screen printing respectively. Printed electronics are portable, thin, tiny and suitable for customized applications such as smart labels, animated posters, and active clothing. Printed electronics is being regarded as the second coming of the semiconductor industry because it can significantly reduce their cycle times and cost structure [3].

FPCB for NFC antenna and wearable system is used in a variety of environments, and 'product reliability' is important as much as the function of each part. But so far, there is no validation for the product reliability. This thesis verified reliability of printed electronics type FPCB used in NFC antenna through environmental stress tests.

An environment test was carried out according to standard of FPCB used in NFC antenna. Seven kinds of test (; High temperature test, Low temperature test, Thermal Shock test, High temperature and humidity test, Salt test, Bending test, Electrostatic test) were carried out. The test items for performance verification were electric resistance, Inductance, Insulation resistance. High temperature test was carried out during the 120 hours in the $(85 \pm 2°\mathrm{C})$. Low temperature test was carried out during the 120 hours in the $(-40 \pm 2°\mathrm{C})$. Thermal Shock test was carried out in high temperature $(85 \pm 2°\mathrm{C})$, low temperature $(-40 \pm 2°\mathrm{C})$ and run for 30 cycles. High temperature and humidity test carried out 120 hours in conditions of $(85 \pm 2°\mathrm{C})/(85 \pm 3)\%$R.H. Salt test carried out 48 hours in conditions of $5\%/(35 \pm 2°\mathrm{C})$. ESD test was carried out according to IEC61000-4-2 and bending test was carried out 10 times, a 180-degree angle. As a result, we knew that environmental immunity levels.

After the environment test, the failed samples were carefully examined with Environmental Scanning Electron Microscope (ESEM) and 2D X-ray. Analysis result, the major failure stress and failure mechanism of the electronics type FPCB were confirmed.

High Temperature Accelerated Test of Tower Mounted Amplifier (TMA) Module Used in 4G Communication

Soon-Mi Hwang, Chul-Hee Kim, and Kwan-Hun Lee
Korea Electronics Technology Institute (KETI), Korea

Abstract— Tower Mounted Amplifier (TMA) is normally used to improve cell coverage, capacity and quality of a wireless communication system. [1]. TMA is used to expand signal coverage through enhancing the uplink receiving sensitivity in the area where call drops and handoff failure happen frequently. Improved receiving sensitivity at base station, TMA also helps to improve signal quality, enhance voice clarity and increase data transmission speed. Usually TMA is installed near to transmit and receive antenna at the top of a cell tower [2]. In general, TMA module is exposed to the outside, it should be guaranteed sufficient immunity for a variety of environmental stresses that can occur in the Outdoor. One of the major failures stresses of the TMA is high-temperature. In this paper, high-temperature degradation of TMA was studied through the accelerated test.

Accelerated test is the basis of the conventional reliability test to inspect the product's reliability during a short period of time. The basic thought of accelerated test is to obtain more failure data within less time via stresses which is higher than normal condition, i.e., accelerated stress, on the premise of keeping the consistency of degradation or failure mechanism. Thus we can inspect the product's reliability after obtaining the parameter under accelerated condition [3]. Accelerated test is a powerful and effective approach to evaluate the high reliability and long life products. At the accelerated life test, by revealing the relationship between life of products and sentimental stress under the consistency of degradation failure mechanism at accelerated stress, it can predict the product's real life from the life data obtained under the high stress environment.

High temperature accelerated test was conducted in four harsh conditions (130°C, 125°C, 120°C, 100°C) over 400 hours. Real-time measurement system (measuring Insertion Loss, Return Loss, Gain, Current) of was used to determine the failure of product.

After the high temperature accelerated tests, we analyzed fail samples using optical microscope and FIB (Focused Ion Beam). Failure of TMA in high-temperature environments is breakdown of the internal amplifier chip.

Test results are analyzed using commercially available reliability software. (Weibull++, ALTA) As a result, The Weibull is suitable for distribution of TMA's lifetime. And temperature coefficient of TMA is 342 if the using temperature is 33.5°C and test temperature is 70°C.

FEM Evaluation of the Novel Cardiac Defibrillation Electrode Placement

Elham Khosrowshahli[1] and Aleksandar Jeremic[2]

[1]School of Biomedical Engineering, McMaster University, Canada
[2]Department of Electrical and Computer Engineering, McMaster University, Canada

Abstract— Defibrillation is a common process in treatment of patients with certain cardiac dysfunctions like ventricular fibrillation and ventricular tachycardia. Different external defibrillation systems use two electrodes to create an electric path in torso to pass current through it, and consequently through heart to regain normal hear beat. Amount of current delivered to heart is an important factor in successful defibrillation and its amplitude (and hence the outcome) is determined by the impedance seen by the defibrillator. In order to gain higher current in the heart, this impedance should be minimized. Reducing the impedance between skin and electrode by the application of proper gels is one of the methods to reduce the total impedance seen by defibrillator. One significant component of this impedance is transthoracic impedance, which is the impedance of current path between two points on the skin under electrodes on the chest. It is not easy to determine the current path in torso because of the internal organs with complicated shapes and diverse electrical properties which results in highly inhomogeneous medium and therefore complex current profile in torso. As it has been shown in electric circuit theory, one of the ways to decrease the impedance would be connecting a parallel impedance to the existing one. Using this rule, if an electric path is added to the conventional defibrillation system, transthoracic impedance can be reduced to attain higher current in torso. To implement this idea, a third electrode is added to the existing defibrillation electrode configuration. Adding this electrode creates parallel paths for current in torso in addition to the existing path. This leads to smaller impedance seen by defibrillator and achieving the desired defibrillation current with lower voltage and power levels of defibrillator. This can decrease size and increase lifetime of batteries of automated and wearable cardiac defibrillators and hence lead to lighter and more efficient systems. To verify the new method, a Finite Element model of torso is developed, and different conventional and novel electrode placements are simulated and total current delivered to heart is obtained when the new electrode is added in different positions. Outcomes show that although the amount of current increase is different, larger current is delivered to myocardium when the system of three electrodes is used in comparison to the conventional system when the same voltage is applied to both versions.

Conductivity Estimation of Breast Cancer Using Stochastic Optimization

A. Jeremic[1] and E. Khosrowshahli[2]

[1]Department of Electrical and Computer Engineering, McMaster University, Canada
[2]School of Biomedical Engineering, McMaster University, Canada

Abstract— According to Canadian Cancer Society, breast cancer is the most frequently diagnosed cancer in women with over 23,400 new cases expected in 2011. Although mammography is extremely important diagnostic technique, it suffers from some limitations such as false negative and positive results and using ionizing radiation. The number of false positives is rather significant in the case of so called dense breasts in which healthy tissue may be mistaken for malignant. Microwave imaging has been recently proposed as an additional medical imaging technique which can potentially overcome some of the shortcomings of the mammography. From the physical point of view this can be represented as a propagation in the medium that contains scatterers. Due to the fact that malignant tissue has larger conductivity the measurements obtained by receiving array of antennas will be different in the presence of scatterers. Most of the image reconstruction techniques minimize a particular cost function where the number of unknowns is much larger than the number of available measurements which requires an additional constraint. In this paper we propose a simplified parametric model which enables detection and estimation of tumors. Previously, we proposed a maximum-likelihood based method which estimates the unknown parameters by minimizing the residual error vector. However we have recently demonstrated that the detection performance can be significantly improved if classical sample covariance estimate is replaced by a structured covariance estimate. In this paper we develop a finite-element model and apply newly proposed weighted Frechet mean estimation to determine the unknown conductivity.

2D and 3D Durable Phantoms for Verification of Capabilities of Microwave Tomography and Hyperthermia Systems

M. Wiewegh, P. Spurny, J. Vrba, Jr., and D. Vrba
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— In this paper, seven different durable phantoms for verification of imaging and heating capabilities of developed microwave tomography and microwave hyperthermia system respectively were developed. The phantoms are based on silicone-graphite powder mixtures.

For microwave tomography systems two 2D cylindrical phantoms as well as two 3D phantoms with simplified shape of a breast were developed. Both types of phantoms consist of a layer of skin-mimicking outer layer and the inner space mimics healthy breast tissue. Tumors are modeled with cylindrical and spherical inclusions in 2D and 3D phantoms, respectively.

For hyperthermia 3D phantoms were developed. For superficial hyperthermia one phantom is homogeneous and mimics muscle tissue and two are heterogeneous with three layers mimicking skin, fat and muscle tissue. One of the heterogeneous phantoms consists of a spherical tumor as well.

Prior to phantom manufacturing, all materials mimicking different biological tissues were prepared and their dielectric properties were measured using an open-ended coaxial probe.

A proper volumetric ratio of graphite powder and silicon was tested. By manufacturing of the phantoms part of the material used for phantoms was used for creation of homogeneous samples and were characterized separately.

Numerical Modeling of rTMS with High-resolution Head Phantoms

M. Shuleska and J. Vrba, Jr.
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— One of the common issues of orofacial pain treatment using transcranial stimulations (TSs) is that the stimulations are applied by MDs based solely on their knowledge and experience and there is no mean to measure exact location, level and extent of the stimulation. The main aim of a planned project is, by means of patient-specific numerical simulations, to further improve current understanding of TSs as well as to investigate new possibilities how to improve their efficacy in pain treatment. Repetitive transcranial magnetic stimulation (rTMS) is relatively new, and most promising, type of method used in pain treatments. It belongs in non-invasive and painless brain cortex stimulation using magnetic fields. The rTSM neuromodulation method is using coils that are positioned on the surface of the head's patient. This method is inducing electrical current impulse in the human brain and causing an increase in the brain activity. The latest studies showed that this method has the ability to cause changes in the central nervous system on a cellular level. Therapeutic effect of the rTMS was confirmed in mental disorders such as depression, hallucination, schizophrenia and post-traumatic stress. This stimulation method was also used in patients with neurological disorder, patients with Parkinson's disease, epilepsy or functional disorders after a stroke. The main focus of this paper is, based on results of numerical simulations, to find extent, location and intensity of the stimulation process for particular patients. Finding out these quantities is accomplished through the following stages: creation of a patient specific numerical model by segmentation of the patient's MRI images, creating numerical model of stimulation device both in SEMCAD X and performance of numerical simulation and evaluation of results. The developed methodology, presented in this paper, will be used in future clinical studies with the aim of improving treatment efficiency.

Segmentation of Brain MR Images

M. Shuleska and D. Vrba
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— One of the common issues of orofacial pain treatment using transcranial stimulations (TSs) is that the stimulations are applied by MDs based solely on their knowledge and experience and there is no mean to measure exact location, level and extent of the stimulation. The main aim of a planned project is, by means of patient-specific numerical simulations, to further improve current understanding of TSs as well as to investigate new possibilities how to improve their efficacy in pain treatment. This paper focuses on different aspects of the segmentation process of magnetic resonance images (MRI), of a human head, using a specialized segmentation program — iSeg. The proper segmentation of human head is a challenging task and is of crucial importance for planned numerical analysis. Availability of suitable (in terms of used MRI parameters) and high resolution MRI of each patient is essential part of the segmentation. The signal weighting (T1, T2, PD) and sequences parameters (TR, TE) of MRI are therefore discussed as well. The segmentation creates three-dimensional (3D) unstructured triangulated surface objects representing gray matter (GM), white matter (WM), the cerebrospinal fluid (CSF), skull, skin and various parts of the head. These surfaces define different domains in a 3D numerical model which can be imported into special programs for numerical simulation on electromagnetic field and develop and explore diverse medical situations. In our case the numerical models are imported in well-proven commercial simulation tool SEMCAD X, where numerical simulations are performed and evaluated.

Abstract— The whole-body exposure system for unrestrained mice was designed in order to analyze the influence of electromagnetic field. The setup operating at 900 MHz was designed with respect to induced uniform field, external radiation elimination, absorbed power determination, sufficient space for mice movement together with even mice exposure and costs. The main aim of this paper is to assure that the dosimetry results reached by computer simulations can be used for determination of absorbed power in the unrestrained mouse. The whole-body exposure chamber with anatomical mouse model was simulated by two different numerical methods: finite-difference-time-domain method (FDTD) and Finite Integration Technique (FIT) and its dosimetry results were compared by computed SAR values. In our contribution we will describe our first results dealing with observed biological effects of EM field, obtained by real exposures of experimental animals.

Numerical Modeling of Dielectric Properties of Silicon Phantoms for Microwave Imaging and Hyperthermia

P. Spurny, J. Vrba, Jr., D. Vrba, and M. Wiewegh
Faculty of Biomedical Engineering, Czech Technical University in Prague, Czech Republic

Abstract— Silicon-graphite powder mixtures with different silicon-graphite powder volumetric ratios were considered as composite material for preparation of solid and durable phantoms. The phantoms were intended for testing of microwave imaging as well as microwave hyperthermia systems. Several samples of these composites were prepared and dielectric properties were measured. The full desired range of dielectric properties of biological tissues were not achieved so far. A 3D concept for the numerical estimation of effective dielectric properties of oil and water emulsions with random droplet distribution was presented in the previous paper. Here this concept was adapted for estimation of effective dielectric properties of silicon-graphite powder mixtures. Geometry of powder particles as well as of the silicon-graphite powder mixtures were optically inspected and used in generation of the numerical models. The adapted concept can be described as follows. A MATLAB script automatically generates a random mixture of impenetrable graphite particles randomly placed in a cubic computational domain. The script assigns a proper boundary conditions to every face located on the outer walls of the computational domain as well as the corresponding dielectric parameters to each subdomain. The script also controls frequency of applied electric field and it also starts the quasi-static electric COMSOL Multiphysics simulation and evaluation of volume integrals (in COMSOL Multiphysics). It subsequently evaluates the effective dielectric properties. For each frequency and volumetric ratio up to ten simulations with independently generated random geometry were performed and statistical quantities, e.g., mean values and standard deviations, were computed. The results of the numerical simulations were compared to data estimated using different two mixing formulas as well as measured data. The main goal is to validate the numerical concept and use it subsequently to numerically test different components to be used for preparation of durable phantoms.

Tunable Polarization Rotator in Bilayered Metamaterial

Zui Tao, Xiang Wan, Bai Cao Pan, and Tie Jun Cui
State Key Laboratory of MWs, Southeast University, Nanjing 210096, China

Abstract— Polarization is one of the most important factors which conveys valuable information for electromagnetic signal processing. Polarization conversion dichroism can lead to an asymmetric transmission (AT) phenomenon, which was discovered in planar chiral metamaterial patterns from microwave to optical frequencies. The AT phenomenon is that a specific polarized electromagnetic can pass through a material from forth to back, but it can't pass back in the same polarization. To get the diodelike AT phenomenon, simple structure and high polarization conversion efficiency polarization rotators are desirable needed. Mostly we need three layered metallic patterns to get a relatively broad work band, but sometimes bilayered polarization rotator is also needed for its simple structure. Although many polarization rotators are reported before, they are mostly designed for a specific function, which mean that they can't satisfy the demand of intelligent control, as the environment changing. To get multi-functional polarization rotator, we designed a newly tunable bilayered metamaterial in this paper, which consists of a two layered polarization rotator and an active diode. The two layered polarizations rotator has simple structure and can provide high polarization conversion efficiency in around 8 GHz. The simulation results show that the performance of the asymmetric metamaterial can be controlled by the voltage of the active diode to work in different situations for linearly polarization waves. When the state of active diode is on, the metamaterial can fulfill AT phenomenon in one polarization, but can be regarded as a reflection plate in the other polarization. However, it is a reflection plate in both two polarizations when the state of active diode is off.

Simulation and Analysis of Radio Wave Propagation Characteristics of Typical Outdoor Environment

Yong Li[1], **Feng Chen**[2], **and Yuan-Jian Liu**[2]

[1]Zhongxing Limited Corporation of Telecommunications, China
[2]College of Electronic Science and Engineering
Nanjing University of Posts and Telecommunications, Nanjing 210003, China

Abstract— As the rapidly development of the mobile communication technology in recent years, predicting the propagation characteristics for urban area has become an important subject. In this paper, the propagation characteristics of typical outdoor environment at 3.5 GHz are simulated and analyzed by using the method of SBR (Shooting and bounding ray tracing). And it is achieved agreement by a comparison of simulated results and results in the literature, so the correctness of the method has been validated. Some propagation parameters are obtained in the simulation, such as the 3-D received power, RMS (Root Mean Square) delay spread, direction of arrival, Doppler shift and so on. These propagation parameters under LOS (Line-of-sight) and NLOS (None-line-of-sight) have been compared in this paper. The study can avoid time-consuming, laborious and the larger cost of testing and analyze radio wave propagation in urban micro-cellular environment by computer simulation. In the typical outdoor environment, the delay spread of the mobile station in NLOS is significantly higher than that in LOS. So the signal quality is poor, and results in the inter-symbol interference. The direct path is in a dominant role in outdoor street environment of radio wave propagation. As the transmitter leave away, the receiver power will reduce. But due to the reflection and diffraction paths, street power distribution has ups and downs, and the received power does not completely depend on the distance between the transmitting and receiving antennas. When the receiver is mainly located in NLOS environment and the transmitter is fixed, the variation of the radio wave propagation Doppler frequency in outdoor micro-cell environment is large. The contrast analysis of the above results provides the theoretical foundation for outdoor micro-cell at 3.5 GHz radio wave communication system, and benefits the base station planning and optimization of urban micro-cellular environment.

Mutual Coupling Evaluation within Waveguide Slotted Antennas

Giovanni Leone and Domenico Russo
Dipartimento di Ingegneria Industriale e dell'Informazione
Seconda Università degli Studi di Napoli, Italy

Abstract— Phased arrays made of a very large number of slot antennas find still appealing applications because of their mechanical advantages. A full wave complete analysis is prevented by the very large electrical dimension of the array. Accurate radiation performance predictions require to consider both internal and external mutual coupling effects between slots of different sizes. These effects can be decoupled by introducing a generalized admittance matrix (GAM) approach. Hereafter, by assuming that slots are embedded within an infinite PEC plane and that tangential fields are expanded under modal expansions of rectangular waveguides over each slot, the external GAM is computed in closed form. It connects the expansion coefficients of the tangential magnetic field over the slots to the ones of the tangential electric field. In principle, a generic element of the matrix requires the numerical evaluation of a quadruple integral. In this paper a cancellation approach is used to remove the singularity of the Green's function and the order of integration is reduced by a suitable changes of variables. In this way self and mutual admittances can be estimated by computing double integrals. By a further approximation mutual admittance elements can be reduced to a single integrals saving computational time and resources. Results of such approach are finally compared with the ones provided by a commercial numerical simulation tool showing good agreement. The approach allows to appreciate the role of the number of expansion modes and the distances between the slots on the accuracy of the array radiation pattern prediction.

Chaotic Low-frequency Fluctuations of the Laser Radiation Emitted by a Diode Laser Working at Currents above the Laser Threshold

I. R. Andrei[1], **A. Baleanu**[2], **and M. L. Pascu**[1, 2]

[1]National Institute for Laser, Plasma and Radiation Physics, Magurele, Romania
[2]Faculty of Physics, University of Bucharest, Magurele, Romania

Abstract— A complex chaotic behavior can be found in nonlinear dynamics of a semiconductor laser under optical feedback provided by an external reflector. When an external cavity is coupled, the laser system switches to an oscillating state; it follows a chaotic trace. The amplitude of the induced chaotic "noise" seems to be important, depending on the feedback intensity which is between 1% and 10% of laser emission power. One of the most studied issues on the chaotic dynamics is the low-frequency fluctuations (LFF) regime which occurs at laser operation near the lasing threshold and behaves as a cyclic dropout almost to zero of the output light beam intensity.

The chaotic behavior of the semiconductor laser emission with external feedback is influenced by laser parameters. Optical feedback intensity, injection current and diode temperature greatly influence the chaotic system evolution.

In this paper an extensive analysis of phenomena observed in the laser emission of an external cavity — semiconductor laser (ECSL) system operating in the low-frequency fluctuations regime has been carried out. We present data about the stability of the LFF chaotic dynamics regimes of a semiconductor laser (AlGaInP Fabry-Perot semiconductor lasers) for different sets of experimental parameters. The injection current during the measurements was adjusted at values near and over the threshold current corresponding to different set temperatures.

LFF regimes were obtained at current values over the threshold current, but only in certain conditions which depend of the intrinsic properties of the active region, respectively at currents where there is instability of mode-hopping type in the laser emission dynamics without feedback. The values of parameters for such regimes can only be determined experimentally, but the high temperatures favor the stability of the LFF regime. Also, the amount of feedback intensity must be of the same order of magnitude as at the operation at threshold current.

An Adaptive Spectroellipsometric Technology for the Diagnosis of Water Ecosystems

F. A. Mkrtchyan, **V. F. Krapivin**, **and V. V. Klimov**
Institute of Radioengineering & Electronics RAS
1 Vvedensky Sq., Fryazino, Moscow reg. 141190, Russia

Abstract— Design and development of methods spectroellipsometry and creation on their basis of a multi-channel polarization-optical devices is regarded as one of the most important stages of the study of water systems in real time. The efficiency for solving multi-parameter problems to a large extent depends on the sensitivity and accuracy of the instruments, their high speed measurements, the possibility of using a wide spectral range. Spectral measurements in aqueous media provide an informative basis for the use of modern detection and classification of pollutants that environment.

In this paper we developed a multi-channel information-measuring system (Adaptive Spektroellipsometric Identifier) for the control of water pollution, based on the combined use of methods spectroellipsometry, learning algorithms, classification and identification. The system differs from existing foreign spectroellipsometric devices using a new method of ellipsometric measurements, the original element base polarization optics and complex mathematical approach to assessing the quality of a water body subjected to anthropogenic influence. The system has the functions of learning recognition and classification of aquatic pollutants. The system allows to realize the function of prediction and decision making for the detection of contaminants in water, detect oil slick and determine their parameters; thickness, the location of the source of contamination, time of occurrence.

The Experimental, Frequency-selective Evaluation of the Pattern of Environmental Radiofrequency Electromagnetic Radiation in Ground and Underground Public Transport Infrastructure in Warszawa

Krzysztof Gryz, Jolanta Karpowicz, and Wiesław Leszko
Central Institute for Labour Protection — National Research Institute (CIOP-PIB)
Czerniakowska 16, Warszawa 00-701, Poland

Abstract— In the city over the million of population, the significant percentage of it is travelling at least 1–2 hours daily by public transport, such as buses, trams, metro. During the drive they are exposed to a specific combination of radiofrequency electromagnetic radiation, emitted by various wireless communications systems (e.g., antennas of mobile phones base transceiver stations and handsets used by passengers, internet public access, etc., and emitters are located in various distances, including very short one — e.g., of mobile handsets of other passengers or base station antennas located inside underground metro. The investigations of radiofrequency environmental electromagnetic radiation inside ground (busses and trams) and underground (metro) public transport infrastructure were performed in Warszawa (capital city of Poland). The frequency-selective exposimeters of electric field strength were used to register a set of exposimetric profiles of exposure of passengers and public transport workers (excluding drivers). The statistical parameters of registered exposure were analysed, with attention to the day-time of measurement, kind of transport and city location (downtown, residential areas) — calculated for each frequency range and for total value (representing wide-band result of complex exposure).

Investigations shown the statistically significant differences in sup-groups of registered exposimetric profiles. It was shown that for the users or workers of public transport infrastructure, the exposure during daily trip to work/school and back home may be a dominating component of the life exposure. In conclusion it is therefore recommended to pay attention on the daily travels habits of any subject of epidemiological studies related to radiofrequency radiation health outcome (e.g., studies related to IARC classification of radiofrequency radiation in the group of possible carcinogenic environmental factors). It was also found that investigated exposure is significantly lower (of an order of a fraction of V/m in the mean value and a several V/m in the maximum value) than international exposure limits (of an order of 50 V/m in the radiofrequency band).

Experimental Analysis by Dual Characterization of Near Field Impact on Humans Level of Occupational Exposure to 30–110 MHz Radiation

Simona Miclaus[1], **Jolanta Karpowicz**[2], **and Paul Bechet**[1]

[1]Department of Technicals Sciences, "Nicolae Balcescu" Land Forces Academy, Sibiu, Romania
[2]Laboratory of Electromagnetic Hazards
Central Institute for Labour Protection-National Research Institute (CIOP-PIB), Warszawa, Poland

Abstract— In the frequency range 30–110 MHz, which is the band of interest in present paper, the induced current in body limbs is regulated in guidelines for limiting human exposure to radiofrequency fields because of the limbs thermal load caused by exposure. The safety limits are set to $I_{limit1} = 45\,\text{mA}$ — for general public and $I_{limit2} = 100\,\text{mA}$ — for occupational exposure (averaged over a six-minutes periods). They supplement the safety levels set for both electric and magnetic field strengths of unperturbed fields where anyone may be present. Practically, the characterization of an occupational exposure situation may be complete by including limb currents evaluation instead of thermal effects numerical calculations. In references presently available, just scarce approaches exist that follow experimentally the simultaneous determination of both indicators, in real exposure conditions. In addition, characterization of near field and mainly its reactive region — presenting steep gradients — from the perspective of occupational exposure assessment, remains a complex task.

Present work analysed individual exposition in a group of 15 human volunteers being placed in the reactive near field of a biconical antenna (2 m distance) fed by continuos wave and input powers levels similar to that used by military radiocommunication equipment in the HF band. The variables of the experiment were: a) intrinsec: the person's position and posture (sitting, standing up facing the antenna, standing up lateral) and contact with the floor (type of shoes sole); b) extrinsec: frequency (three values were used: 30, 70 and 110 MHz), input power level (low and medium) and antenna polarization (horizontal and vertical). Incident field stregth (omnidirectional) in a fixed position was measured by an electric-field sensor while induced current in the feet of the human was determined by using an ankle fastened clamp-on current meter.

Descriptive statistics applied on experimental results showed: 1. Frequency and posture are the most sensitive parameters relating to induced currents for the same polarization. 2. Grounding/shoe sole type is not so important in near-field exposure level determination. 3. No correlations were obtained between induced currents and subjective parameters — height, weight, BMI, water content, fat content. 4. Strong correlations were obtained between induced currents at different frequencies but only for postures presenting high area of received field (in both standing postures, but not in sitting posture — this conducts to the idea of a body shape efficiency factor). 5. High correlation coefficients were obtained between induced currents and incident E-field strength for the same posture for all three frequencies, indicating that E-field level can be a proper predictor of induced current levels for the same polarization and same posture in the reactive near field. 6. Average height of volunteers presented a resonance at 70 MHz which is approx. 40% of the wavelength in free space (the ground was low conductive).

Wideband Dual-mode Dielectric Waveguide with Applications in Millimeter-wave Interconnects and Wireless Links

Nemat Dolatsha and Amin Arbabian
Center of Integrated Systems (CIS), EE Department, Stanford University, Stanford, CA, USA

Abstract— With the exponential growth in data traffic arising from new subscriptions and emerging web and mobile applications, there is a significant need for efficient and extremely high throughput wired and wireless links that can provide similar gains in network capacity at all levels. A substantial improvement in bandwidth and energy efficiency is required. Thanks to the recent progress in developing efficient CMOS transceivers, a relatively large bandwidth is now available at millimeter/sub-millimeter waves. The available large bandwidth can be still boosted by deploying multi-mode excitation of waveguide interconnects and antennas. Here, the challenge is the efficient excitation of appropriate modes.

To this aim, recently, we have proposed an all-electrical, low-cost and easy-to-package structure based on mm-wave dielectric waveguides for high-throughput interconnects [see Fig. 1(a)]. Use of mm-wave dielectric waveguides addresses the low-loss transmission requirement and leads to high energy-efficiency especially for short to medium range applications. A planar feed structure excites two *polarization-orthogonal* modes of a rectangular dielectric waveguide, namely the E_x^{11} and E_y^{11} modes. A printed electric dipole (in x direction) placed on top of the waveguide simply launches the E_x^{11} mode (with electric field in x direction) into the waveguide. The E_y^{11} mode is coupled into the waveguide using a printed slot dipole placed on the bottom side of the waveguide. In the current paper, to simplify the implementation, the feed structure is modified and both mode couplers are mounted on the single side of the waveguide. Due to difficulties in together integration of electric dipole and slot dipole on a single side, the slot dipole is replaced by a planar horn-like structure realized in a substrate-integrated waveguide (SIW) [see Fig. 1(b)]. The upper metal plate of the SIW structure is extended to serve a reflector for the electric dipole. Its lower metal plate is truncated after the *metal wall* to efficiently couple SIW fields into the E_y^{11} mode (with y polarization electric field) into the dielectric waveguide. The coupling efficiency of better than 4 dB over a wide frequency range from 60 GHz to 90 GHz is shown in Fig. 1(c). The isolation to the unwanted mode is better than 35 dB for both mode couplers. In practice, the electric dipole and the SIW feed will be connected to transceivers using appropriate microstrip transitions printed on the upper RO3003 dielectric. The complete feed network input return loss, transmission and isolation of modes in the back-to-back structure with a polyethylene dielectric

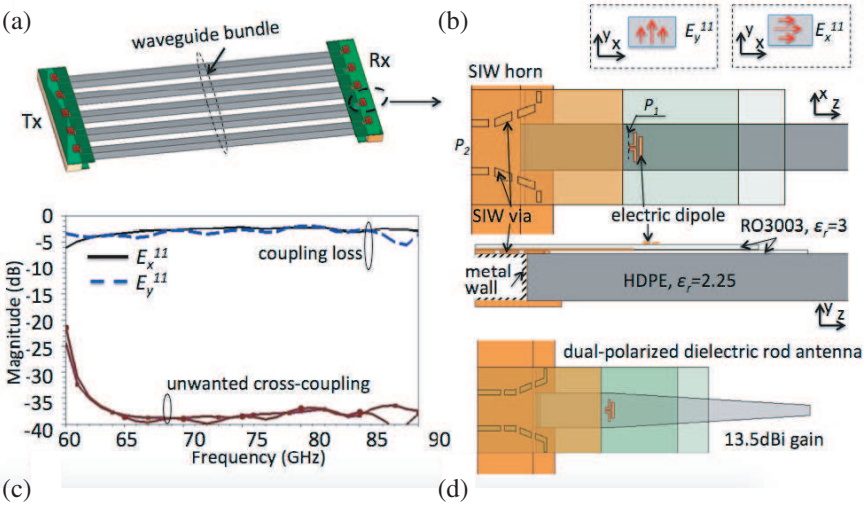

Figure 1: (a) Conceptual schematic of the proposed multi-mode dielectric waveguide for high throughput wireline links, (b) top view and side view of the planar multimode excitation structure, electric dipole for E_x^{11} mode and the SIW horn for the E_y^{11} mode (p_1 and p_2 shows the excitation points of electric dipole and the SIW horn structure), (c) coupling efficiency and mode isolation between launched modes, (d) high gain dual-polarized dielectric rod antenna fed by the proposed planar excitation structure.

waveguide in between will be discussed in the full-paper. The proposed feed structure is also used for dual polarization excitation of a high gain dielectric rod antenna (Fig. 1(d)). This doubles the available capacity of the single rod antenna. Simulations show gains of better than 13 dBi for each of polarizations at the center frequency of 75 GHz.

Some Results of Troposphere Mesoscale Fluctuation Analysis in City by Using Network of GPS-GLONASS Receivers

V. E. Khutorov, **G. M. Teptin**, **and O. G. Khutorova**
Kazan Federal University, Russia

Abstract— In this paper we show results of troposphere fluctuation analysis and its influence on radiowaves refractive index variations. For comparison of inhomogeneous impurities structure we used electromagnetic waves refraction index data which don't depend on impurity but depend on atmospheric parameters only. Our main object of investigation is a mesoscale process in troposphere. These processes have size from 1 km to 1000 km and time frames around few hours. This task requires system with good temporal and spatial resolution. We can estimate space structure of atmospheric parameters, using the data from network based on Global Navigation System receivers.

On the stage of the calculation of the tropospheric delay measurements were divided into two samples in the first included delay calculated for radiopaths passing over the town. In the second sample included radiopaths going out of town. Compared diurnal variation of the structure function zenith tropospheric delay resulting from these two samples.

We used structure function to estimate characteristics of impurities and refraction index fluctuation. Structure function is a basic characteristic of process with random increments. Physically, structure function is a square of fluctuation of investigated parameter. Function shows the contribution of the processes of the defined scale in the total variance of the fluctuations.

It is shown that remote sensing signals, of GLONASS and GPS satellites passed though troposphere, measured by a network of receivers, allows us to study the quantitative characteristics of inhomogeneities of the refractive index dm radio waves at different heights of the troposphere, in particular, the horizontal structure functions of the index of refraction and troposphere delay of signals, including their diurnal variations. Comparison of results obtained in the data of independent ground-based measurements of the structural function of the refraction index and high-altitude radiosonde measurements showed good agreement. The results obtained in this paper do not contradict the previously known publications.

Development of Wireless Power Induction Cooker Using Magnetic Induction-based Technology

Wonho Jang[1], **Seonghun Lee**[2], **Jeongsug Yeom**[3], **Byungduk Min**[4], **Goonyeon Kim**[1], **and Sangho Choi**[1]

[3]Komatech, Seoul, Korea
[4]R&D Department of Green Power, Suwon, Korea

Abstract— Tightly coupled (TC) wireless power transmission offers higher power transmission and higher efficiency of power transmission compared to the loosely coupled technology which is magnetic resonance-based technology. We develop wireless power cooker using magnetic induction-based technology which means tightly coupled technology. The cooker has over 90% dc-to-dc power transmission efficiency and transmits high power up to 2.4 kW. We used 20 kHz frequency to resonate between transmission coil and reception coil.

Introduction: Wireless power transfer (WPT) systems are becoming ubiquitous with applications in powering smartphones, transportation and a range of kitchen appliance devices such as induction cooker.

Weight Reduction Structure for Wireless Charging Vehicle

Hyung-Wook Shim, Dang-Oh Kim, Jong-Woo Kim, and Dong-Ho Cho
Korea Advanced Institute of Science and Technology, South Korea

Abstract— For replacing fossil fuel to eco-friendly resources, many types of transportation have been introduced in our life. Wireless charging transportation (WCT) such as electric vehicle and bus is one of the transportation developed in KAIST (Korea Advanced In Science and Technology) since 2009. Although it have a few hinders regarding power, transfer efficiency and heavy cost, it is obvious that WCT will bring out ripple effect in transportation trend for convenient charging and various applications. To develop performance of WCT at the level of commercialization, it is essential to achieve acceptable power transfer efficiency. Moreover, according to the limitation of battery capacity, the alternative solution about the increasing mileage should be needed. Despite an advanced technology such as magnetic shaping technology and the massive capacity battery have been introduced recently, the effective and fundamental solution is a weight reduction structure. If the lighter structure is installed, suppose that has as same power efficiency as before, it is possible to increase driving distance or room for battery. However, there are two important issues of weight reduction. First, maintain the power transfer efficiency. Second, maintain the strength of system structure. That is, as mentioned above, it is the key to design of lighter charging system without fluctuation of efficiency and strength. Therefore, the research regarding these issues should be carried on. Connected to upper states, in this paper, the weight reduction wireless charging system for a railroad is suggested to promote eco-friendly rail system. Since, it is used the diffraction property of electromagnetic fields, it shows prominent performance with little power efficiency drop and strength.

A New UWB Antenna with Unidirectional Radiation

Mingjian Li, Kwai-Man Luk, and Yue Zhao
Electronic Engineering Department, City University of Hong Kong
83 Tat Chee Avenue, Kowloon, Hong Kong SAR, China

Abstract— A new ultra-wideband antenna with unidirectional radiation pattern is proposed. The antenna is based on the model of magneto-electric dipole and excited by utilizing a new pair of differential feeds to provide an ultra-wideband impedance matching. Besides, a rectangular box-shaped reflector is employed to reduce the back radiation and the fluctuation of the antenna gain. Experimentally, an antenna prototype was fabricated and tested. The proposed antenna exhibits an impedance bandwidth of over 130% covering the whole UWB spectrum. The antenna gain varies between 7.16 and 14.1 dBi. More importantly, this antenna radiates unidirectionally with low cross polarization and low back radiation over the operating frequency range.

Miniaturized Transmitter in Digital Modulation System with Non-constant Envelope for VHF Band

Heon-Kook Kwon, Sung Jun Lee, Byung-Su Kang, and Bong-Hyuk Park
Electronics and Telecommunications Research Institute (ETRI), Korea

Abstract— In this paper, compact transmitter included power amplifier linearization in digital modulation with non-constant envelope for VHF band using cartesian feedback loop is presented. The digital modulation (QPSK/16-QAM/64-QAM) signal is non-constant envelope with constant peak to average power ratio. Digital modulation signal is used when linearized PA is 64-QAM, 70 ksps symbol rate, 0.35 of roll-off factor, and 7.5 dB PAPR. We used the Mitsubishi's Silicon power module, RA60H1317M1A, as a results, obtained an Adjacent Channel Power Ratio(ACPR) of less than −72 dBc, Error Vector Magnitude (EVM) of 2.8% at +39 dBm in VHF band. This technique is utilized to achieve miniaturization of transmitter with high linearity.

Session 1P1
FocusSession.SC2: Nonlocal and Spatially Dispersive Electromagnetic Media

Nanophotonics in Material-systems of Large Sizes

Marin Soljacic
Department of Physics, Massachusetts Institute of Technology
Cambridge, Massachusetts 02139, USA

Abstract— Recent nano-fabrication developments enabled implementation of many nanophotonic techniques to macroscopic scales, which is crucial for many applications of interest (e.g., energy conversion, displays, lighting). Some exciting new opportunities in this area will be presented.

Photonic Hypercrystals

E. E. Narimanov
Purdue University, USA

Abstract— We describe a new class of artificial optical media — the photonic hyper-crystals. These hyperbolic metamaterials with a periodic spatial variation of dielectric permittivity on a subwavelength scale, combine the features of optical metamaterials and photonics crystals within the same medium.

Metamaterials [1] and photonic crystals [2] currently represent the two primary paradigms for new optical materials. An artificial medium for electromagnetic applications generally relies on either the effect of a subwavelength pattern that changes the average electromagnetic response of the medium, or on Bragg scattering of light due to a periodic variation that is comparable to the wavelength. Due to this inherent scale separation, the corresponding metamaterial and photonic crystal concepts are generally considered mutually exclusive within the same environment.

The situation is however dramatically different in the case of hyperbolic metamaterials [3], where the opposite signs of the dielectric permittivity components in two orthogonal directions ($\epsilon_n \epsilon_\tau < 0$) lead to a hyperbolic dispersion of TM-polarized propagating waves

$$\frac{k_\tau^2}{\epsilon_n} + \frac{k_n^2}{\epsilon_\tau} = \frac{\omega^2}{c^2}, \tag{1}$$

with the wave numbers unlimited by the frequency. As a result, a periodic variation in the dielectric permittivity, regardless of how small is its period, will necessarily cause Bragg scattering of these high-k waves, leading to the formation of photonic bandgaps in both the wavenumber and the frequency domains.

The resulting hyper-crystals [5] — the hyperbolic metamaterials with a periodic spatial variation of dielectric permittivity on a subwavelength scale — bring a broad range of the physical phenomena from the field of photonic crystals to the metamaterial realm, leading to an unprecedented degree of control of light propagation in this new class of optical media.

Investigation of the Permittivities of Metal Films at Nanometer Scales

Haoliang Qian, Yuzhe Xiao, Dominic Lepage, and Zhaowei Liu
Department of Electrical and Computer Engineering
University of California, San Diego, 9500 Gilman Drive, La Jolla, California 92093-0407, USA

Abstract— With the development of nano-fabrication techniques, the dimensions of the plasmonic device have been shrunk into the nanometer scales. To understand the physics in such small plasmonic devices, the quantum confinement effects need to be considered. Here we choose the ultra-thin metal film as a platform to study this effect. We focus on their optical properties by studying the reflection and transmission of gold thin films with thickness varying from 30 nm to 2.5 nm. A theoretical model based on the self-consistence solution of Schrodinger equation and Poisson equation is proposed. According to this model, the transmission of a few nanometer gold film increases with increasing incident wavelength, which is completely different to the predictions based on Drude model and nonlocal model. We fabricated a series of ultra-thin gold films and ellipsometry results agree well with our theoretical model.

Ultra-transparency Induced by Spatial Dispersions

Abstract— Transparencyis usually not perfect in nature. Reflection of light on the surface of transparent materials such as glass is usually small but inevitable, except for transverse magnetic (TM) polarization and a single incident angle called the Brewster's angle. Light of any other incident angles or of transverse electric (TE) polarization willbe partly or totally reflected due to impedance mismatch. Based on the principle of destructive interference, most anti-reflection coatings have been widely applied to reduce reflection but only for light at normal incidence.Wide-angle and even omni-directional non-reflection and total transmission, which we denote as ultra-transparency, is really difficult if not impossible.

In this work, we propose a possible solution to ultra-transparency by going beyond the framework of local photonic media by incorporating spatial dispersions, in which $\boldsymbol{\varepsilon}(\omega, \mathbf{k})$ and $\boldsymbol{\mu}(\omega, \mathbf{k})$ are not only dependent on the angular frequency ω, but also on the wave vector $\mathbf{k}$. We find that the Brewster's angle can thus be expanded from a single one to a wide range of angles, leading to the property of wide-angle and even omnidirectional non-reflection and total transmission. By designing pure dielectric photonic crystals with a shifted elliptical dispersion, we numerically and experimentally demonstrated such an ultra-transparency effect. This new type of photonic media, with the new degree of freedom of spatial dispersion introduced, opens possibilities to novel optical designs.

Dislocated Double-layer Metal Gratings as an Efficient Unidirectional Coupler

Yang Shen and Chongjun Jin
State Key Laboratory of Optoelectronic Materials and Technologies
School of Physics and Engineering, Sun Yat-sen University, Guangzhou 510275, China

Abstract— We propose and demonstrate a dislocated double-layer metal grating structure, which operates as a unidirectional coupler capable of launching surface plasmon polaritons (SPPs) in a desired direction under normal illumination. The structure consists of a slanted dielectric grating sandwiched between two gold gratings, as a result, the upper gold grating has a latitudinal relative displacement to the lower one. Numerical simulations show that a grating structure with 7 periods can convert 49% of normally incident light into surface plasmons, with a contrast ratio of 78 between the powers of the surface plasmons launched in two opposite directions. We explain the unidirectional coupling phenomenon by the dislocation-induced interference of the diffracted waves from the upper and lower gold gratings. Furthermore, we developed a simple and cost-effective technique to fabricate the structure via tilted two-beam interference lithography and subsequent shadow deposition of gold. The experimental results demonstrate a coupling efficiency of 36% and a contrast ratio of 43. The relatively simple periodic nature of our structure lends itself to large-scale low-cost fabrication and simple theoretical analysis. Also, unlike the previous unidirectional couplers based on aperiodic structures, the design parameters of our unidirectional coupler can be determined analytically. Therefore, this structure can be an important component for surface-plasmon-based nanophotonic circuits, by providing an efficient interface between free-space and surface plasmon waves.

Bridging Classical and Quantum Optics

Yu Luo
School of Electrical and Electronic Engineering
Nanyang Technological University, Nanyang Avenue 639798, Singapore

Abstract— The miniaturization trend in experimental nano-optics is currently approaching the subnanometer regime, where the quantum effect plays a key role. On the one hand, the classical macroscopic electromagnetism cannot describe the quantum nature of electrons. On the other hand, previous full-quantum approaches demand high computational resources, preventing their applicability to realistic nanophotonic devices. In this talk, I will introduce a multiscale model able to describe realistic nanophotonic systems in the quantum regime. I will show how to connect the quantum simulation and the classical electromagnetic method at the mesoscopic scale through an appropriate modification to the local dielectric function at critical geometrical features. Our approach incorporates radiative, nonlocal, and quantum tunnelling effects, and thus can be applied to design large-scale plasmonic systems with Angstrom-sized geometrical features. As an example, I will show how to use this model to design super-resolution imaging system able to resolve sub-10-nm objects.

Manipulating of the Surface State between a Photonic Crystal and a Metasurface

Abstract— A surface state is introduced between a photonic crystal and a metasurface. The surface state is excited when the reflection phase matching condition is satisfied. The reflection phase of metasurface can be tuned by changing the structural parameter. The resonance properties of surface state can be manipulated in the process. Field enhancement induced by the surface state will have important applications in nonlinear and quantum optics.

Probing Spatial Nonlocality Effects in Plasmonic Nanostructures with Surface-enhanced Raman Scattering Spectroscopy

Dang Yuan Lei[1, 2]

[1]Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China
[2]Shenzhen Research Institute, The Hong Kong Polytechnic University, Shenzhen, China

Abstract— Spatial nonlocality effects, arising from atomic interactions and electron-electron repulsion, are recently believed to set the ultimate limits of plasmonic near-field enhancements in metallic nanostructures with critical dimensions on the order of a few nanometers or less [1, 2]. In a different context, surface-enhanced Raman scattering (SERS) spectroscopy has become a versatile vibrational spectroscopic technique with a number of applications in the chemical, material and, in particular, life sciences in the last decades. In this talk, I will show our recent work on the use of SERS spectroscopy for probing the spatial nonlocality effect in rough metal films with controlled surface roughness [3]. Our results reveal that this quantum mechanical effect on the metal dielectric response of metal has to be taken into account for more accurate prediction of the SERS enhancement at large surface roughness. Our current work focuses on the SERS spectroscopy of both spatial nonlocality and quantum tunneling effects in metal nanoparticle dimers with tunable interparticle distance down to sub-nanometer scales which are prepared by a sophisticated layer-by-layer self-assembly method [4].

Abstract— Miniaturization and integration are two continuing trends in the production of photonic devices. Metamaterials, the artificial materials, whose optical properties are determined by their geometrical structures instead of their constituent material composition, have opened new avenues in the manipulation of the light propagation. Metasurfaces, the emerging field of metamaterials, which consist of a single layer of artificial "atoms" have captured the attention of the scientific community over the past several years. At the interface of a metasurface, wave front shaping is accomplished within a distance much smaller than the wavelength of light beam, thus providing new opportunity to develop ultrathin devices that are easy to integrate into compact platforms. This technique does not require complicated three-dimensional nano-fabrication techniques but can provide full control of light propagation, which promises a whole variety of amazing applications, e.g., quarter-wave plates, spin-hall effect of light, and spin controlled photonics. In this talk, we are going talk our recent work in developing new ultrathin optical devices with unusual functionalities, including metasurface for characterization of light polarization, longitudinal multi-foci metalens for circularly polarized light and high efficiency functionality-switchable devices. Full and arbitrary phase control is achieved without extra look-up table or phase accumulation along an optical path. New ultrathin optical devices with unusual functionalities will be demonstrated. These findings are still under investigation and promise new exciting applications.

Multirefringence Phenomena in Plasmonic Multilayers

Abstract— We show that a light beam incident on a multiperiodic plasmonic multilayer, which is different from a conventional periodic multilayer in that its unit cell is composed of more than two layers, undergoes unusual refraction. Namely, splitting of the incident beam into more than two refracted beams having the same polarization is numerically observed.

Plasmonic multilayers can be used to manipulate light in various ways and at different scales down to the nanoscale [1]. They are also known to exhibit strong spatial dispersion and thus to demonstrate novel electromagnetic phenomena. In this talk we study refraction of macroscopic beams at the interface between an ambient dielectric and a plasmonic multilayer.

In particular, complicated plasmonic layered structures involving more than two different kinds of metal and dielectric layers, so that the unit cell of the structure is composed of four rather than two layers [2], are especially worth considering. Due to their inherent strong optical nonlocality, such structures have a multi-band plasmonic wave dispersion relation, so that several waves with the same frequency but different wave vectors can propagate simultaneously. This in turn gives rise to multirefringence phenomena, occurring when all these waves are excited simultaneously by an externally incident light beam (Fig. 1). This effect is distinct from trirefringence in photonic crystals, which occurs due to extreme polarization mixing arising from the structure patterning [3].

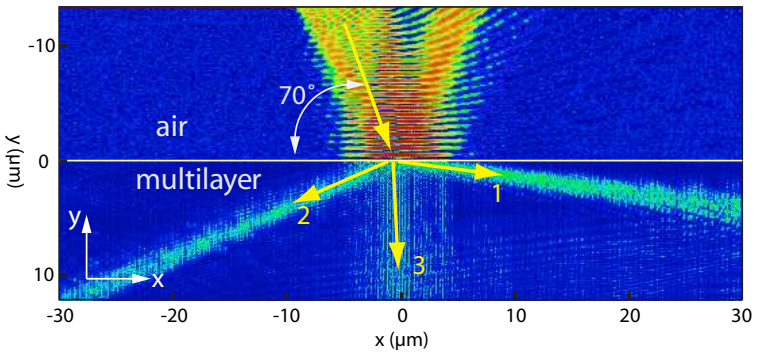

Figure 1: Numerically simulated field distribution ($|H|^2$) of a TM-polarized light beam impinging on an air/multilayer interface. Splitting into three refracted beams is observed.

Plasmonic Waveguide Array: Simulating Topological Photonic States and Massless Dirac Fermion

Tao Li, **Yiming Pan**, **Q. Q. Cheng**, **B. B. Xu**, **and S. N. Zhu**
National Laboratory of Solid State Microstructures
College of Engineering and Applied Sciences, Nanjing University, Nanjing 210093, China

Abstract— Topological phases have been successfully extended to the optical system, which gives rise to the novel optical phenomena (e.g., one-way optical propagations and robustness against scattering from defects in two-dimensional (2D) photonic crystals) [1]. Recently, the optical mimics of the 1D topological Su-Schrieffer-Heeger (SSH) model [2] were investigated in systems [3, 4]. However, the light diffraction in waveguide array, as an important simulator for the condensed matter physics, has not yet been demonstrated within such a 1D topological system. In this work [5], we proposed and demonstrated, a topologically protected plasmonic interface mode in metallic ridge waveguide array based on the SSH model. Here, we investigate the surface plasmon propagations in PWAs with two kinds of kinked defects, where the immunity against structural disorders is mainly discussed. It is well demonstrated that one of the interface modes is immune to the structural disorder and nanofabrication errors, while another kinked defect cannot support such an optical mode. Furthermore, due to the convenience in modulating the coupling coefficient in the ridge waveguide array, it is possible to construct an alternating positive and negative couplings in such a binary PWAs. From this point, we successfully find appropriate parameters to model a linear dispersive photonic energy band with a Dirac point [6, 7]. In this system the CMT equation is analog to the massless Dirac equation, so that we can use this PWA to simulate the massless Dirac Fermion. It is really realized by our COMSOL simulation, that a bidirectional non-dispersive SPP propagations in the PWA.

Nonlocal Effective Medium Theory and Its Relation with Zak Phase in Two-dimensional Photonic Crystals

Meng Xiao, **Xueqin Huang**, **Anan Fang**, **Z. Q. Zhang**, **and C. T. Chan**
Department of Physics and Institute for Advanced Study,
The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China

Abstract— We build a nonlocal effective medium theory (EMT) for a two-dimensional (2D) photonic crystal (PC) comprising a square lattice of dielectric cylinders with the incident electric field polarized along the axis of the cylinders. In particular, we discuss the feasibility of constructing an EMT for the case where the effective wave vector is far away from the center of Brillouin Zone (BZ). When the k-vector is away from the center of BZ, the optical response of the PC is necessarily anisotropic, implying that effective medium description becomes inevitability angle dependent, or in other words, nonlocal. While traditional EMT is only good near the zone center, we extend the effective range by including nonlocal effect. We employ the layer-by-layer scattering method as well as the parameter retrieval method to analytically obtain the effective impedance (Z_{eff}) and the effective refractive index (n_{eff}).

The obtained Z_{eff} is purely real for the pass band and purely imaginary in band gaps. While Z_{eff} is a function of frequency, sgn[Im(Z_{eff})] is a constant for all the frequencies inside a band gap, which means that we can classify the band gaps using sgn[Im(Z_{eff})]. We further prove that the sgn[Im(Z_{eff})] of each gap is related to the summation of Zak phases of all the bands below this gap. The relationship between the value of Zak phase and the symmetries of the band edge states is well studied, and the latter ones can be predicted with the group theory, which means we can obtain the sgn[Im(Z_{eff})] from symmetry argument with little effort.

With the sgn[Im(Z_{eff})] of each gap determined, we can predict the existence of interface state between two different systems. For example, we can explain why there is usually no surface state on the boundary of typical fully gapped PCs. Our non-local EMT also allows us to quantitatively predict the dispersion of surface states between different PCs for surface wave vectors that are well beyond the zone center.

Conditions for Negative Refraction and Negative Refractive Index in Lossy Media

Liming Ji and Vasundara V. Varadan
Microwave and Optics Laboratory of Imaging and Characterization, Department of Electrical Engineering
University of Arkansas, 700 W. Research Center Blvd., Fayetteville, Arkansas 72701, USA

Abstract— Negative refractive index (NRI) has been reported to be the requirement for negative refraction of waves (NRW) in lossless, isotropic electromagnetic media. Metamaterials have been used to create effective media with NRI by exciting plasmon-like resonances. In reality, there are no lossless metamaterials. For example, metamaterials composed of Split Ring Resonators (SRR) show significant loss at the SRR resonance frequency. It has been pointed out by other authors that in lossy media, NRI does not result in NRW. In this paper, we present a comprehensive list of conditions on material properties that are required for NRW to occur in lossy media.

Beginning with a straightforward derivation of refraction of obliquely incident waves from free space into a lossy, isotropic medium characterized by complex dielectric permittivity $\varepsilon'+\mathrm{j}\varepsilon''$ and complex magnetic permeability $\mu'+\mathrm{j}\mu''$. The angles for phase refraction and energy refraction are one and the same for waves travelling across lossless media. It is understood that they are different in lossy media. NRI is required for negative phase refraction but is not a requirement for negative energy refraction in lossy media. Since actual metamaterials are lossy and experiments measure the angle of refracted power flow into such materials, conditions need to be derived for this to occur in lossy media. Our derivation shows that certain parameter combinations of the complex permittivity and permeability and the conditions are polarization dependent. Negative permittivity is a requirement for TM polarization and negative permeability is a requirement for TE polarization in order for NRW to occur in lossy media. A complete table of conditions on the complex permittivity and permeability will be presented for TE and TM polarizations for both NRI and NRW. The amount of loss, that is the values of ε'' and μ'' also determine whether NRW will occur. These results are new.

We have tried to prove these conditions experimentally. However, our results depend on a big assumption, that our SRR metamaterial samples are isotropic, at least in the direction of wave propagation. In reality, there are no manmade metamaterials that are isotropic at the resonance frequency. In order to provide some guidance for designing and fabricating metamaterials, an assumption of isotropy in the direction of wave propagation is justifiable. Material samples with negative permittivity, permeability and NRI were constructed using periodically spaced Cu SRRs, Cu wires and a combination of SRRs and wires. The samples were characterized in a free space measurement system. There are three scenarios for wave refraction based on our derivation: a) simultaneous negative energy refraction and negative phase refraction; b) simultaneous positive energy refraction and negative phase refraction and c) simultaneous negative energy refraction and positive phase refraction. We will present experimental results for the three cases.

Spatially Dispersive Inhomogeneous Dielectric Wire Media with Periodic Structure

J. Gratus[1, 3], **R. Letizia**[2, 3], **and M. McCormack**[1]

[1]Physics Department, Lancaster University, LA1 4YB, UK
[2]Engineering Department, Lancaster University, LA1 4YW, UK
[3]Cockcroft Institute of Accelerator Science, Darsbury WA4 4AD, UK

Abstract— Spatially dispersive electromagnetic media are considered where the parameters defining the permittivity relation vary periodically [1]. This contrasts with most theoretical articles which consider inhomogeneous spatially dispersive media, where the inhomogeneity is restricted to looking at two homogeneous media which are connected and investigating the corresponding additional boundary conditions.

The use of a spatially dispersive inhomogeneous medium enables one to shape the propagation modes, extending the possibilities from the usual sinusoidal shape. This may have a number of advantages. For example in an accelerating drift tube, one could flatten the mode shape to enable higher acceleration for a given peak field. By contrast in signal transmission one may desire a higher peak for a given total energy.

In order to construct an inhomogeneous spatially dispersive medium it is necessary to consider a medium where the permittivity and permeability depend on both the wave vector $\mathbf{k}$ and the position $\mathbf{x}$ within the unit cell, i.e., $\tilde{\epsilon}(\omega, \mathbf{k}, \mathbf{x})$ and $\tilde{\mu}(\omega, \mathbf{k}, \mathbf{x})$. In order to make sense of the arguments of $\tilde{\epsilon}(\omega, \mathbf{k}, \mathbf{x})$ we no longer interpret $\tilde{\epsilon}(\omega, \mathbf{k}, \mathbf{x})$ as the Fourier transform of the permittivity response function $\epsilon(t, \mathbf{x})$ but in terms of a differential equation.

Maxwell's equations then give rise to a difference equation corresponding to the Floquet modes. Two methods are given for solving this equation and numerical method and an approximate solution, which are valid when the inhomogeneity is small. In the latter case the set of approximate solutions is calculated.

A new feature arises when considering spatially dispersive media, that is the existence of coupled modes. These change the frequency and the shape of the mode.

A medium which is both inhomogeneous and spatially dispersive is an inhomogeneous wire media. This is constructed from a grid of parallel wires with diameters which change sinusoidally as one goes along them. This can be used to the shaping of the propagation modes. The modelling of such a structure may be done using a standard 3D FDTD EM solver (which does not include spatial dispersion). However it is much quicker to model it in terms of a 1-dimensional spatially dispersive medium. The results of the two methods are compared.

Local Field Effects and Spatial Dispersion of Dielectric Permittivity

A. A. Tishchenko
National Research Nuclear University "MEPhI", Moscow, Russia

Abstract— Local field, i.e., the average acting field in system of many particles, is known to differ from average macroscopic field. This fact is well known in optics, spectroscopy and indeed in all branches of electrodynamics. For example, the Clausius-Mossotti relations join the microscopic and macroscopic properties of a substance and they are well known and widely used in the optics, spectroscopy of condensed media and many other fields of physics. Usually, these relations take into account only frequency dispersion, not the spatial one. The effects of frequency and spatial dispersions are caused by the nonlocal properties of response functions in time and in space, correspondingly.

In natural materials effects of frequency dispersion are usually much more considerable than that of spatial dispersion and only in special cases like electrons in plasma spatial dispersion plays vital part. But sometimes, despite their smallness, the latter may play a vital part. For example, one should take the spatial dispersion of dielectric function into account to describe the gyrotropy (natural optical activity) of some materials, optical anisotropy of nongyrotropic cubic crystals, and so on [1]. The spatial dispersion of dielectric function may change the number of the roots of the dispersion equation. Therefore, taking into account of the spatial dispersion may give us the additional, new types of electromagnetic waves, which are absent in the medium without spatial dispersion [2]. For example, spatial dispersion can be very important for artificial structures, like photonic crystals or metamaterials.

In this work proceeding from local field theory we demonstrate that spatial dispersion of permittivity can be caused not only by effects of moving electrons — as it takes place in plasma and so on — but directly by the structure of the material. At example of Clausius-Mossotti relations we show this for 3D material; in case of 2D-structure (monolayer of particles with arbitrary dielectric properties) we manage to improve our previous results [3] and get the relations with spatial dispersion. The analytical properties of responses functions are discussed. There are two of responses functions that are obtained: the one describing the response of the monolayer to the field of external sources, and the second one describing the response to the field of eigenmodes. Our results for 3D and 2D systems are valid not only for materials and artificial structures consisting of dielectric particles, but also for metal ones, including nanoparticles.

Session 1P2
SC3: Nanoscale Platforms for Molecular Sensing

Recent Progress in Nanoscale Sensing Using Surface-enhanced Raman Scattering

Kenneth B. Crozier
The University of Melbourne, Australia

Abstract— This presentation reviews recent work by the author and his research group on plasmonic structures for surface-enhanced Raman scattering.

Plasmonic dimers, consisting of two closely spaced metallic nanoparticles, represent a highly effective means for achieving very strong electromagnetic (EM) enhancement for suface-enhanced Raman scattering (SERS). It was recently suggested that quantum effects start to play a significant role for gaps $< 10\,\mathrm{nm}$ [1, 2]. We review work [3] in which we fabricate dimers in a highly controllable manner using electron-beam lithography, perform SERS, and correlate the results with transmission electron microscope (TEM) images of the dimers. We show that quantum mechanical tunneling across the gaps limits the enhancement in SERS.

We furthermore review our recent work [4] in which we demonstrate a micro-patterned silicon structure that enables the preparation of a SERS substrate and pre-concentration of the analyte molecules. The structure is designed to produce a hydrophobicity gradient. As a result, a water droplet placed on it will remain centred on the structure as it dries, enabling delivery of materials to its center. The structure is therefore referred to as a superhydrophobic bull's-eye. A water droplet containing gold colloids placed on it dries to produce a cluster at the bull's-eye center. A second water droplet placed on it, this time containing analyte molecules, dries such that the molecules are delivered to the gold colloid cluster. We demonstrate the detection of molecules at low concentrations (Rhodamine 6G at $10^{-15}\,\mathrm{M}$) from small droplets.

Hot Spots of Plasmonic Nanostructures and Their Spectroscopic Potential for Molecular Probing at the Nanoscale and at the Single Molecule Level

Katrin Kneipp[1], **Harald Kneipp**[1], **and Janina Kneipp**[2]

[1]Department of Physics, Danmarks Tekniske Universitet DTU, Lyngby 2800, Denmark
[2]Department of Chemistry, Humboldt Universität zu Berlin, Berlin 12489, Germany

Abstract— Frequencies of collective oscillations of the free electrons in metal nanostructures, called surface plasmons, fall in the optical range of the electromagnetic spectrum. Resonances between light and the surface plasmons result in enhanced local optical fields in the vicinity of metal nanostructures including also dramatic changes of field intensities within a few nanometers and the formation of so-called "hot spots". Hot spots open up exciting capabilities in optical spectroscopy by enhancing weak spectroscopic signals ("surface-enhanced spectroscopy") and by limiting probed volumes to (sub) nm dimensions.

Surface enhanced Raman scattering (SERS) is a prominent example to demonstrate the power of spectroscopy performed in hot spots. Moreover, Raman spectroscopy is of particular interest since spectroscopic observation of vibrational modes provides a non-invasive key to the molecular structure of matter. Raman spectra measured in hot spots can provide molecular structural information of a single individual molecule. At the same time, spectroscopic signals collected from a single molecules deliver sensitive information on the optical field at the location of the molecule.

We discuss recent developments for studying plasmonic metal nanostructures and related local optical fields as well as spectroscopic capabilities of these local fields. We start with considering Raman experiments using one- and two-photon excitation. Complementary to photons, we discuss Electron-energy-loss spectroscopy (EELS) as an emerging novel characterization tool for plasmonic structures which can provide high spatial resolution at the subnanometer scale. The complementary use of photons and electrons enables us to access a new level of information by combining the high energy selectivity of laser radiation with the atomic scale spatial resolution of electron microscopy.

New capabilities to characterize plasmonic properties become of particular interest for structures where quantum effects play a role, such as metal nanoaggregates with atomic scale interparticle gaps. Interestingly, such structures at the transition from the classical to the quantum regime seem to provide the hottest hot spots.

We discuss the unique potential of SERS performed in these hottest spots for chemical probing and sensing.

Abstract— Surface Plasmon Resonance (SPR) in metallic nanostructures is an optical effect, which can be exploited for the detection of small molecules. The current research aims for the development of nanostructures with high detection sensitivity and their easy implementation into a sensing schema. There is a broad range of metallic nanostructures supporting different SPR modes, and nanostructures can be even geometrically combined leading to the creation of new hybridised SPR modes. Most commonly, either spherical metal nanoparticles supporting localised surface plasmon resonances or thin metal layers supporting propagating plasmon resonances are implemented in bio-sensing.

In our study, we investigated the properties of a hybridised SPR mode (gap modes GM) created by the placement of metallic nanoparticles onto metallic layers and its use as a sensitive sensor. The spectral characteristic of these GM are highly sensitive on the nanoparticle substrate separation, which makes it an attractive sensing mechanism. We experimentally observed the creation of the GM for nanoparticle-substrate separation smaller then 10 nm and measured the effectivity of the excitation depending on the illumination conditions.

As a contrary to the commonly used far field light excitation of the SPR modes, an innovative way of electrically driven excitation of the GM was applied. Due to the planar geometry of the metallic layer, it was possible to extend this single metallic layer structure into metal-insulator-semiconductor (MIS) structure. The tunnelling current passing through such MIS structure generates supported SPR modes, which can be then scattered by the GM. This concept was experimentally confirmed. The MIS structures with tunnelling junctions were lithographically produced prior to electrical and optical characterization. We showed that the spectral emission is changed when the MIS structure also supports the GM. This was achieved by placing metal nanoparticle onto the upper metallic layer.

In such a scheme also other than spherical gold nanostructure supporting localised SPR can be used, which has a potential advantage in a stronger and spectrally shifted resonances. However, the stability of these nanostructures for further use has to be considered. In the remaining part of the talk, the stability issue of the triangular shaped silver nanoparticles is discussed. We were able to experimentally follow the degradation of such nanoparticles under ambient conditions in real time. Using atomic force microscopy and optical spectroscopy we observed that an anisotropic corrosion, that is starting from the tips of the nanoparticles.

Silicon Nanostructuring for SERS Applications and Hybrid Infrared Light Sensing Devices

Abstract— Inorganic semiconductor materials have for a long time been a standard member of electronic devices ecosystem, with silicon being the material of choice for most applications. Introducing structuring in silicon has proven to be advantageous for its many properties and applications. Introduction of silver nanocrystals in the porous silicon is promising for Surface Enhanced Raman Sppectroscopy (SERS). Heterojunction interfaces between organic and structured silicon substrate in devices show promise in using the advantages of both materials simultaneously. Here we present the results on preparation of stable and uniform SERS solid substrates using macroporous silicon (pSi) with deposited silver and gold and on the devices based on heterojunctions of porous silicon formed by anodisation in HF-based electrolytes and organic thin films formed by vacuum evaporation. Macroporous silicon is produced by anodisation of p-type silicon in hydrofluoric acid. The as prepared pSi is then used as a template for Ag and Au depositions. The noble metals were deposited in three different ways: by immersion in silver nitrate solution, by drop-casting silver colloidal solution and by pulsed laser ablation (PLA). Substrates obtained by different deposition processes are evaluated for SERS efficiency using methylene blue and rhodamine 6G at 514.5, 633 and 785 nm. Substrate concentrations detected in most of the cases were in the nanomolar range suggesting that it may be possible to detect lower analyte concentrations when using porous instead of crystal silicon template. For inorganic part of the heterojuction we choose porous silicon due to its compatibility to established CMOS technology and its enormous surface area being presented to thin organic films. For organic part of the junction we investigated the applicability of various organic semiconductor thin films for optoelectronic and biosensing applications. Our porous silicon-based devices show in optical response and moderate sensitivity in infrared spectral region.

Surface Enhanced Raman and Fluorescence Spectroscopies

P. M. Adam
Laboratoire de Nanotechnologie et d'Instrumentation Optique (LNIO)
Institut Charles Delaunay, Université de Technologie de Troyes, UMR 6281
12 rue Marie Curie, BP 2060, Troyes Cedex 10010, France

Abstract— Plasmonics is a field connected to optics dealing with the properties and applications of surface plasmons which are modes of metal dielectric interfaces. Nanoplasmonics concerns the excitation, manipulation and detection of the surface plasmons at the nanometric scale. It has highly potential applications for ultrasensitive biochemical sensing. Surface enhanced spectroscopies are the ultimate sensor tools as they can reach single molecule sensitivity. We will present in this paper our latest results towards the realization of highly controllable and reproducible nanoplasmonics substrates.

Plasmonics is a now well established field finding numerous applications in pharmacology, biology, optoelectronics and metamaterials among others. For the sensitive detection of molecules or markers Surface Enhanced Spectroscopies are well widespread [1]. Among them, Surface Enhanced Raman Spectroscopy (SERS) and Metal Enhanced Fluorescence (MEF) or Surface Enhanced Fluorescence (SEF), are the most used for applications. Both these enhanced spectroscopies are based on local field enhancement entailed in the near vicinity of metallic nanoparticles when Surface Plasmon oscillations are driven for a specific optical wavelength. SERS can achieve single molecule detection when two or more metallic nanoparticles are near-field coupled, resulting in enhancements ranging between 8 and 10 orders of magnitude, even if absolute magnitude of enhancement is still a subject of debate. However, these particular SERS substrates are difficult to reproduce.

Less enhancement is obtained with MEF/SEF but usually the intrinsic fluorescence cross section of a molecule is 14 orders of magnitude more important than that of its Raman cross-section. In MEF/SEF one has to take into account the finite lifetime of the excited levels of the molecule of interest, which results in quantum yield modifications in the presence of the metallic nanoparticles. Quantum yield can be enhanced or even reduced, leading in the latter case to a competition with local field excitation enhancement and thus the possibility of quenched fluorescence of the emitters.

This contribution will show the ties between SERS, MEF and sensors in the light of recent works done in the LNIO laboratory [2, 3].

Abstract— Core/shell nanostructures are intensively investigated for broadband light trapping and management, because they can play as optical cavities and directly take advantage of morphology dependent resonances. The same properties can be exploited in imaging and vibrational spectroscopy (Raman, IR), in order to enhance their analytical sensitivity [1–3]. Moreover, the synergistic combination of plasmonic nanoantennas with dielectric core/shell colloids allowed for fabricating near-field optical light concentrators, which are very efficient in stimulating photon-driven processes at metal-semiconductor interfaces and show an impressive decrease in degradation time (minutes instead of hours) of organic pollutants [4].

This presentation will review some applications of core/shell light nanoconcentrators as non-plasmonic Raman enhancers, which have been used to investigate biochemical reactions in aqueous environment, and their coupling to plasmonic nanoantennas for promoting and *in-situ* monitoring light-assisted chemical reactions [1–6]. Using both approximated analytical models and full wave numerical simulations, the role of morphology dependent optical resonances in driving the spectral response of different systems will be discussed also taking into account the nonlinear properties of the metallic nanostructures [7, 8].

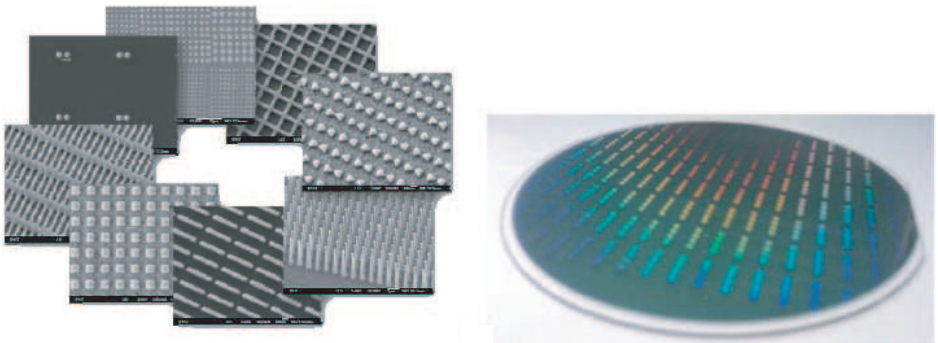
Abstract— Plasmonic substrates for surface enhanced vibrational spectroscopy (i.e., SERS or SEIRA), which use strong local electric field enhancement, are currently being developed for chemical and bio-sensing application fields. These artificial nanomaterials are constructed of millions of very small metallic pattern with typical feature sizes down to $\lambda/10$ and layered dielectric thin films. To test the substrates a sufficiently large number of test samples are needed. In addition, for future applications the fabrication of such nanomaterials over large areas, with a few million nanostructures per mm^2 presents a major challenge for the top-down lithography not at least due to frequently changing layouts.

In this work we present our unique e-beam lithography with Character Projection (CP) which is a promising technique for the fast fabrication of complex nanomaterials and optical metamaterials on wafer scale areas. Compared to the serial working standard e-beam lithography the Character Projection lithography operate in a partially parallel processing exposure mode which offers a significant advantage in writing speed by factors > 100 compared to the relative fast Variable Shaped Beam mode (VSB) [1, 2] and it opens the way for the fabrication of devices with large areas which are impossible to realize with SEM based Gaussian electron beam-writers often used in R&D. For example, the exposure times for a metamaterial accounts for nearly 1 year for the Gaussian-mode, whereas 2.4 h for the VSB-mode and only 1.4 min for the CP-mode are needed! Due to the enormous write time reduction also the pattern quality and the pattern homogeneity on large areas are improved significantly [3].

This write time reduction together with a high flexibility in terms of pattern diversity was achieved by the implementation of a computer controlled aperture stage with a multi-stencil diaphragm array in our SB350 OS Variable Shaped e-beam system (from Vistec Electron Beam GmbH Jena) [2]. More than 2000 different aperture geometries (= characters) can be addressed within one exposure job. The types of available pattern include various 1D-gratings with pitches down to 100 nm and with different angles of orientation, 2D-gratings and also patterns with geometries which are hard to approximate by geometrical primitives like circular dots and dot arrays, spirals, split-rings, rhombus, rod shape and bow-ties (Fig. 1). All these shapes can be combined and aligned to realize even more complex layouts.



(a) (b)

Figure 1: (a) Examples for different nanogratings and metamaterials, fabricated by means of the Character Projection (CP) mode. (b) A 100 mm-wafer with nanogratings. In CP-mode, the e-beam writing time for this wafer is only 1.5 hours.

Transfer-printing-based Fabrication of 3-dimensional Plasmonic Superlattice Nanostructures for Surface-enhanced Raman Spectroscopy Analyses

Jae Won Jeong and Yeon Sik Jung
Department of Materials Science and Engineering
Korea Advanced Institute of Science and Technology (KAIST)
291 Daehak-ro, Yuseong-gu, Daejeon 305-701, Republic of Korea

Abstract— Three-dimensional (3D) plasmonic nanostructures for surface-enhanced Raman spectroscopy analyses (SERS) have recently attracted much attention due to their superior signal enhancement capability compared to two-dimensional nanostructures. However, the controlled fabrication of ultrafine 3D super-structures that can maximize SERS hotspots is not straightforward. This talk will present the use of a solvent-assisted nanotransfer printing (S-nTP) technique for the 3D stacking of plasmonic nanostructures in a fast and convenient manner. General nanotransfer printing (nTP) technology offers outstanding simplicity and throughput in the fabrication of transistors, metamaterials, epidermal sensors, and other emerging devices. Nevertheless, the development of a large-area sub-50 nm nTP process has been hindered by fundamental reliability issues in the replication of high-resolution templates and in the release of generated nanostructures. In contrast, our S-nTP is based on high-fidelity replication of ultrahigh-resolution (8–20 nm scale) patterns using a dual-functional polymer thin film and solvent-assisted release of such nanostructures. We show how the signal intensity can be maximized with the choice of nanoscale geometries and the number of stacks. Based on the same principle, facile printing of plasmonic nanostructures for non-destructive and rapid surface-enhanced Raman spectroscopy (SERS) analyses can also be achieved. The utilization of S-nTP can significantly enhance the analysis throughput of SERS by decreasing the analysis preparation time for the formation of plasmonic nanostructures on analytes. As another example of a near-term application, this talk will also demonstrate that Ag nanowires printed on the inner surface of a vial glass can enhance SERS signals, enabling direct and convenient detection of molecules dispersed in a solution at an extremely low concentration.

Silver Nanowires as Efficient Sensing Platforms

Sebastian Mackowski
Institute of Physics, Faculty of Physics, Astronomy and Informatics
Nicolaus Copernicus University, Torun, Poland

Abstract— Silver nanowires are unique metallic nanostructures, which on the one hand are characterized with strong plasmon resonance, while on the other, can be imaged using standard fluorescence microscope. With appropriate surface functionalization both aspects of silver nanowires can be efficiently explored for sensing biomolecules. Chlorophyll-containing biomolecules, which participate in photosynthesis, exhibit strongly enhanced fluorescence upon conjugation with silver nanowires. In addition to intensity increase, the emission of chlorophylls is decaying much faster pointing towards radiative rate increase upon coupling with plasmon excitations. However, for large proteins, where coupling with plasmon excitations in silver nanowires is much weaker and induces at most minute changes in their spectral properties, silver nanowires play a role of geometrical constrain. In other words, through proper functionalization of the surface of silver nanowires, fluorescent biomolecules can be attached to them and their position can be precisely determined. Both these approaches can be combined for real-time observation of attachment and glowing of properly designed structures, also at a single molecule level.

Additional features of potential sensing platforms composed of silver nanowires can be introduced by covering them with graphene or its derivatives. Recent results of these experiments will be presented.

Abstract— Metal nanoparticles have attracted great scientific and technological interest in biomolecular detection and clinical diagnostic application due to their specific physical and chemical characteristics. Several reported experimental results illustrated that nanomaterial based non-linear optics assay can be used for monitoring chemical processes, biological and chemical toxins with excellent sensitivity and selectivity [1–4]. Linear optical properties and plasmon resonances of metallic nanoparticles or nano-antennas are well described in the literature by extinction and/or scattering spectroscopies and by radiation patterns in direct or in Fourier space. However, much less is known on their non-linear optical properties, and in the role of plasmon resonances in the enhancement of these effects. Two-photon luminescence (TPL) and second harmonic generation (SHG) both are prominent examples of non linear effects observed on metallic nanoparticles. In this study, we focused on the linear and non linear optical characterization of Au-Al heterodimers (Fig. 1). These dimers have been fabricated by a two-step electron-beam lithography process and the diameters of the Au and Al nanoparticles have been independently varied, as for the gap distance. The linear optical properties (single dimer scattering spectra) and the non-linear optical properties (SHG images and TPL spectra) have been compared to understand the main physical phenomena involved.

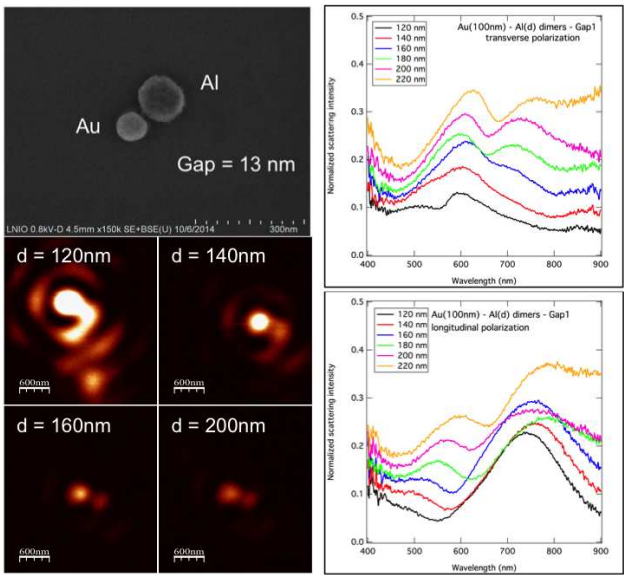

Figure 1: Linear and non linear optical characterization of single dimers composed by a 100 nm diameter Au nanoparticle and varying diameter Al nanoparticles.

Enhancing the Interaction of Light and Matter Using Photonic Nanostructures

S. Götzinger
Max Planck Institute for the Science of Light (MPL) and
Friedrich Alexander University Erlangen-Nürnberg, Erlangen 91058, Germany

Abstract— Clever methods to enhance the interaction of light and matter are at the heart of ultra-sensitive optical sensing. Prominent approaches are based on large field enhancements inside optical cavities or in the close vicinity of metallic nanostructures supporting plasmonic resonances. The latter can show extremely large enhancement factors [1]. Their performance is, however, strongly dependent on the exact shape of the structure. I will report on the controlled fabrication of gold nanocones using focused ion beam milling. The precision of the fabrication procedure allows us to control the plasmon resonance of the nanocones. Theoretical investigations predict an enhancement of the spontaneous emission rate of a single emitter by several hundred times. I will show an experiment where we could indeed observe a factor of about 340 in the spontaneous emission rate enhancement of a single colloidal semiconductor quantum dot [3]. In the second part of the talk I will report on an ultrasmall scannable Fabry-Perot microcavity with a mode volume of $0.5\lambda^3$ [4, 5]. The cavity is made of a gold coated curved micromirror fabricated on a silicon cantilever using focused ion beam milling and a planar distributed Bragg reflector. By scanning the curved gold mirror across the planar mirror we detect 80 nm gold nanoparticles by measuring the change in the cavity finesse This type of cavity is attractive for a number of studies ranging from sensing to quantum optics.

Air Quality Monitoring by Using One Dimensional Nanomaterial Based Gas Sensors

Inkyu Park
Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, South Korea

Abstract— Recently, the interest and importance in environmental monitoring, especially real-time tracking of air quality are dramatically rising. With the advent of manufacturing industry, the sources for harmful gaseous species such as nitrogen dioxide (NO_2), carbon monoxide (CO), hydrogen (H_2), hydrogen sulfide (H_2S), hydrocarbon (HC), volatile organic compounds (VOC) are continuously increasing. Although there already exist engineering systems that can provide accurate measurement of critical air quality factors, they are heavy, expensive and require high maintenance costs. Therefore, ultra-compact, inexpensive, yet high quality gas sensors based on integrated semiconductor chip should be developed for personalized, localized and real-time environmental monitoring for individual users. In this talk, we will introduce our effort to develop highly integrated gas sensors enabled by one dimensional (1D) nanostructures (e.g., nanorods, nanowires and nanotubes) of functional sensing materials such as silicon (Si), metal and metal oxides. 1D nanostructures provide high sensitivity and fast response due to high surface to volume ratio, chemical reactivity and electrical sensitivity. Here is the list of different 1D nanostructure-based gas sensors that we will discuss: (1) top-down fabricated silicon nanowires for H_2 gas detection: silicon nanowires that are fabricated by photolithography or electron beam lithography processes and functionalized with catalytic metal nanoparticles can provide high sensitivity and fast response to H_2 gas. Furthermore, self-heating provides higher selectivity to H_2 in the background of humidity (H_2O) or CO gases; (2) template synthesized metallic nanotubes for room temperature H_2 gas detection: multimetallic nanotubes can be easily fabricated by wet chemical process along hydrothermally synthesized zinc oxide (ZnO) nanowires and can be used for highly sensitive H_2 gas detection, (3) metal oxide nanostructures for multi-component gas detection: multiplexed array of heterogeneous metal oxide nanomaterials can be synthesized by focused energy field (FEF) method in liquid precursor environment and can be used for multi-component (e.g. NO_2 and CO) gas detection. We believe that these sensors will be very useful component for smart mobile telecommunication platforms (e.g., smartphone, table PC or handheld accessories) and wearable electronics systems.

Nanoscale Energy Transfer Sensing

Jana B. Nieder
INL — International Iberian Nanotechnology Laboratory
Av. Mestre Jose Veiga, Braga 4715-330, Portugal

Abstract— Advanced fluorescence spectroscopy with single molecule sensitivity can be used to unravel details of excitation energy transfer on the nanoscale.

Time-dependent single-molecule spectroscopy at low temperatures was used to study the emission of different pigments being part of a photosynthetic light harvesting system. Correlation analysis of the various emission contributions of such time resolved spectra revealed multiple and interchangeable excitation energy transfer pathways in individual photosynthetic complexes [1].

Besides high-resolution low temperature single molecule spectroscopy, a more recent experimental technique based on ultrafast femtosecond pulse shaping excitation with single complex fluorescence emission read out [2] prove to be suited to unravel the quantum coherent nature of energy transfer in individual light-harvesting complexes. This study was performed on a highly symmetric light harvesting system, with two main absorption bands, which can individually be addressed with resonant pulses with defined phase relations.

To this end we developed a pulse compression and characterization technique with simultaneous femtosecond and nanometer sensitivity based on the second harmonic signal generated from nonlinear nanoparticles positioned in the focus of the microscope objective used for single molecule studies [3].

In this contribution we will describe the application of low temperature and ultrafast pulse shaping single molecule spectroscopy techniques to study energy transfer characteristics of photosynthetic pigment protein complexes and we will additionally present the sensitivity of such techniques to study the effects of plasmonic interaction [4]. Enhanced knowledge of (plasmonic) metal interaction effects bears the opportunities of advanced molecular sensing and new approaches for real time live cell super resolution microscopy as recently demonstrated by Chizhik et al. [5], such concepts will be discussed.

ACKNOWLEDGMENT

In this contribution on nanoscale energy transfer I will present works developed mainly in the single molecule research groups of Prof. Robert Bittl at Freie Universitaet Berlin, Germany and of Prof. Niek van Hulst at ICFO — The Institute of Photonic Sciences in Barcelona, Spain with funding via the Cluster of Excellence UniCat and support via the advanced ERC grant NanoAnntennas awarded to Prof. Niek van Hulst.

Silver Capped Silicon Nanopillars as Surface Enhanced Raman Spectroscopy Substrates

Kaiyu Wu, **Michael Stenbæk Schmidt**, **Tomas Rindzevicius**, **and Anja Boisen**
Department of Micro- and Nanotechnology, Technical University of Denmark
Ørsteds Plads, Building 345B, Kgs. Lyngby 2800, Denmark

Abstract— In order to achieve widespread use in practical applications, a Surface-enhanced Raman Scattering (SERS) substrate should possess (i) a compatibility with high volume manufacturing process flows (ii) high and reproducible enhancement factors (EF), i.e., enhancement uniformity, over large surface areas and (iii) a tunable localized surface plasmon resonance (LSPR) wavelength over a broad spectral region. Using a novel lithography free reactive ion etch process, we fabricate wafer-scale silicon nanopillars with a high aspect ratio and subsequently coat them with silver by electron beam evaporation [1] to form plasmon supporting structures. The fabricated pillars (Fig. 1(a)) are flexible and will lean towards their nearest neighbors as the deposited analyte solution evaporates, creating self-assembled SERS hot spots at which the analyte molecules are exactly located. The fabrication method has been optimized with an emphasis on improving the SERS signal-to-noise ratio, to realize molecular detection at ultra-low concentrations [2]. The employed etching process is wafer-scale, and since it does not require any lithographic step, is fast and repeatable, thus allowing the produced substrates to be used as cheap and expendable consumables. Additionally, the produced substrate exhibits a highly uniform EF across a large area (Fig. 1(b)). It also displays a broad LSPR band (Fig. 1(c)), enabling SERS sensing at various excitation wavelengths. In the hot-spots in-between the pillars, strong localized fields are generated by the hybridized LSPR modes and the cavity LSPR mode (Fig. 1(d)). This presentation will highlight the key features of this SERS substrate and give examples of sensing applications.

Abstract— Metamaterials, artificially structured nanomaterials, have enabled unprecedented phenomena such as negative refraction. In this abstract, I will discuss recent development of hierarchical fabrication techniques for three-dimensional metamaterial and plasmonic structures based on ultra-accurate and precise electron-beam lithography overlay. The examples include 3D bulk negative index metamaterials, chiral metamaterials in optical frequencies and so on. Also, quick discussion about plasmonic sensing in complex nanostructures will be followed. This unique technique will provide the opportunity to achieve true isotropic metamaterials and the bulk properties induced from the metamaterials.

Source Reconstruction from Near- and Far-field Data with Antenna and Radome Applications

Mats Gustafsson
Department of Electrical and Information Technology
Lund University, Box 118, Lund SE-221 00, Sweden

Abstract— Electromagnetic problems are often analyzed using numerical solutions of the Maxwell's equations. In addition to being fast and cost effective, these solutions are useful for our understanding of the interaction between electromagnetic fields and devices through visualization of currents and fields. Although the numerical solutions are indispensable, they must be supplemented by measurements, where the radiated field is measured in the far-field or in the non-reactive near field. This provides valuable information but does not visualize the interaction between the device and the electromagnetic fields in the same way as a numerical simulation.

Visualization is much harder in measurement situations where we are restricted to far-field data or near-fields on a circumscribing structure. The near fields and sources are reconstructed from the measurements of the fields outside the object or volume of interest. This reconstruction is performed as the solution of an inverse source problem. This inverse problem is ill-posed and the solution requires regularization. Here, we review the theory of inverse source problems, non-uniqueness, and regularization. We present formulations based on equivalent currents using integral equations and integral representations for planar, spherical, body of revolution, and general geometries. The results are compared with analytic results for spherical and cylindrical structures. Source reconstruction is useful in applications such as non-destructive testing of antennas and radomes [1–7]. We illustrate how they can be used in antenna and radome diagnostics to, for example, image the radome thickness.

Reconstruction of 3D Anisotropic Magnetodielectric Objects with the Mixed Order BCGS-FFT and DBIM

Zhiru Yu and Qing Huo Liu
Duke University, Durham, NC, USA

Abstract— Although inverse scattering problems for isotropic materials have seen widespread applications in recent year, little has been done so far for objects that are anisotropic and magnetic. The inverse scattering problem for reconstructing anisotropic magnetodielectric material distributions is investigated in this work. Similar to isotropic media, this inverse scattering problem formulated by the integral equations is generally nonlinear. To solve the nonlinear problem efficiently, Chew et al. proposes the born iterative method (BIM) and distorted born iterative method (DBIM), where the true total fields inside objects are approximated by the total fields calculated from estimated material properties in the previous step. Therefore, material properties are updated by solving a linear problem in each iteration. However, the forward scattering problem has to be solved in each iteration, which can be time consuming and requires a lot of computational resources. Several fast methods for solving integral equations are available; nevertheless most of them are not appropriately formulated for anisotropic magnetodielectric objects.

This work proposes a mixed order BCGS-FFT method based DBIM to solve the inverse scattering problems for anisotropic magnetodielectric objects. The forward scattering problem is formulated by the combined field volume integral equations (CFVIE). Volume equivalent theorem is chosen because it is flexible in handling inhomogeneous anisotropic objects. The CFVIE is solved by a fast frequency domain solver called the mixed order BCGS-FFT method. The mixed order BCGS-FFT method expands the electric and magnetic ux densities ($\mathbf{D}$ and $\mathbf{B}$) with first order divergence conforming basis functions and expands the magnetic and electric vector potentials ($\mathbf{A}$ and $\mathbf{F}$) with second order curl conforming basis functions. The benefits of the mixed type and mixed order basis functions are two folded: 1. It can account for correct boundary conditions for both the ux densities and the vector potentials so that the calculated results are more accurate. Thus, objects with higher contrasts can be handled. 2. The mixed order basis functions formulation avoids zero terms caused by the divergence or curl operations on the vector potentials in the weak form integral equations. Therefore both dielectric and magnetic contrasts can be taken into account with higher order basis functions. This means magnetodielectric objects can be handled. The inverse problem is solved by the DBIM method. Reformulation of the DBIM to incorporate inhomogeneous anisotropic objects is shown in this work. Examples are given to demonstrate the performance of the mixed order BCGS-FFT based DBIM on anisotropic magnetodielectric objects. Discussions are also given on the key factors that might affect the performance of this method.

Efficient Imaging of Dielectric Targets Based on Contrast Source Inversion Method

S. C. Yan, C. X. Yang, J. Zhang, and M. S. Tong
Department of Electronic Science and Technology
Tongji University, 4800 Cao'an Road, Shanghai 201804, China

Abstract— Solving inverse scattering problems is challenging because the involved governing equations are nonlinear and the solutions are inherently nonunique. This is particularly true when measuring conditions are unfavorable and diverse scattering data are not available. Usually, the inverse problems are solved by linearizing governing equations and gradually minimizing the mismatch between calculated data and measured data in an iterative scheme. In the integral equation approach (IEA) for reconstructing dielectric objects, there are forward scattering integral equation (FSIE) and inverse scattering integral equation (ISIE) and traditionally we need to alternatively solve them in the context of Born iterative method (BIM) or its variations. The solution of permittivity from the ISIE can reveal the profile of unknown object in the imaging domain.

In this work, we use the contrast source inversion method (CSIM) to reconstruct the dielectric objects for the application in target recognition and atmosphere or space sensing. In such an application, the details of object are not important but obtaining a sufficient observation or measurement to the object may be difficult. The CSIM is motivated by and similar to the modified gradient method (MGM), but it updates the contrast source and contrast simultaneously instead of the field and contrast. The CSIM can avoid the direct solution of FSIE because it defines a cost functional including mismatches or errors from both the FSIE and ISIE and update them together. Compared with the MGM, the CSIM is more computationally efficient and also requires less measurement data. This is particularly desirable when we consider the reconstruction with a poor measurement condition which may be encountered in many applications. Numerical examples for reconstructing typical dielectric objects under a limited view are presented and good images can be observed.

Inverse Scattering Approach without Information on Incident Field Using Gradient-based Optimization Method

Takashi Takenaka[1], **Toshifumi Moriyama**[1], **Toshiyuki Tanaka**[1], **and Zhi Qi Meng**[2]

[1]Graduate School of Engineering, Nagasaki University, Nagasaki 852-8521, Japan
[2]Faculty of Engineering, Fukuoka University, Fukuoka 814-0180, Japan

Abstract— Inverse scattering analysis generally assumes the knowledge of the incident field in a region of interest (ROI) as well as on a measurement surface. In some measurement situations, the transmitting antenna producing an incident field is placed close to the ROI. This causes antenna characteristics to change due to the coupling with the ROI. This characteristics change makes it difficult to know the incident field generated by the antenna accurately. In our previous work [1], we have proposed an inverse scattering approach based on the field equivalence principle which does not require the knowledge of the incident field and applied it to a nondestructive testing problem to detect homogeneous defects by a genetic algorithm (GA). GAs are not appropriate optimization techniques for estimating a large number of unknowns such as electrical parameter distributions of an inhomogeneous object.

In this paper, we apply a gradient-based optimization method to our inverse scattering approach for imaging an inhomogeneous object. In [1], we have shown that the inverse scattering problem can be reduced to an optimization problem where the following functional of the parameters $\mathbf{p} = [\varepsilon_r(\mathbf{r}),\ \mu_r(\mathbf{r}),\ \eta\sigma(\mathbf{r})]$ is to be minimized:

$$Q(\mathbf{p}) = \sum_{m=1}^{M} \int_0^{cT} \int_{\Omega_e} \left|\mathbf{v}_m^{eq}(\mathbf{p};\mathbf{r},t)\right|^2 d\mathbf{r}d(ct) \tag{1}$$

where Ω_e is the region exterior to the measurement surface S and T is the measurement time. The total field $\mathbf{v}_m^{eq}(\mathbf{p};\ \mathbf{r},t)$ is the solution of the equivalent problem for the object with estimated parameters $\mathbf{p}$ under the mth illumination. The quantities c and η are the light speed and the intrinsic impedance of the background, respectively. We minimize the functional (1) by a gradient method. The Fréchet differential of (1) is represented as an inner product of a parameter variation $\delta\mathbf{p}$ and the gradient $\mathbf{g}(\mathbf{r}) = [g_\varepsilon(\mathbf{r}),\ g_\mu(\mathbf{r}),\ g_\sigma(\mathbf{r})]$. Due to space limitations, only the expression of g_ε is shown:

$$g_\varepsilon(\mathbf{p};\mathbf{r}) = \sum_{m=1}^{M} \int_0^{cT} \mathbf{u}_m^e(\mathbf{p};\mathbf{r},t) \cdot \frac{\partial \mathbf{E}_m^{eq}(\mathbf{p};\mathbf{r},t)}{\partial(ct)} d(ct) \tag{2}$$

where $\mathbf{E}_m^{eq}(\mathbf{p};\ \mathbf{r},\ t)$ and $\mathbf{u}_m^e(\mathbf{p};\ \mathbf{r},\ t)$ are, respectively the electric components of the total field and the adjoint field under the mth illumination for the object with an estimated parameter $\mathbf{p}$. Numerical simulations were carried out using the conjugate gradient algorithm for minimizing the cost functional and the results indicate the effectiveness of the method.

Application of Domain Decomposition Techniques to Quantitative Inverse Scattering Problems

I. Voznyuk, **A. Litman**, **and H. Tortel**
CNRS, Centrale Marseille, Institut Fresnel UMR 7249, Aix-Marseille Université, 13013 Marseille, France

Abstract— Often, inverse scattering schemes are based on iterative techniques which require to call a forward solver at each iteration. This forward solver must simulate in an efficient way the scattered field associated to the predicted permittivity map provided at that specific iteration. It must also take into account the environment in the vicinity of the object (rough surface, medias with complex shapes) .... Moreover, this forward solver is also exploited to estimate efficiently the various gradients which are necessary to compute the descent direction updates. Indeed, due to the reciprocity properties of the wave equations, it is possible to directly provide close-form expressions of these gradients by means of a point-by-point complex multiplication of the electromagnetic field and of a so-called ajoint field.

Various works take profit of the finite element method in order to solve inverse problems in different scientific domains, such as in optical imaging, electroencephalography imaging, electro-cardiographic imaging, and, of coarse, in microwave imaging. Thanks to its flexibility and its capabilities of managing complex geometrical configurations, this type of modelling scheme is more than appropriate to tackle biomedical and non-destructive testing applications.

Nevertheless, the numerical resolution of the Helmholtz equation in heterogeneous media at high wave number is a challenging problem for the classical finite element method. A way to overcome these difficulties is to apply a domain decomposition (DDM) technique. The principal idea of DDM is to split the entire computational domain into smaller non-overlapping sub-domains and to solve a sequence of similar sub-problems on these sub-domains. Among a variety of DDMS, the Finite-Element Tearing and Interconnecting (FETI) method and its electromagnetic counter part, the Finite-Element Tearing and Interconnecting-Dual Primal Electromagnetic methods (FETI-DPEM) are shown to be powerful techniques with an excellent scalability. In this method the computationnal problem is divided into non overlapping subdomains in order to construct and solve an equivalent reduced-order interface problem. The solution inside each subdomain can then be evaluated independently by imposing knwon mixed boundary conditions at the internal interfaces between subdomains. We will present in this talk the combination and the optimization of this direct solver in a Newton-type minimization scheme and inversion results obtained from 3D experimental datas will be displayed.

Virtual Experiments for the Solution of Inverse Scattering Problems

M. Bevacqua[1], **L. Crocco**[2], **L. Di Donato**[3], **and T. Isernia**[1]

[1]DIIES, University 'Mediterranea' of Reggio Calabria, Italy
[2]IREA, CNR, Naples, Italy
[3]DIEEI, University of Catania, Catania, Italy

Abstract— Inverse scattering is an active area of research in applied electromagnetics, due to its relevance to many applications ranging from sub-surface prospections to biomedical diagnostics or safety and security surveying operations. Unfortunately, the non-linearity and ill-posedness of the inverse scattering problem [1] make the development of effective and reliable solution methods a still open and challenging task.

The *virtual* experiments framework [2–6], is an emerging paradigm that has been conceived to smartly cope with these fundamental difficulties. The basic idea is to exploit the linearity of the scattering phenomena to recombine the available scattering experiments into new, "virtual" ones, without performing additional measurements. The main advantage is that properly designed virtual experiments allow to enforce some properties of the field or, equivalently, of the contrast source, which in turn can be helpful to reduce the difficulty of the problem. For example, by enforcing focused fields or contrast sources, it is possible to estimate the contrast of non-weak targets within a linear inversion framework or even to retrieve the unknown contrast solving a set of algebraic equations (see [2–6]).

The contribution will review the basics of the virtual experiments concept, describe the simple but powerful inversion techniques that can be derived from it and address the many future methodological developments that can steam from this emerging paradigm.

On Constructing Globally Convergent Algorithms: Applications to GPR and Marine CSEM Sounding

A. Timonov
University of South Carolina Upstate, USA

Abstract— The challenging problem of constructing the globally convergent algorithms for electromagnetic sounding is addressed. The traditional numerical techniques, such as the gradient or Newton like methods, require an initial approximation in a sufficiently small neighborhood of the true solution. On the other hand, the global optimization algorithms are extremely time-consuming and heuristic. In the last decade the so-called convexification method was proposed by Klibanov and Timonov. Later, some modifications of this method were developed by Klibanov and Beilina. Being a special form of the Carleman-weighted nonlinear least squares, the method allows for constructing some iterative algorithms that do not require the proximity of an initial approximation to the true solution. However, being approximate by its nature, the method provides convergence to an approximation of the true solution. The main challenge is constructing algorithms that guarantee the maximum closeness of the approximate solutions to the true one. In this talk we present two such algorithms. The main distinctive feature of the first algorithm is the refinement procedure, in which we search for a better approximation performing matching the interior field generated by the iterative solution by the solutions of the forward problem in the region of interest. In the second algorithm the Tikhonov's regularizing functional is used in combination with the alternating split Bregman algorithm. The computational effectiveness of the proposed algorithms is demonstrated in some numerical experiments with the inverse models of GPR and marine CSEM sounding of layered media. The latter has become significant only in the last decade due to the growing interest to hydrocarbon deposits on a shelf, as well as to the rapid development of technologies used in marine geophysics.

Modeling of Random Media for Controlled Light Scattering

Olga Korotkova
Department of Physics, University of Miami, USA

Abstract— We propose a new method for modeling of scattering from weakly random, statistically stationary media based on manipulation of the two-point correlation function of its scattering potential (CFSP) for generating of the scattered far-fields with prescribed intensity distributions. This method is based on the fact that the far-field intensity distribution is the 3D Fourier transform of the CFSP calculated at the momentum transfer vectors. We illustrate that regardless of the size, the geometrical shape and the boundary profile of the scatterer, the scattered average intensity distribution can be tuned solely by prescribing the CFSP.

In particular we introduce mathematical models for the CFSP that lead to scattered fields with flat circular, ring-like and flat rectangular-like average intensity distribution. Without loss of generality we always assume a spherically symmetric particle, employing either solid-sphere or soft-sphere (Gaussian) functions for the average refractive index distribution. Our mathematical modeling of the CFSP involves 3D multi-Gaussian families of functions that may have circular, cylindrical and Cartesian symmetry. Such families are the sums of Gaussian functions with different heights and widths with alternating signs. The 1D, 2D and 3D multi-Gaussian functions have been previously employed in optics for different purposes, such as the control of the aperture functions, the modeling of the radiation field correlation function, the intensity shaping, etc.. They allow designing of the distributions (of scattered intensity in our case) ranging from soft (Gaussian) for the single term in summation to square-pulse like for the number of terms approaching infinity. We also investigate under which conditions the component of the CFSP along the axis of scattering does not influence the scattered distribution.

After outlining the scalar treatment valid for a single scatterer and the incident plane wave, we also discuss the extension of the theory to particulate collections, other incident waveforms and electromagnetic treatment. In the latter case the polarization properties of the far field, such as degree of polarization and the parameters of the polarization ellipse can be adjusted at will.

Demonstration of Radiative and Inductive Couplings of Traveling Wave to a Phantom in a Small-bore 16.4 T MRI

University of Minnesota Medical School, MN, United States

Abstract—

Introduction: At ultra high field strength propagating RF field effects emerge [1] making traditional MRI less effective for achieving ultimate SNR [2]. To date few systems have been adopted to demonstrate traveling wave MRI (TW-MRI), among these preclinical human scanners (7 T, 9.4 T) [3, 4] and research small bore systems (16 T, 21.1 T) [5, 6]. Whole body scanners correspond to above cut-off cylindrical waveguides with one or two TW modes propagating in the unloaded bore. On the contrary, most of the small-bore research as well as clinical (< 4 T) systems correspond to below cut-off undermoded waveguides that require special high dielectric inserts [7] or coaxial transmission lines [8] for mode propagation. Hence, the TW excitation methods vary in such systems; for example, the typical RF probes for preclinical TW-MRI are patch antennas or other electric dipole probes in a radiative wave regime [9]. In undermoded waveguides it is much more difficult to excite TW due to relatively large free-space wavelength that makes regular patch antennas impractical. Therefore, previous demonstrations of TW-MRI at below cut-off were limited to loop-coils that inductively couple to long (few wavelengths) dielectric inserts that limits SNR. Here, we demonstrate a new TW coupling mechanism that involves a specially designed patch antenna and a metal waveguide and compare its performance to that with an inductive TW coupling using loop-coil.

Methods: The system of interest is 16.4 T (Varian) horizontal bore small animal NMR imaging system with a bore diameter of 26 cm (~ 12 cm with gradient insert) and the resonance frequency of 698 MHz ($\lambda = 43$ cm). The typical setup with inductive coil coupling consists of a dielectric waveguide made of an acrylic tube ($L = 34$ cm, $D = 9$ cm) and filled with deionized water or saline ($\varepsilon_r = 80$) and a simple transmit-receive loop-coil ($D = 8$ cm) placed at the edge of the tube. The orientation of the loop with respect to the edge of the tube (vertical or horizontal planes) defines the specific single or multiple modes excitation in the dielectric tube. A second setup uses a circular patch probe antenna (ground plane diameter 20 cm, patch diameter 7 cm, Fig. 1(c)) that provides circular polarization with a single coaxial feed and a crossed-slot polarizer in the patch ground plane [10]. The measured match to the 50-Ω feed of the patch inside the bore is $|S_{11}| = -20$ dB. A cylindrical array of 3-cm wide longitudinal strips 2-m long and 12 cm in diameter is inserted in the bore with a goal of modifying the travelling-wave mode content in the gradient coil region. The patch probe is placed 5 cm from the edge of the bore at the start of the strip cylinder. The MR images were obtained with a GRE sequence: FOV = 20×20 cm, TR/TE = 275 ms/2.1 ms, slice thickness of 1 mm for both axial and coronal slices. In addition to GRE we used SE imaging with: TR/TE = 1 s/20 ms, FOV = 20×20 cm, matrix = 256×128, slice thickness of 2 mm, 0.8 mm gap, 10 slices. We carried out simulations of the modes inside the dielectric guide using FEM E&M solver COMSOL Multiphysics (Burlington, MA).

Results and Discussions: For comparison study of the two excitation methods: by loop-coil and patch probe. We placed the loop-coil vertically (coaxially) (Fig. 2) and horizontally (Fig. 3) at the edge of the dielectric guide. These two arrangements allow excitation of a various modes, as predicted by the corresponding simulations: TE01 (Fig. 2), and mixture of TE11 and TM11 (Fig. 3(a)) that matches mode population by the patch probe (Fig. 3(b)). The patch probe excitation efficiency is maximal when it is placed close to the gradient coil section and couples TW from the air region into the dielectric phantom (Fig. 1), providing the best SNR (Fig. 3(b)). The nulls on z-axis (sagittal slices) correspond to the standing waves of various modes due to reflection from the far end of the dielectric guide. The high spatial frequency fringes and edge brightening correspond to artifacts due to unencoded volume of the dielectric guide that extends beyond the gradient insert. Apart from the artifacts the modes structure between the radiative

and inductive couplings looks similar with comparable SNR. For the next step, we used the patch probe antenna placed at the entrance of the optional 2-m long copper strip guide enclosing the dielectric guide. Although the guide diameter of a metal guide is too small implying the TW are below cut-off, we found this system to provide seven time higher SNR (Fig. 4) as compared to the patch probe without the strip cylinder (Fig. 3(b)). The axially oriented strips provide a frequency-dependent anisotropic surface impedance which modifies the modal content, and in addition to the presence of the high-permittivity dielectric cylinder, allows for travelling wave propagation. Such high SNR allowed us to utilize SE sequence (Figs. 4(d)–(f)). Another feature of the new probe system is the presence of higher order modes that could potentially be used for B_1 field shimming.

Conclusion: We have demonstrated new TW excitation schemes that involves a loop-coil or patch antenna and an optional metal guide that provides coupling to a phantom via far-field. The combined patch probe is robust and does not require extensive tuning inside the scanner. The excitation scheme provides high order modes that potentially could be used for B_1 field shaping for homogeneity improvement. The experimental method is scalable to the other MRI systems with below cut-off conditions such as clinical scanners.

Raw Data Generation of Maritime Scenes Using MOCEM V4 and PHYS-IQ V1

Christian Cochin[1], **Jean-Christophe Louvigne**[1], **and Julien Houssay**[2]

[1]DGA MI, French MoD, Bruz, France
[2]Corentin LE BARBU, Nicolas Pinel, Goulven Monnier Alyotech, Rennes, France

Abstract— Since years, DGA MI — expertise center of French MoD develops simulation tools for SAR surveillance applications. These tools have now capabilities of raw data generation and therefore can be used for many other applications that their first purpose of simulation. The GPU computing has recently opens news efficient ways for raw data simulation. For advanced processing and new imagery modes (SAR/ISAR with or without use of CS technics), the simulation of realistic raw data is crucial. In this paper we'll illustrate the possible use of the tools in the context of maritime applications.

We'd like to focus on opportunities offered by this set of tools, part of the French DGA simulator SIROS — **S**imulation toolset for **I**magery **R**adar and **O**cean **S**urveillance —, for studies and for tuning processing.

For maritime scenes, we have to take into account:

- For the target, realistic 3D ship models with Electromagnetic (EM) materials, inertial ship motions.
- For the sea clutter, it is essential to deal with the grazing angle challenge or effects associated to High sea states (shadows, sea spikes, heavy tail distributions).
- We have also to consider interactions that include coupling effects, wakes ...

MOCEM V4 has been shown in conferences and detailed in several publications. But MOCVIEW has been newly developed in order to generate raw data. PHYS_IQ is also a new tool dedicated tool to create raw data of a dynamic sea. We will illustrate possible combinations and configurations of the tools to several needs and uses. We'd like also to focus how methods and time computation can be adjusted to the user's needs, including precision and phenomena taken into account to limit computation time. We will illustrate the tools capabilities in the field of polarimetry, interferometry, multi-channel, in addition to high resolution in range and all the dynamic aspects, associated to a radar acquisition of a complex and dynamic maritime scene.

The problem of the maritime scenes is the variety of parameters concerning the target, the environment, the radar mode. To deal this that, it is essential to create number of cases to test and tune a new processing or radar mode. The availability of efficient and realistic tools is a real opportunity to prepare experimental modes and develop new detection technics and imagery products.

Institute of Solar-Terrestrial Physics SB RAS
Lermontov st. 126a, P/O Box 291, Irkutsk 664033, Russia

Abstract— This paper presents results of active space experiment "Radar-Progress" conducted by FSUE Central Research Institute of Machine Building (TsNIIMash), Rocket and Space Corporation Energia, and Institute of Solar-Terrestrial Physics of Siberian Branch of Russian Academy of Sciences (ISTP SB RAS). More than 80 sessions were conducted in 2007–2014. The experiment is aimed at studying parameters of ionospheric disturbances generated by exhaust jets of propulsion devices of the Progress cargo spacecraft. The following ISTP SB RAS ground-based facilities for remote sensing of the ionosphere are used: Irkutsk Incoherent Scatter Radar. The experiment sessions were carried out under different helio- and geophysical conditions, given various directions of the jet efflux and duration of operation of different propulsion devices. Space-time characteristics of ionospheric irregularities were assessed. The dependence of observability of irregularities on height, direction of jet efflux and exhaust amounts was examined too.

Two Dimensional Inverse Scattering Problems with Four Different Boundary Conditions

Xudong Chen[1], **Rencheng Song**[2], **and Xiuzhu Ye**[3]

[1]Department of Electrical and Computer Engineering, National University of Singapore, Singapore
[2]Halliburton, Singapore
[3]Department of Electrical and Computer Engineering, Beihang University, Beijing, China

Abstract— This paper deals with a special inverse scattering problem, where four different boundary conditions, i.e., Dirichlet, Neumann, impedance, and transmission boundary, simultaneously exist. We present a general inversion method to simultaneously reconstruct scatterers with four different boundary conditions without prior information on their locations, shapes, or types of boundary condition. In the forward problem, the scattering of mixed scatterers is modeled by the T-matrix method, where the scattered field is expanded in multipole radiation series. Regardless of the type of boundary condition, the multipole expansion of scattered field is always applicable, and thus it provides a unified framework for representing the four different boundary conditions. The unknowns in the inverse problem are T-matrix coefficients, and the first step of the inversion solver is to reconstruct the T-matrix coefficients. The objective function considered in the inverse problem is solved by a subspace-based optimization method. In the second step of inversion, the types of boundary conditions of scatterers are inferred from the T-matrix coefficients.

Numerical Simulation of Aquifer Detection Using Low Frequency Pulsed Radar

K. van den Doel[1] and M. Robinson[2]

[1]University of British Columbia, Vancouver, Canada
[2]Adrok Ltd., Edinburgh, United Kingdom

Abstract— We describe two numerical models of the detection of aquifers under limestone using low frequency pulsed radar which we use for experimental design, depth range estimations, and testing data analysis methods. The first model implements a 1D FDTD scheme for Maxwell's equations coupled to a ground model incorporating dielectric permittivity, conductivity, and a Debye polarization model. The material parameters of the model were obtained from in situ measurements through limestone pillars performed underground in a mine [2]. The input to the simulation is the measured output of a low frequency pulsed radar system manufactured by Adrok Ltd. The complicated radar pulse produced by the transmitter contains frequencies from 3 to 65 MHz and the low frequency component allows for deep penetration in suitable materials, see for example [1], where a similar simulation for deep surface probing on Mars is described.

The simulated pulse propagates through the limestone with a relative permittivity avaraging $\epsilon_r = 6$ and is re ected by an aquifer which we model as a layer with $\epsilon_r = 40$. After reflecting off the wet layer the pulse travels back up and is measured on the surface as a time domain trace. Synthetic noise calibrated to match measurements from the actual equipment is added to the computed result. In normal operation mode (STARE), 8000 traces are stacked, and the reflection is detected from the data using either visual identification of the return or, when the return signal is very weak, by analysing the correlations between stacked traces. Results indicate the aquifer is detectable up to about 350 m depth and that extending the range to 500 m depth is achievable by increasing the stacking by a factor 25. Detecting a reflection from 650 m would require stacking 2000×8000 traces, and down to 800 m would require 100000×8000 traces. Assuming a trace length of 20 µs, suitable for detecting reflections up to 1km for $\epsilon_r \leq 9$, the latter would require a theoretical minimum acquisition time of about 5 hours, which is probably close to what is practical.

In order to convert the reflection time of the pulse to depth we need to know the velocity which is governed by the relative permittivity ϵ. In some practical applications this may be known from geology, but if it is not it can be obtained from a WARR scan, where measurements are taken with transmitter and receiver at increasing separations and using a normal moveout method or a velocity spectrum (as used in seismic) to estimate velocity and ϵ_r. Because of the high frequency components in the pulse and the high accuracy required of the FDTD simulator (due to the large dynamic range that needs to be simulated) the required grid spacing is about 5 cm and large computational resources would be required for a full 2D FDTD simulation which is why we model the WARR scan with a raytracing method. Simulated data is rendered by propagating the measured input pulse through all rays that reach the surface using computed re ection/transmission coefficients and an attenuation filter derived from the FDFT model. The ground is modeled as a layer with mean $\epsilon_r = 6$ with random fluctuations with standard deviation 0.5 at intervals which are distributed exponentially with a mean of 5 m. This models irregularities and causes complicated backscatter similar to what is observed in practice. From a velocity spectrum analysis (suitably modified to incorporate radar specific losses) it appears that the velocity can be estimated from the backscatter up to about 150 m down and from the stronger aquifer re ection at 350 m with about 5% accuracy leading to a similar accuracy in depth estimation.

Session 1P4a
SC3: Laser Writing of Optical Waveguides and Optical Components in Novel Materials

Expanding the Parameter Space in Optimizing Ultrafast Laser Written Structures for Photonics Device Applications

T. Toney Fernandez, J Siegel, and J Solis
Grupo de Procesado por Láser, Instituto de Optica
Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain

Abstract— An ultrafast laser irradiation based optical micropipette is proposed, able to manipulateand control the laserinduced plasma distributions and — as a consequence — ionmigration, net refractive index change and aspect ratio of the induced structures.

Production of micrometer to nanometer scale structures isone of the major strengths of ultrafast laser-based micromachining. Short pulse duration leading to heat accumulation rather than heat diffusion help induce much smaller structures. When combined with complementary strategies, such as slit shaping of the laser beam and the use of high repetition rates, extraordinary results can be obtained. Applied to direct writing of optical waveguides, we have recently found a counterintuitive result in a study operating at 500 kHz repetition rate, leading to a reduction of the aspect ratio of the waveguide cross section to almost 4 times that of a structure written at low repetition rate (1 kHz). Adjoining this approach with the control of ion migration in the laser excited volume, we propose a novel light based tool — an optical micropipette. By means of simple shaping techniques of the focal volume a strong control can be exerted on the shape of the laser-induced plasma distribution, directly controlling ion migrating mechanisms, achievable refractive index change and the area/aspect ratio of the written structure. It appears that multivalent ions migrate towards regions which feature a higher density in the final structure, whereas monovalent ions migrate towards the rarefied zones. The behavior of multivalent ions could be classified in two regimes, where light elements (atomic weight $< 31u$, observed in a lanthanum aluminium phosphate glass doped with Erbium and Ytterbium, Figure (a1) and heavy elements (Figure (a2)) play the role of densification. The migration directions of such group of ions with respect to the laser propagation direction can be inverted (Figures (b1) and (b2)) by inducing strong positive or negative spherical aberration in the beam, effectively inverting the laser-induced plasma distribution. Figures (c) and (d) show the effect of slit shaping in two different glasses with two different laser writing parameters. (c1) (no slit) and (c2) (1.4 mm slit) are single scan waveguides produced inside a phosphate glass. (d1) and (d2) are multiscan waveguides produced inside a Borosilicate glass.

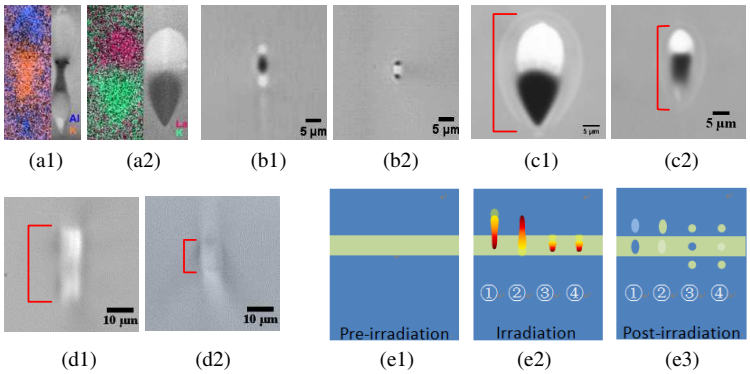

Figure 1: (a1) demonstrate the cross migration between (a1) and K, where as (a2) shows cross migration of La and K. Figures (a), (b) and (c) are structures produced inside a phosphate glass using 500 kHz, (b1) written with 0.68 NA objective, 260 mW, 80 µm/s at a depth of 100 µm. (b2) 0.85 NA aberration-corrected objective, 100 mW, 100 µm/s at a depth of 100 µm. (c1) and (c2) written with 500 kHz, 0.68 NA without (395 mW) and with slit (365 mW, 1.4 mm), respectively. (d1) and (d2) are structures written with and without slit (2 mm), respectively using the following parameters: 500 kHz, 0.4 NA objective, 140 mW, 1 mm/s and at a depth of 100 µm. In all cases the laser is incident from the top. (e1) Sample before irradiation, Green layer could be an implanted region or a sandwich region, (e2) four possible laser induced plasma scenarios and (e3) their possible finalresult.

Combining these effects, we propose that an optical micropipette could be designed to relocate/remap/transfer ions from an area of interest to another. A proper tuning of laser fluence, spherical aberration and slit shaping offers a good control of the type and direction of migrating ions. Four possible potential application scenarios are sketched in Figure (e).

Corning, New York 14831, USA

Abstract— Flexible glass is a brand new class of glass materials that is attracting widespread interest from industry and research groups. Designed as substrates for flexible electronics and display applications, this new type of glass substrate exhibits remarkable mechanic flexibility. Compared with flexible polymer substrates, flexible glass materials show superior thermal capability, dimensional stability, surface quality, barrier properties, hermiticity, and durability beyond the fundamental limitations of polymeric substrates.

From an optical perspective, propagation loss in the flexible glass substrates could also be substantially lower than the polymer materials currently used to build flexible photonic circuits. In this paper, we present three-dimensional photonic devices and sensors written in flexible Corning® Willow® Glass and other glass substrates. Using the ultrafast laser direct writing technique, low-cost and highly symmetrical optical waveguides were fabricated in flexible glass with thicknesses between 25 µm and 100 µm. The waveguide propagation loss at 1550-nm is between 0.11 dB/cm and 0.25 dB/cm, and birefringence of waveguides is less than 0.5×10^{-6}. The flexible waveguide devices exhibit excellent thermal stability when heated above 450°C. Using laser assisted etching, we discuss possibility of flexible lab-on-chip opto-fluidic devices and their applications for bio- and –chemical sensing. By laser inscribing waveguide Bragg grating at different depths of glass substrates on and off neutral planes inside the flexible glass substrates, we demonstrate smart optical sensors that can perform simultaneous measurements of temperature, axial strain, and magnitude and directions of bending. This paper presents new possibilities to develop smart flexible sensors that are environmentally robust using glass substrates.

Realization of Birefringent Nanogratings in Various Glasses

S. Richter[1], **F. Zimmermann**[1], **A. Tünnermann**[1, 2], **and S. Nolte**[1, 2]

[1]Institute of Applied Physics, Abbe Center of Photonics, Friedrich-Schiller-Universität Jena, Germany
[2]Fraunhofer Institute of Applied Optics and Precision Engineering, Jena, Germany

Abstract— One of the most fascinating effects of the irradiation of glasses with ultrashort laser pulses is the formation of birefringent domains [1]. This birefringence is due to periodic nanostructures, so-called nanogratings, whose orientation is perpendicular to the laser polarization [1, 2]. Nanogratings in fused silica consist of small anisotropic cavities with a size of several tens of nm [2]. The arrangement of these cavities forms a grating structure with a period smaller than the wavelength of the incident laser pulses. The anisotropic structure of the modified material results in form birefringence which can be used to realize polarization sensitive optical devices such as waveplates, zone plates or polarization converters [2].

So far, it was assumed that nanogratings can be induced only in pure fused silica or slightly doped silica glasses. We report on the ultrashort pulse laser induced formation of birefringent structures in the volume of different glasses: Borofloat 33, BK7 and ULE [3]. We conducted an intensive study to analyze the formation process and structure of these birefringent structures using polarization contrast microscopy, Focussed Ion Beam milling, Small Angle X-Ray Scattering and Raman spectroscopy. Thus, we could prove that the birefringence is induced by nanopores in these glasses, too. In addition, the retardance achieved in ULE is even slightly higher than in fused silica facilitating the realization of photonic devices with tailored birefringent domains in isotropic host materials.

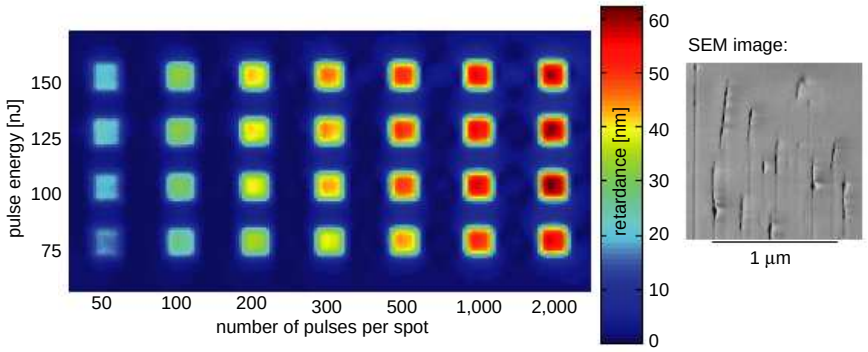

Figure 1: Retardance of laser induced nanogratings in ULE for different irradiation parameters. On the right, an SEM image of the induced modification is shown. Here, a Focussed Ion Beam was used to dissect the sample and expose the nanopores.

3D Laser Sub-μm Structuring for Novel Near- and Mid-IR Photonics: Recent Advances in SiO_2, $LiNbO_3$ and YAG Processing

A. Ródenas, **J. Martínez**, **H. D. Nguyen**, **and F. Díaz**
Departamento de Química Física e Inorgánica, Universitat Rovira i Virgili, Tarragona 43007, Spain

Abstract— Mid-infrared photonics are rapidly emerging as a powerful technology platform for the biomedical and chemical fields. Mid-infrared spectroscopy takes advantage of the unique fingerprints of inorganic/organic molecular bonds for identifying chemical compounds, biological tissues, cells or biofluids. From the device engineering point of view, having an optically resonant medium close to the anomalous dispersion regime also allows for designing novel robust sensing schemes where different photonic building blocks such as optical waveguides, photonic crystals or fluidic pores, can be interconnected to monolithically operate across infrared resonant ranges to perform fast sensing functions. In this talk I will present recent efforts on 3D micro- and nano-structuring techniques focused on achieving these infrared photonic elements embedded in industrially relevant optical materials like electro-optic lithium niobate, yttrium aluminum garnet (YAG) laser crystals, or the ubiquitous fused silica glass. I will present results on: (i) a laser micro-manufactured glass fibre-interconnected infrared sensor tuned to monitor water-ice transitions with fast response, which has applications in the aircraft industry (for monitoring ice formation on the wings or inside kerosene tanks), or in the pharmaceutical and food industries for freeze-drying (lyophilization) control processes; (ii) on micro-stress engineering and analysis of mid-infrared waveguide structures in lithium niobate circuits for propagation and bend loss minimization; and (iii) on the sub-micron resolution 3D structuring of YAG crystals towards interconnected waveguides and photonic crystals, as well as for enabling novel sensing schemes on sub-wavelength structures for light guiding and optofluidic device engineering.

Femtosecond Laser Micro Fabricated Structures for Lab on Chip Applications

Surya S. K. Guduru[1, 2], **Francesco Scotognella**[2], **Luigino Criante**[1], **Rebeca Martinez Vazquez**[3], **Roberta Ramponi**[3], **and Krishna Vishnubhatla**[1]

[1]Center for Nano Science and Technology@PoliMi
Istituto Italiano di Tecnologia, Via Giovanni Pascoli, 70/3, Milan 20133, Italy
[2]Dipartimento di Fisica, Politecnico di Milano, Piazza Leonardo da Vinci 32, Milan 20133, Italy
[3]Istituto di Fotonica e Nanotecnologie — CNR, Piazza Leonardo da Vinci 32, Milan 20133, Italy

Abstract— Femtosecond laser micromachining (FLM) is a very versatile 3D micro-fabrication techniques. Tightly focused femtosecond laser pulses can be viewed as a pen for fabricating such devices in both transparent and opaque materials [1]. This technique can be exploited for creating complex micro architectures in an integrated lab-on-chip device [2, 3].

Motivation: Here in this work we envisage the demonstration of wavelength selective light harvesting in a fully integrated opto-fluidic chip configuration. Creating such an integrated many functionalities in one device creates possibilities for high sensitivity sensing applications. The idea is to excite the analyte inside a microchannel and try to collect the fluorescence from them in a wavelength selective manner. The schematic of the idea is given in Fig. 1(a).

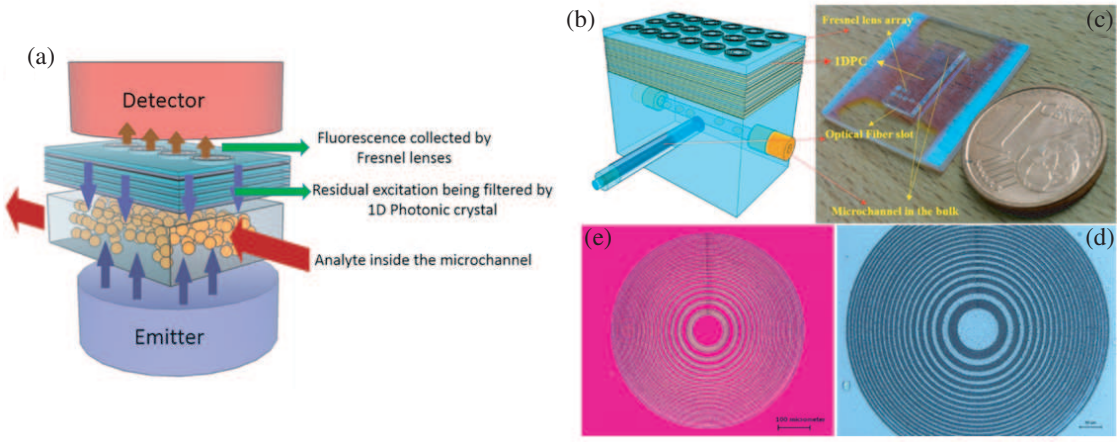

Figure 1: (a) Schematic of the motivation of the work. (b), (c) The schematic of the chip and picture of the actual chip in fused silica substrate. (d), (e) Images of the Fresnel lens in reflection and transmission respectively.

Experimental: The chip contains a 1D photonic crystal (1DPC) as one of its components. The 1DPC is customized in the fabrication stage to reflect the excitation wavelength of the dye. While we fabricate binary Fresnel lenses which are designed to focus the fluorescence of the dye. In essence the device as a whole acts a wavelength selective light harvesting device [4]. For the purpose of demonstrating the principle we conceived the fabrication of such a chip in two different configurations. One chip in PMMA substrate with microchannels on the surface while the other chip in fused silica substrate with microchannels sub-surface. In the former we have the 1DPC fabricated by spin coating alternating layers of two different polymers with a refractive index contrast, while in the latter we create the 1DPC using inorganic materials with a refractive index contrast. Fig. 1(a) is the schematic of the motivation of the work while 1(b) & 1(c) the schematic of the chip and picture of the actual chip in fused silica substrate. (d) & (e) Images of the Fresnel lens in reflection and transmission respectively. Creation of such devices is a very strong demonstration of the capability of micro-fabrication by FLM in creating prototypes in lab on chip specific applications.

University of Leeds, Leeds LS29JT, UK
[2]Institute of Microwave and Photonics, School of Electronic and Electrical Engineering
University of Leeds, Leeds LS29JT, UK

Abstract— The simultaneous implantation of multiple, atomically dissimilar ions into silica glass is achieved using ultrafast laser processing for fabricating rectangular and step index optical waveguides. The high refractive index contrast ($> 10\%$) waveguides in silica with and without rare earth co-doping allows us to engineer novel integrated optic waveguide devices with small footprints that facilitate the realisation of high density data optical interconnects Precise engineering of the waveguide parameters are obtained by tuning the process parameters like femto second laser energy and target glass compositions. Record levels of doping concentrations and fluorescent life-times without rare earth segregation can be achieved with the ultrafast laser plasma implantation (ULPI) process. The multi-ion doping adopted in this process helps to maintain the large distance between the Er^{3+}-ions, essential for lowering the concentration quenching at higher doping concentrations. For an Er^{3+}-ion doped waveguide the absorption and emission cross sections at 1534 nm are estimated as $3 \times 10^{-22}\,\mathrm{cm}^2$ with a measured fluorescence lifetime of 129 ms. The 1 mm thick substrates with the planar waveguides on it were measured to have a high optical transparency of 95% and the waveguide propagation losses are $< 0.5\,\mathrm{dB/cm}$ at 1550 nm. Selective doping and un-doped regions are achieved with masked implantation approach in the same substrate with a good control over the step index waveguide formation. The proposed approach can support the mass manufacturing of photonic integrated circuits in a CMOS foundry line. Further this method can be extended for engineering the optical devices and sensors with hybrid integration of silica, silicon, metal and polymer materials.

Laser Fabrication in Diamond for Photonic Applications

Patrick Salter, **Bangshan Sun**, **and Martin Booth**
Department of Engineering Science
University of Oxford, Parks Road, Oxford OX1 3PJ, UK

Abstract— Diamond's remarkable characteristics make it a promising medium for many optical devices, since it is ideal for structures allowing light manipulation on small scales across a broad spectrum. Other advantages include a high degree of biocompatibility, rendering it useful in biological studies. Colourcentres formed by inclusions or vacancies in diamond's crystal structure are being used as tools in quantum optics, opening up numerous possible applications of quantum-enhanced technologies. Recent breakthroughs in the manufacture of affordable high-grade synthetic diamond substrates are fuelling interest for such photonic applications in diamond.

Laser fabrication offers many potential advantages over traditional methods used for diamond processing. For the first time truly 3D structures embedded in the diamond can become a reality. However, this can only be made possible through the compensation of the optical aberrations induced when focussing inside the diamond. Diamond has a high refractive index meaning the spherical aberrations generated at high numerical aperture are particularly pronounced. To this end, adaptive optic elements are used during the machining to remove the depth-dependent aberration and create high resolution uniform features deep into the diamond.

When the laser is focused into the diamond, the electric field is sufficiently strong at the focus for non-linear absorption leading to breakdown of the diamond lattice and the formation of a graphitic phase. By tracing the diamond through the laser focus, continuous graphitic wires may be machined within the diamond bulk. The microwires, with lateral dimensions as low as 400 nm, can be fabricated to follow any three dimensional path within the diamond. Properties and applications of the embedded graphitic microwires will be discussed.

Surface laser processing of bulk single crystal diamond will also be demonstrated for the manufacture of optical elements. Diamond optics are temperature-insensitive, can withstand high power radiation and thus have wide applications. Using fine control over the incident laser fluence, it is possible to operate in the "nano-ablation" regime to give control over the surface topology whilst maintaining optical quality.

3D Printed Optical Components

M. Thiel
Nanoscribe GmbH, Eggenstein-Leopoldshafen, Germany

Abstract— We present our recent progress in fabricating high-quality optical components by additive manufacturing based on multiphoton polymerization.

Fabrication of high-quality optics: In the last decade, additive manufacturing based on multiphoton polymerization has set new standards for three-dimensional (3D) microfabrication [1–3]. Due to its sub-micrometer spatial resolution, the technique also allows for the fabrication of high-quality optical elements [4]. Here, we present our efforts to standardize 3D manufacturing based on multiphoton polymerization for optical applications.

High-speed fabrication is enabled by a set of pivoted galvomirrors insuring highest spatial resolution (printer is commercial available [3]). To enlarge the patterning volume, we employ stage stitching allowing for the fabrication of highly complex photonic structures on areas in the cm^2 range on arbitrary substrates. We follow a standardized workflow for digital production using typical CAD data of 3D printers. To demonstrate the validity of our approach, we fabricate and characterize (i) diffractive optical surfaces (DOEs), (ii) 3D photonic crystals, and (iii) microoptics. As an example for integrated optics, we finally present the concept of optical wirebonds (iv).

Additive manufacturing based on multiphoton polymerization allows for sub-100 nm feature sizes, i.e., printing of DOEs becomes possible. We show examples of photonic color materials [5] which are built up by 10s of millions of nanodots on reflective silicon substrates. We also fabricate and characterize transmissive DOEs and phasemasks. 3D photonic crystals are well-studied optical materials that, e.g., may exhibit a complete photonic band gap for sufficiently high refractive index contrast of the constituent material. To tune the Bragg reflection bands to optical frequencies, rod spacings of a few hundred nanometers are necessary, i.e., highest accuracy of the fabrication process is required. We demonstrate the fabrication of woodpile photonic crystals and of chiral photonic crystals. Next, we demonstrate 3D free-form microoptics. The geometrical parameters of the unitcells (e.g., pyramids and hemispheres) are in the 10 micrometer range. To validate the optical properties of the fabricated structures we use laser diodes at green and red wavelengths in a forward-scattering setup. Qualitative agreement between approximate calculations and experiments is good. Finally, we explain the concept of photonic wire bonds that allow on-chip optical communication due to their waveguiding properties.

Conclusion: In conclusion, we have demonstrated high-speed 3D printing of microoptics. We have fabricated and characterized a couple of examples showing the versatility of the additive manufacturing method. We argue that the technique opens new routes for free-form optics that are not accessible with other fabrication techniques.

Dielectric Platforms for Surface Enhanced Spectroscopies

Stefan A. Maier
Imperial College London, London, SW7 2AZ, UK

Abstract— Plasmonic nanostructures serve as the main backbone of surface enhanced sensing methodologies, yet the associated optical losses lead to localized heating as well as quenching of molecules, complicating their use for enhancement of fluorescent emission. Additionally, conventional plasmonic materials are limited to operation in the visible part of the spectrum. We will elucidate how nanostructures consisting of conventional and polar dielectrics can be employed as a highly promising alternative platform.

Dielectric nanostructures can sustain scattering resonances due to both electric and magnetic Mie modes. We have recently predicted high enhanced local electromagnetic field hot spots in dielectric nanoantenna dimers [1], with the hallmark of spot sizes comparable to those achievable with plasmonic antennas, but with lower optical losses. Here, we will present first experimental evidence for both fluorescence and Raman enhancement in dielectric nanoantennas, including a direct determination of localized heating, and compare to conventional Au dimer antennas. The second part of the talk will focus on the mid-infrared regime of the electromagnetic spectrum, outlining possibilities for surface enhanced infrared absorption spectroscopy based on polar [2] and hyperbolic [3] dielectrics.

Technical University of Denmark, Kongens Lyngby DK-2800, Denmark
[2]Centre for Nanostructured Graphene (CNG)
Technical University of Denmark, Kongens Lyngby DK-2800, Denmark

Abstract— Graphene opens up for novel optoelectronic applications thanks to its high carrier mobility, ultra-large absorption bandwidth, and extremely fast material response. In particular, the opportunity to control optoelectronic properties through Fermi-level tuning enables electrooptical modulation, optical-optical switching, and other optoelectronics applications. Except for the statistic gating and chemical doping, the Fermi level of graphene can also be optically tuned. With the aid of external optical pumping, electrons can be excited in the substrate, then move to the graphene layer, leading to the electrical doping in graphene. In this talk, I will firstly discuss how the graphene property changes when applying the optical pumping with different incident power. Then I will discuss graphene-silicon microring devices with having a high modulation depth and with a relatively low bias voltage. Finally, I will discuss a novel hybrid graphenemetal system for studying light-matter interactions with gold-void nanostructures exhibiting resonances in the visible range. The hybrid system is further explored for sensing of Rhodamine 6G molecules with respect to the strong surface-enhanced Raman scattering.

Electron Tunneling in Plasmonic Nanogaps Explored Using the Self-consistent Hydrodynamic Model

Abstract— The optical response of coupled metallic nanoparticles in the tunneling regime is strongly affected by non-local screening and electron spill-out effects, which originate from the quantum nature of the electron-electron interaction. Under such extreme coupling conditions, classical electrodynamics breaks down and quantum mechanical ab-initio methods must be employed to describe the electron tunneling across sub-nanometric gaps [1]. However, these methods are critically limited with respect to the number of considered atoms. Currently, such ab-initio methods cannot be applied to realistically sized nanoparticles. Orbital-Free Density Functional methods are preferred to describe such realistic systems, since they do not calculate single-particle orbitals, but employ effective energy functionals which approximate the full quantum calculations [2]. We propose here to use our recently developed Self-Consisted Hydrodynamic Model (SC-HDM) to explore the electron tunneling in tiny gaps between plasmonic nanoparticles of arbitrary shape [3]. The SC-HDM is an orbital-free method thas has proven to accurately describe the plasmonic response of isolated metallic nanoparticles. We will present selected results for a dimer of sodium spheres and benchmark them against the results obtained with more refined TD-DFT calculations. Finally, we will compare the performances of our SC-HDM with those of a quantum-corrected method (QCM) for electron tunneling proposed by Esteban et al. [4].

Quantifying the Field Enhancement Spectra of Individual Nanoantennas Using Single Quantum Dots

Jianwei Tang[1] **and Sailing He**[1, 2]

[1]Centre for Optical and Electromagnetic Research

Abstract— Nanoantennas have become an enabling technique in the field of nanophotonics, owing to their great capabilities of strongly enhancing light-matter interactions by concentrating light energy into highly condensed plasmonic hot spots, and of effectively modifying quantum emissions by providing large local densities of photon states. Theoretical and numerical tools are rich for design and analysis of nanoantennas, whereas experimental techniques are very limited for revealing comprehensive near field properties. Here we proposed an experimental method to quantify the field enhancement spectra of individual nanoantennas by quantitatively detecting the modified fluorescence of single quantum dots in the hot spots. The fluorescence modification of a single quantum dot by the nanoantenna is the combined effect of both the absorption enhancement and the emission modification. By pumping the single quantum dot towards its saturation, the absorption enhancement effect was ruled out in the detected emission modification, and the emission modification was obtained. Then by pumping the single quantum dots at different wavelengths (thanks to the broad absorption spectra of semiconductor quantum dots) in the linear pumping region, we obtained the absorption enhancement factors at different wavelength to build the absorption enhancement spectrum, which was taken as the field enhancement spectrum of the nanoantenna at the specific point defined by the single quantum dot's position coordinates. In our preliminary experiment, single quantum dots were fixed on the substrate surface while the antennas were assembled by moving chemically synthesized plasmonic nanoparticles to around the single quantum dots. Further development of this technique is to stabilize a single quantum dot at a scanning nanoscale tip so that 3D mapping of field enhancement spectra can be performed.

Revealing a Symmetry Class of Periodic Gratings Using Transformation Optics

Matthias Kraft[1], **Yu Luo**[2], **and John B. Pendry**[1]

[1]Blackett Laboratory, Imperial College London, SW7 2AZ, UK
[2]Nanyang Technological University, Singapore

Abstract— Symmetries are omnipresent in physics. However, sometimes they are hidden from plain sight. Transformation optics can help us to reveal those symmetries, which are not obvious at first sight. In a recent paper [1], we showed how a hidden spherically rotational symmetry of spheroids, can be used to classify their plasmon eigenstates and calculate their optical properties. Here, we present some new results extending this approach to treat other systems. Specifically, we study two-dimensional periodic gratings.

We present a novel transformation mapping a simple slab to a periodic grating. Since the spectrum of a nano-particle is conserved under conformal mappings in the quasi-static limit, the grating derives its spectrum from the simple slab system. An interesting result on its own, it becomes even more intriguing. Because the transformation from the slab to the grating contains two free parameters, we can modulate the grating's depth and periodicity. However, since all gratings are derived from the same slab, they all inherit the slab's spectrum. Thus a whole symmetry class is revealed through a single transformation, as all gratings within that class derive their spectral properties from the symmetry of the slab.

With the spectral properties and eigenstates of the grating known, we calculate the optical properties of the grating under plane wave illumination. Results for the reflection, transmission and absorption spectra are compared to COMSOL simulations and very good agreement is found between analytics and simulations. Finally, we model the grating as a metamaterial and discuss the limitations of our analytical approach, such as its inability to predict the bi-anisotropic coupling parameter for very strongly modulated gratings.

Defect Tolerance and the Effect of Structural Inhomogeneity in Plasmonic DNA-nanoparticle Superlattices

Michael B. Ross[1], **Jessie C. Ku**[2], **Chad A. Mirkin**[1, 2], **and George C. Schatz**[1]

[1]Department of Chemistry, Northwestern University

Abstract— Bottom up assemblies of plasmonic nanoparticles exhibit unique optical effects such as tunable reflection, optical cavity modes, and tunable photonic resonances. However, because all bottom-up assemblies use chemically synthesized nanoparticles, which are not uniform in size and shape, nanoparticle assemblies incorporate various inhomogeneities including defects, grain boundaries, and vacancies. Here, we use the comparison of detailed simulations with experiment to explore the effect of structural inhomogeneity on the optical response in DNA-nanoparticle superlattices. In particular, we explore the effect of background environment, nanoparticle polydispersities ($> 10\%$) and variation in nanoparticle placement ($\sim 5\%$). We identify that at volume fractions less than 20% Au, the optical response is robust to defects and inhomogeneity in the superlattice. However, at elevated volume fractions (20 and 25%), structures built using different sized plasmonic nanoparticles (10, 20 and 40 nm diameter) each exhibit distinct far-field extinction and near-field properties. As such, these structures are beyond that which can be described as an effective medium; that is, the properties of these superlattices are sensitive to the fine structure of the nanoparticle lattice. Moreover, the incorporation of experimentally informed inhomogeneity in these higher volume fraction superlattices exhibit distinct variation in far-field extinction and inconsistent electric field intensities throughout the lattice, in contrast with those systems with less than 20% Au. The variation between randomly generated superlattices is more pronounced for higher volume fractions (closer nanoparticle spacings) due to stronger plasmonic coupling between particles. In turn, these data have important implications for building consistent and scalable nanomaterial architectures where reproducibility and sample-to-sample variation remains a challenge.

Sub-wavelength Magnetic Field Enhancement via Fano Coil-type Resonances

Abstract— In the last decade, several efforts have been spent in the investigation of the "artificial magnetism". Structures able to locally modify the magnetic susceptibility present unique properties with applications in super-lensing [1], cloaking [2] and spintronics [3]. Within this context, the study on split-ring resonators has provided one of the first proof-of-concepts for this phenomenon.

In concomitance, plasmonic nano-assemblies have been deeply studied for the high field enhancement properties which they exhibit in the visible/near-infrared range [4]. In particular, the employment of *symmetry breaking* [5] approaches on plasmonic oligomers in strong coupling condition, has revealed the arising of Fano-like interferential features. The extraordinary enhancement properties presented by these sub-wavelength systems result from the hybridization of strongly radiative *bright* modes and low-loss *dark* modes [6]. In the last years, the exploitation of these concepts on circulating plasmonic currents has produced magnetic-like Fano resonances at optical frequencies [7].

Here, we apply a symmetry breaking process on a strongly coupled nanodisk trimer, inducing a radical modification in the optical response of the plasmonic system. In particular, the gradual increasing of the upper disk diameter (see panel (a), from bottom to top) promotes the arising of a pronounced Fano-like extinction dip inside the broad trimer spectrum (see spectra evolution in panel (b)). The magnetic character of the Fano resonance is confirmed by the near-field analysis inside the trimer gap region (see panel (c)). For small upper disk diameters (panel (a)), the local magnetic field enhancement is around the unity (black dots in panel (c)) and the associated plasmonic currents are in phase (see (i) inset of panel (c)). However, beyond a diameter size threshold (around 250 nm), the magnetic enhancement in Fano resonance condition presents a steady increase towards a factor around 10. The arising of a magnetic hot-spot (see (iii) inset of panel (c)) inside the gap region is attributed to the mutual de-phasing of the localized surface plasmons supported by the three disks. In Fano resonance condition indeed the strongly coupled plasmonic currents undergo a re-arrangement which results in a coil-type plasmonic mode within

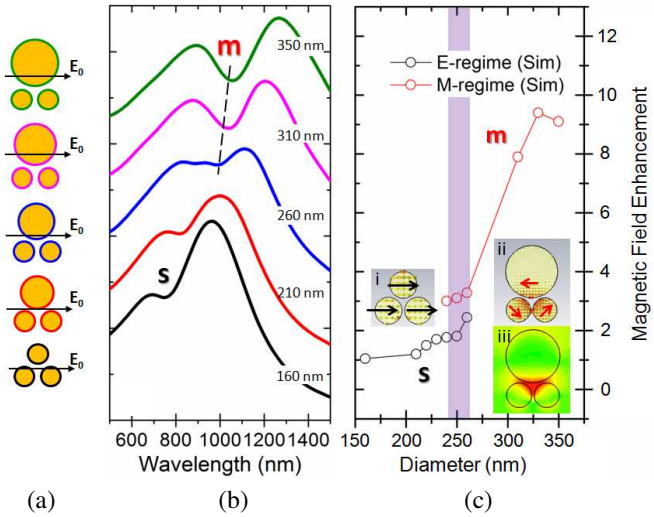

Figure 1: Panel (a) Sketches reporting the morphological symmetry breaking on nanodisk trimer. Panel (b) Simulated extinction efficiency spectra of nanodisk trimer for increasing upper disk diameter. Panel (c) Simulated magnetic field enhancement associated to the triemr gap region, as a function of the upper disk diameter.

the gap region (see (ii) inset of panel (c)). Gold trimer arrays have been fabricated by electron beam lithography and optically characterized by far-field spectroscopy, observing the occurrence of the coil-type Fano resonance in the visible/near-IR range.

The intense magnetic hot-spots generated in Fano resonance condition promote arrays of strongly coupled disk trimers as feasible plasmonic platforms for a wide variety of nano-photonic applications. In fact, the possibility to enhance the optical magnetic fields in sub-wavelength regime, opens fascinating scenarios in high-resolution imaging, bio-sensing and enhanced nonlinear optical spectroscopy.

Plasmonic Optical Binary Storage Based on Nematic Liquid Crystal Layers

Mahmoud A. Elrabiaey[1], **Nihal F. F. Areed**[1, 2], **and Salah. S. A. Obayya**[1]

[1]Centre for Photonics and Smart Materials, Zewail City of Science and Technology, Gizza, Egypt
[2]Faculty of Engineering, Mansoura University, Mansoura, Egypt

Abstract— A novel design for an easily and compact integrated optical 2-bit binary storage is presented and analysed using 2D-finite difference time domain (2D-FDTD) method. The proposed structure utilizes silver sheet with two nano-holes and two nematic liquid crystal (NLC) layers of type E_7. The suggested device can be used to store the visible light beam to one of the two holes based on the biasing states of the two NLC layers. The suggested device offers absorption efficiency and crosstalk of 0.4 and 13 dB, respectively. In addition the reported structure opens-up the revenue to build optical n-bit binary storage through the use of appropriately positioned n metallic nano holes and n NLC layers.

Design and Numerical Results: In this paper, a combination of plasmonic holes and NLC layers has been investigated using 2D FDTD [1] to realize optical 2-bit binary storage. Figure 1 shows the proposed optical device that consists of two nano-holes each of 20 nm width which are drilled in silver sheet of thickness 200 nm. The silver sheet is sandwiched between layers of silicon compositions and coplanar two NLC layers. The confining to the required nano-hole is mainly depending on the equivalent permittivity upon this hole which can be easily controlled through the tuning of NLC layers. In this way, we have 3 states for the proposed 2-bit binary storage which are "10", "01" and "11". In the 1st storage state "10", NLC_1 is biased while NLC_2 is unbiased. In this case, the light will be confined around $hole_1$. In the 2nd state "01", NLC_1 is unbiased while NLC_2 is biased. Therefore, the light will be confined around $hole_2$. Finally, in the 3rd storage state the two NLC layers are biased, and then the light will be confined and distributed equally among the two holes. The pre-recorded information can be retrieved by near field spectroscopic optical detection method [2]. Figure 2 shows the calculated absorption power efficiency (η) around the two holes for the 1st storage state. It is evident from the figure that the majority of the absorbed light with $\lambda = 722$ nm is confined around $hole_1$ where the magnitudes of the η_{hole1} and η_{hole2} are equal to 0.406 and 0.02, respectively. Figure 2 shows the steady state electric field distribution along xy plane for the 1st state. The shown distribution clearly agrees with the behaviour of the calculated absorbed efficiency.

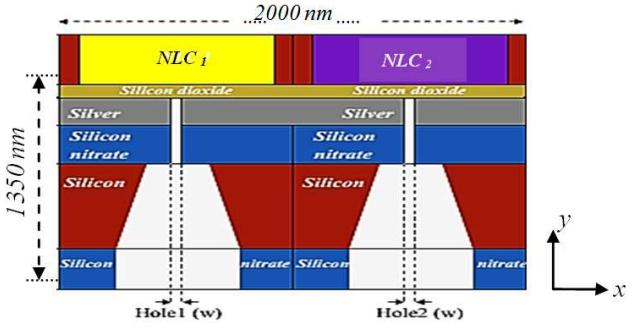

Figure 1: Proposed 2 bit binary storage.

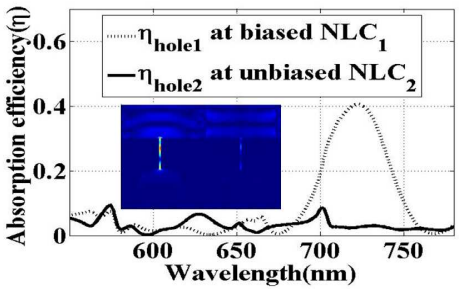

Figure 2: Absorption efficiency for the first storage state.

Quantifying Light-matter Interaction in Plasmonic Nanogaps

Shunping Zhang[1] **and Hongxing Xu**[1, 2]

[1]Center for Nanoscience and Nanotechnology, School of Physics and Technology
Wuhan University, Wuhan 430072, China
[2]Institute for Advanced Studies, Wuhan University, Wuhan 430072, China

Abstract— Plasmonic nanogaps serve as a perfect configuration for light concentration owing to the extreme localization of surface plasmons [1]. Nanogaps in different type of neighboring metallic structures are widely exploited, e.g., for surface enhanced Raman spectroscopy [2]. However, the plasmon resonances and the field enhancement depend sensitively on the gap distance, the geometry of the nanoparticle etc.. Therefore, a controlled nanogap is highly demanded to quantify the light-matter interaction inside the gap, such as changing the gap distance in situ [3]. Here, we used a nanoparticle over mirror to obtain stable SERS enhancement, quantify the gap dependence [4] and push the limit into atomic thin nanogap [5].

Antennas, Signals, HPEM and EMC Problems 2

Prediction of Signal Fadings in Air Radio Communications

Leszek Nowosielski and Marain Wnuk
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— Radio in aviation plays very important role. It allows to communicate the pilot with the fly control tower in order to provide security in the air as well as good coordination of air operations. Within the VHF, the frequency band of mobile radio communication air service is in the range of 118.000 MHz to 136.975 MHz. It is divided into channels with the spacing of 25 kHz, what gives 720 channels in the whole frequency band. Radio telephones used in this communications employ amplitude modulation (AM). The resistance to Doppler effect is the only, but also the most important argument speaking for using it. When a plane is flying it cause considerable voice distortions. There, in the article, the analysis of the fading deepness of the signal at the receiving antenna input of the aircraft flying in the air space between the repeater station and a power line were presented as well as it was determined if the level of fadings generated by signal reflections from power columns has destructive effects to the quality of radio link used.

To this purpose, the analysis of the terrain between the repeater station and individual power columns was carried out. Basing on the analysis results it could be accepted that the propagation of the radio link at the sector of the ray reflected, i.e., the repeater station antenna, reflecting surface of particular power columns and receiving antenna installed on the plane, can be modeled using the free space propagation model.

The signal level R at the input of receiving antenna installed on-board of the plane depends on the level and phase of the direct ray signal Ray_1 as well as the level and phase of the component being the sum of the rays Ray_2 reflected from the power columns. The signal level R can be calculated from the dependence:

$$R = Ray_1 + Ray_2$$

The computer simulation was done of effects of the rays reflected from particular power columns present in the antennas beam to the signal level R. The reflecting coefficient was defined as the ratio of metal surface area exposed directly to the influence of the incident electromagnetic wave, being a part of the spherical area sector comprising the angular range of the azimuth and elevation corresponding, to the segment of power line operated by one power column to the total surface area of the spherical sector comprising the angular range of the azimuth and elevation corresponding to the segment of power line operated by one power column.

In order to evaluate effects of particular power columns to the radio communication quality, the signal level R coming to the receiving antenna installed on-board of the plane with taking into account the level and phase of the direct ray signal Ray_1 as well as the level and phase of the ray signal Ray_2 reflected from a given power column. It allowed to determine deepness values of fadings at the input of the receiving antenna installed on the aircraft created by the effects of amplitude and phase of the direct ray Ray_1 and reflected one Ray_2. Basing on this, it can be stated that the coefficient of signal reflection from metal structure of particular power columns has the deciding effect to the fading deepness of the signal at the input of the receiving antenna.

The Reflectivity of the Ni-Zn Ferrite Tiles in the Microwave Frequency Range

Roman Kubacki
Faculty of Electronics, Military University of Technology, Warsaw, Poland

Abstract— To obtain high shielding performance for suppressing the radio frequency reflections inside the anechoic chamber the broadband absorptive materials with low level of reflection coefficient is necessary. Ferrites are the most commonly used materials as a kind of electromagnetic wave absorber. In this study the electromagnetic properties of commercially available Ni-Zn ferrite, were investigated. Typically this material is used as metal-backed absorber. The principle of the metal-backed microwave absorber is to make use of the reflection reduction by impedance matching. The impedance matching condition depends on the values of the absorber electromagnetic parameters. The permittivity and permeability of Ni-Zn ferrite tiles were measured using Hewlett-Packard Vector Network Analyzer (VNA) with a synthesized sweep oscillator and an S-parameter test set. Material parameters of the complex permeability and permittivity were calculated from the measured S parameters using the Reflection/Transmission Nicolson-Ross model.

The reflection coefficient expressed in dB can be given as:

$$L_R = 20\log(\Gamma)$$

where:

$$\Gamma = \frac{\sqrt{\mu}\tanh(\gamma d) - \sqrt{\varepsilon}}{\sqrt{\mu}\tanh(\gamma d) + \sqrt{\varepsilon}}$$

γ and d are: propagation constant and the thickness of the ferrite tile, respectively.

Modelling of the Angle of Arrival Scattering Using the Von Mises Function for Compatibility Analysis

Leszek Nowosielski, **Marian Wnuk**, **Jan M. Kelner**, **and Cezary Ziółkowski**
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 Str., Warsaw 00-908, Poland

Abstract— A designing and building of sector antenna systems in the modern wireless communication systems require an analysis of a cross-sectors electromagnetic compatibility. This is due to the occurrence of the angular dispersion of the received signal. It is result of the multipath phenomena. This problem is particularly important in the urban environment.

To analyse the angle of arrival (AOA) are used two model types: the probability density function (PDF) of AOA and the power azimuth spectrum (PAS). PDF of AOA models are theoretical. In contrast, PAS models are practical, because the PAS characteristics are determined on the basis of measurements. PAS and PDF of AOA models can be divided into two main groups, i.e., theoretical geometric and empirical models. The empirical models, e.g., the Gaussian and Laplacian models, use the well-known functions (distributions) for modelling the statistical properties of AOA. Physical interpretation of such models is difficult, however, these functions fit well PAS characteristics obtained in the real environment.

This paper presents an empirical model based on the von Mises distribution. This model allows a varied shapes of AOA distribution. If model parameter equal to zero then this distribution is uniform that is often used for modelling of the local isotropic scattering. If the von Mises parameter tends to infinity then distribution has the high concentration and small variance like the Dirac delta. The fit of the von Mises model to empirical PAS is presented in figures. Results of measurements taken from the open literature are used as reference data. Authors present brief characteristics of measurement scenarios. Accuracy assessment of the fit of the proposed model and empirical data is shown. The least square error and the rms angle spread are used as evaluation criteria.

The rms delay spread is used to classify the type of propagation environment. An example of such classification is presented in COST 207. This parameter can be determined based on the power delay profile (PDP) or the power delay spectrum (PDS). The relationship between the rms delay spread and the rms angle spread obtained on the basis of the empirical PAS and von Mises model is presented. Methodology of the von Mises model parameter selection depending on the environment type is based on the obtained relationship. As a result, the proposed model can be applied to the channel modelling for the various scenarios and propagation conditions.

Influence of the Environment on the Cross-sector Compatibility in Wireless Access System

Leszek Nowosielski, **Cezary Ziółkowski**, **and Jan M. Kelner**
Faculty of Electronics, Military University of Technology
gen. Sylwestra Kaliskiego St. No. 2, Warsaw 00-908, Poland

Abstract— Multipath of the wave propagation is the phenomenon that plays a dominant role in formation of internal disturbances in radio systems. This phenomenon significantly limits the possibilities of signal transmission in wireless systems. To increase the capacity of access system, the spatial sectorisation of areas that are supported by the access base station (BS), is used. The multipath phenomenon that occurs in urban area, is the cause of the signal power permeation to neighbouring sectors. It is reason the occurrence of additional disturbances in access neighbouring sectors. This phenomenon is especially important in the case of mobile object (mobile station MS) location near the border of neighbouring sectors. In wireless access systems, the effect of the phenomenon is important for the implementation handover procedure.

This paper is devoted the evaluation of power permeation to BS from MS that is in neighbouring sector. The basis for the analysis is power azimuth spectrum (PAS) that describes the angle distribution of signal power at the input of the receiver. For different tapes of environments, these characteristics are differentiated. The results of the numerous measurements show that with the increase of the environment urbanization degree, the angular dispersion of the received signal is increased. From among the many models, the von Mises function is used as PAS model. Influence of the environment differentiation on PAS is taken into account by the adaptive selection of van Mises parameter. The model validation is made on the basis of the results that are obtained for five measurement scenarios taken from open literature. As criterion of model validation, the least square error (LSE) minimization is used. The characteristic that shows the functional relationship of permeation power and location angle of MS with respect to BS of neighbouring sector is the analysis result presented in the paper. The obtained characteristic is the basis for the evaluation of the disturbance power level that originates from the neighbouring sectors of the wireless access system.

Mobile Recorder for Electrical Activity of the Heart

M. Bernat and Z. Piotrowski
Faculty of Electronics, Military University of Technology, Warsaw, Poland

Abstract— The presented study is dedicated to a mobile recorder designed to keep log of electric activity of the heart and incorporated into the expert system developed to detect fatigue status of a patient. The newly designed recorder has a modular structure and its enclosure houses two double-sided printed circuit boards (PCBs), separately for the analog part (BtECG) and the digital one (BtECGradio).

The analog module is responsible for measurement of electric signals received from the patient's body with their further amplification, filtration and conversion to digital form. In addition, in comprises a source of stabilized voltage(s) for both analog and digital circuits. The digital module receives binary data, extracts its useful portion, carries out formatting of the data to form of frames required for RF communication according to the Bluetooth standard and enables wireless communication with a collaborating unit.

The analog subassembly is meant to record electric potentials within the range from 0.2 to 2 mV and owing to the high level of the CMRR factor it substantially eliminates the common-mode signals. Furthermore, it enables two-stage amplification, filtration of high-frequency interferences, high-pass filtration and active, five-staged low-pass filtration.

The digital module of the recorder enables RF data transmission according to the Bluetooth v.4.0 standard, communication with a host unit with use of the UART and SPI interfaces (reading of RF packages from the CPU module) as well as communication with a host unit with use of the Full Speed USB 2.0 (BGAPI) protocol. Its power consumption is ultra low and the communication sessions is controlled by a microprocessor of the 8051 architecture. The digital module also enables the user to embed own application and to debug them via the CC Debugger Connector link.

The base chip for development of the digital module is the BLE112 Bluetooth Smart module from Bluegiga.

Implementation of a Steganographic Algorithm in an Internet VoIP Phone

Damian Bachmat and Zbigniew Piotrowski
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 Str., Warsaw 00-908, Poland

Abstract— The paper describes implementation of the steganographic method based on the least significant bits (LSB) in a program Internet phone VoIP. In the developed program Internet phone VoIP a library PJSIP has been used. Selected technology — LSB is characterized by easiness of implementation and high data rate and perceptual transparency of a signal with embedded steganographic sequence. In case of the LSB method a change in the least significant bits in a datagram takes place after quantizer of an analog-digital converter circuit. This solution enabled simple implementation of the embedding algorithm by modification of a source code of a codec G.711. The way of the method implementation protects data from errors since mechanisms of the error control and correction of the RTP protocol monitored correctness of sent data. One of the advantages of the method is the fact that for determined number of the least significant bits it does not cause an audible speech degradation and therefore, modified speech signal is perceptually transparent for a subscriber at the receiver side. The paper includes results of tests of developed steganographic phone, among others, subjective audible tests based on signal fidelity estimation standard — ITU-R BS 1116-1, tests of minimal, required time of transmission and integrity tests of steganographic sequence.

Multimedia Filter for Data Hiding Counteraction

Zbigniew Piotrowski
Faculty of Electronics, Military University of Technology
Gen. S. Kaliskiego 2 str., Warsaw 00-908, Poland

Abstract— Data hiding methods are realised in the form of steganographic communication channels and in the form of digital content labelled with watermark while employing as the carrying layer among the others: speech signal, audio, video and photos. Detection of the fact of additional data hiding is hindered among the others because of constantly improved and increasingly advanced methods for embedding and extraction of hidden data. In the article there is presented the concept of the program container based on which the filtration of the above-mentioned signals is carried out in order to remove the hidden data. The purpose of multimedia filter action is to remove from the original signal (carrier) the hidden data or its significant degradation, but in such manner that the original signal itself is not degraded significantly.

Printable Interdigitated Ferroelectric Varactors for Reconfigurable Antennas

Mahdi Haghzadeh, **Craig Armiento**, **and Alkim Akyurtlu**
Department of Electrical and Computer Engineering, Raytheon UMass Lowell Research Center
University of Massachusetts Lowell, Lowell, MA 01854, USA

Abstract— In this work we propose, analyze and implement a novel printable varactor based on barium strontium titanate (BST)/polymer composite filled interdigitated capacitors (IDCs). The model of the BST material filled IDC was simulated by CST Microwave Studio and compared with a conventional model of IDC on BST thick film in terms of capacitance value and tunability. Ferroelectric varactors are of special interest for RF and microwave applications due to their higher performance, and reduced power consumption, size and cost. Among various ferroelectric materials, Barium Strontium Titanate ($Ba_xSr_{1-x}Ti$, or BST), a perovskite-type compound, is the material of choice since it is the most studied composition for microwave applications, and its Curie temperature is controllable by Ba content and is below room temperature for $x < 0.7$. Therefore, it is in the paraelectric phase at room temperature and has a high dielectric constant, high tunability, low loss tangent, and high switching speed. In addition, its relative permittivity is decreased in a nonlinear fashion with no hysteresis when a bias voltage is applied across it. BST-based varactors are usually used in a coplanar-plate design called Interdigitated Capacitor (IDC), where plates are placed on top of a thick or thin film of BST, and are interdigitated in order to increase the capacitance per unit area. From the printed electronics perspective, utilizing thick or thin films of BST are impractical since processing BST films require very high sintering temperatures (above 850°C) and they are brittle in nature, thus failing to be compatible with flexible substrates. One promising solution to this critical problem may be a BST/polymer composite made by suspending micro- or nano-BST particles in a polymer matrix. Such a solution is a compromise between the processing flexibility of a polymer and the desired ferroelectric properties of BST. The fabrication and material properties of many BST/polymer composites have been reported using various polymers such as silicon-rubber, epoxy resin, polymethylmethacrylate (PMMA), polyphenylene sulfide (PPS), cyclic olefin copolymer (COC), and polypropylene-graft-poly(styrene-stat-divinylbenzene) (ER). The multi-phase, solvent-based composite was made by mixing nanoparticles of BST, 4-tert-butycatechol (BTC) as a dispersant, and thermoplastic cyclic olefin copolymer (COC) in toluene. This resulted in developing a nano-BST ink to be used for ferroelectric dielectric printing purposes. A coplanar waveguide (CPW)-based test structure was used to enable GSG probe based RF measurements of IDCs. Plates of IDCs as well as the CPW test structure were printed on 5 mil Kapton sheets by Optomec Aerosol Jet printer using nano-silver ink. BST/polymer composites were printed by Sonoplot printer using the nano-BST ink between and on the IDC fingers. RF measurements were performed to gain insight into the dielectric properties of the printed composites.

A Dualband Circularly Polarized Rectangular Dielectric Resonator Antenna with L-shaped Slots on the Ground

Yuxiang Sun, **Kwok Wa Leung**, **and Wei Wei Li**
Department of Electronic Engineering and State Key Laboratory of Millimeter-Waves
City University of Hong Kong, Hong Kong SAR, China

Abstract— This paper presents a dualband circularly polarized (CP) rectangular dielectric resonator (DR) antenna (DRA). Its fundamental TE_{111} mode and higher-order TE_{113} mode are excited simultaneously to obtain two working bands. The dimensions of the dual-band DRA are calculated by solving simplified formulas of the dual-mode rectangular DRA. To generate circularly polarized fields, two asymmetric diagonal L-shaped slots are etched on the ground plane to excite two degenerate orthogonal modes in each band, giving a CP dualband antenna. For demonstration, a dual-band dual-sense CP antenna working in GPS L1 band (1.575 GHz) and 2.4 GHz WLAN band are designed using ANSYS HFSS. Its reflection coefficient, axial ratio (AR), antenna gain, and radiation pattern are studied. The antenna radiates right- and left-hand circularly polarized fields in the lower and upper bands, respectively.

Bidirectional Dielectric Resonator Antenna Using Slotted Ground Structure

Nan Yang, Kwok Wa Leung, and Wei Wei Li
State Key Laboratory of Millimeter Waves, Department of Electronic Engineering
City University of Hong Kong, Hong Kong SAR, China

Abstract— A bidirectional cylindrical dielectric resonator antenna (DRA) is proposed in this paper. The DRA operating in its fundamental $TM_{01\delta}$ mode is fed by an axial coaxial probe protruded from a circular ground, which has the same radius of the DRA. Two slots are fabricated on the ground to obtain a bidirectional radiation pattern. It was found that the measured gain on the azimuth plane is 3.75 dBi and −10.16 dBi in the main-lobe and side-lobe directions, repsectively.

Impact of Bending on the Performance of Circularly Polarized Wearable Antenna

Muhammad Rizwan, **Lauri Sydänheimo**, **and Leena Ukkonen**
Department of Electronics and Communications Engineering
Tampere University of Technology, Tampere, Finland

Abstract— Wearable electronic devices are becoming a part of human clothing for applications such as sensing, navigation and health monitoring. Textile antennas are a strong candidate for transceiver node in wearable applications due to their flexibility and low cost. In wearable systems, flat surfaces are not always available so the antenna should be able to retain its performance in bent conditions. This paper analyses the effects of bending on the performance of a circularly polarized textile antenna. The antenna under test is fabricated on thin denim substrate and operates for Industrial, Scientific and Medical (ISM) band and Wireless Body Area Network (WBAN) applications at 2.45 GHz. Copper tape with thickness 0.25 mm is used as the conductive material for the patch and the ground plane on denim substrate. Rectangular slot along diagonal axes at the center of the circular patch is used for achieving circular polarization at 2.45 GHz while bandwidth enhancement is done by using partial and slotted ground plane. The measured operating frequency range of antenna spans from 2.42 GHz to 2.58 GHz with gain of 2.25 dB at 2.45 GHz. Bending in both xz and yz plane is done by placing the antenna on cylinders with different radii (50 mm and 75 mm) and then analyzing the effects on return loss, bandwidth, axial ratio and radiation characteristics. Fabricated antenna shows good conformity between simulated and measured results. A set of comparative results of antenna in free space and bending conditions are discussed to validate the operability of antenna with bending in different planes. In future, the performance of antenna can be analyzed on different body parts like arms and legs etc. to validate its operability for BAN applications in vicinity of human body.

Design and Optimization of Miniaturized Dual-band Implantable Antenna for MICS and ISM Bands

Muhammad Ali Babar Abbasi, Salman Arain, Photos Vryonides, and Symeon Nikolaou
Department of Electrical Engineering, Frederick University, Nicosia, Cyprus

Abstract— This work discusses the design method towards the implementation of a compact, stacked, implantable antenna for biotelemetry applications. The proposed antenna consists of three stacked layers, printed on high permittivity grounded substrate, namely, Roger's RO3210. The bottom layer of the antenna above the ground plane, contains a meandered structure with a symmetrically placed T-shaped slot. The middle layer consists of two U-shaped radiators and on the top layer, an M-shaped metallic segment is added to enhance the radiation efficiency of the antenna. The bottom and the middle layers are excited at the top right corner with an extended coaxial feed. A via connecting the top with the middle layer of the antenna, at top left corner, opposite to the coax feed corner, enables symmetrical virtual feeding for the middle layer. Two vias, placed at right and left bottom corners, additionally connect the middle with the top layer of the stacked antenna. These three stacked layers, consist a symmetrical closed loop structure resonating on its fundamental resonant mode, at 402 MHz, for the Medical Implant Communication Service (MICS) band. A shifted higher order mode of the same closed loop structure, along with the two radiating U-shaped coupled resonators on the middle layer and the M-shaped resonator on the top layer, enables wide band operation, at 2.45 GHz, for the industrial, scientific, and medical (ISM) band.

To resolve the constraints associated with implanting an antenna in human body that usually results in detuning and impedance mismatch, the antenna's most important radiating sections were thoroughly investigated. A fully parameterized solution is proposed that makes the antenna a good candidate for a device implanted at different areas of the human body with potentially different electric properties with consequently different detuning effect. For further investigation, the particle swarm algorithm was implemented to optimize the antenna's performance while operating inside a compact, $23 \times 23 \times 5\,\text{mm}^3$ block of human skin equivalent phantom. The simulated performance of the proposed prototype antenna, indicates that it can be used for either in vitro or in vivo operations. Finally, the small size of the proposed antenna ($18 \times 15 \times 2\,\text{mm}^3$) is compared favorably against the sizes of previously reported antennas, operating in both MICS and ISM bands.

[3]Department of Electrical & Computer Engineering
Democritus University of Thrace, Xanthi, Greece

Abstract— There are many methods for analysing diffraction gratings and other periodic structures. When the structure is invariant along one axis, modal methods not only allow to calculate the electromagnetic field but have also the advantage to easily give insight into the physical phenomena. Lamellar gratings are the most simple structures that can be analyzed with a modal method. Since the dielectric constant depends only on one spatial coordinate, it is possible to expand the electromagnetic field in the grating region in terms of the eigenfunctions of the Helmholtz equation.

Modal methods include analytical modal method [1] in which the only numerical parameters-the eigenvalues-are obtained as the zeros of a transcendental equation, the Fourier modal method [2] and many other variants based on finite differences [3], polynomials [4], and B spline expansions [5], and also the pseudo-spectral modal method [6].

Among the above methods, the Fourier modal method is certainly the most popular and has been intensively researched which has lead to dramatic improvements. Its main drawback is that discontinuous fields are represented using a finite number of Fourier coefficients, which leads to the unavoidable Gibbs' phenomenon. One of the main reasons why convergence rates are so different from a given implementation of the method to another lies in the treatment of the discontinuities of the electromagnetic field at the interface between different dielectrics or metals. This is particularly true when materials with negative permittivity or permeability are involved.

The goal of our presentation is to make a fair comparison of the various numerical modal methods in terms of accuracy and speed of convergence for dielectric and metallic lamellar gratings.

Hypersingularity of Transverse Electric Field at Sharp Edges: A Case Study of a Special Lamellar Grating

Lifeng Li
Department of Precision Instrument, Tsinghua University, Beijing 100084, China

Abstract— After half century of research the rigorous electromagnetic theory of gratings has been developed to an advanced level so that to date many theoretical theories exist, including the integral methods, the differential methods, the modal methods, the coordinate transformation method, the finite difference time domain method, and the finite element method, and most practical grating problems can be solved by one or more of the numerical methods based on the theoretical theories. However, some old challenges remain and some new challenges have appeared. The advent of plasmonics and metamaterials research has brought about the necessity of studying electromagnetic wave guiding and scattering by structures consisting of lossless metals (media of negative permittivities). In particular, it was recently noted that when a grating contains sharp edges formed by a lossless metal surrounded by some lossless dielectrics, the transverse magnetic grating diffraction problem cannot be solved by any existing numerical method, if the permittivity ratios of the media fall in certain ranges. While the root cause of the problem has been clearly identified as the excitation of hypersingular surface modes at the sharp edges, many questions remain unanswered: Is hypersingularity physical? If yes, why do all well-established numerical method fall to work, and how to solve the diffraction problem when hypersingularity is excited? If no, how to solve a practical problem that is nearly hypersingular? Is the hypersingular diffraction problem well-defined? If no, can we impose additional conditions to make it well-defined?

In this work, I perform a case study on the diffraction of a transverse magnetic incident plane wave by a lossless metallic lamellar grating. The theoretical analysis is carried out in the framework of the exact modal method. The diffraction problem is made as simple as possible so that the mathematical steps leading to the expression of the diffraction amplitudes are the fewest. It is hoped that this research may shed some light on the numerical divergence due to hypersingularity.

Gegenbauer Polynomial Expansion Applied to Crossed Binary Gratings

B. Guizal[1], **K. Edee**[2], **and J. P. Plumey**[2]

[1]Laboratoire Charles Coulomb, UMR 5221 du CNRS, University Montpellier 2, France
[2]Universit Blaise Pascal, Institut Pascal, BP 10448, F-63000 Clermont-Ferrand, France

Abstract— We present the modal method based on Gegenbauer polynomials (MMGE) as applied to crossed binary gratings [1]. We use the version of the MMGE that incorporates boundary conditions into the definition of a new basis of polynomial functions, that are adapted to the boundary value problem of interest. We will discuss the performances of this approach against the famous Fourier Modal Method (FMM) [2] eventually equipped with the Adaptive Spatial Resolution Concept (ASR) [3] and illustrate that on the extraordinary optical transmission phenomenon [4, 5].

Abstract— The fundamental and most useful electromagnetic quality of diffraction gratings is the ability to operate as frequency selective structure (FSS) [1, 2]. Various materials have been used for construction FSS for solving different optical and electromagnetic tasks [3, 4]. The modern advanced technologies facilitated the production of artificial materials with diverse astonishing electromagnetic features. Among them there are materials with extraordinary dispersive properties with constitutive parameters varying within rather narrow frequency range from negative values (of considerable magnitude) to conventional domain of positively valued constitutive parameters.

Combination of dispersive materials and geometrical periodicity, characteristic to diffraction gratings, open new possibilities for construction FSS having pronounced electrically and geometrically controlled dispersive features.

In present communication we discuss the scattering of inhomogeneous electromagnetic wave by periodic interface (with determined arbitrary profile) of dispersive medium that is certain artificial material with already defined dispersion relation describing constitutive parameters. Our study is based on accurate solution to boundary value problem [2] and robust numerical algorithm which efficiency ensure reliable, extensive, profound simulation of complicated scattering processes. The main attention here is concentrated on the study of regularities and mechanism of scattered electromagnetic field enchantment and suppression; the transformation of the energy of incident electromagnetic field into the energy of the eigen surface waves and investigation of their nature in the case of artificial media with various dispersion properties.

As an example we present in Fig. 1 the total energy $W_T(k)$ of scattered field inside the media, characterized by the Drude law $\varepsilon(k) = 1 - \frac{k_\varepsilon^2}{k(k+i\nu_\varepsilon)}$; $\mu(k) = 1 - \frac{k_\mu^2}{k(k+i\nu_\mu)}$, for lossless media $\nu_\varepsilon \cong 0$; $\nu_\mu \cong 0$ with $k_\varepsilon = 0.1$; $k_\mu = 1$, k is dimensionless frequency parameter, $\beta = \nu/c$, ν is normal to the interface corrugation railings component of phase velocity of incident wave.

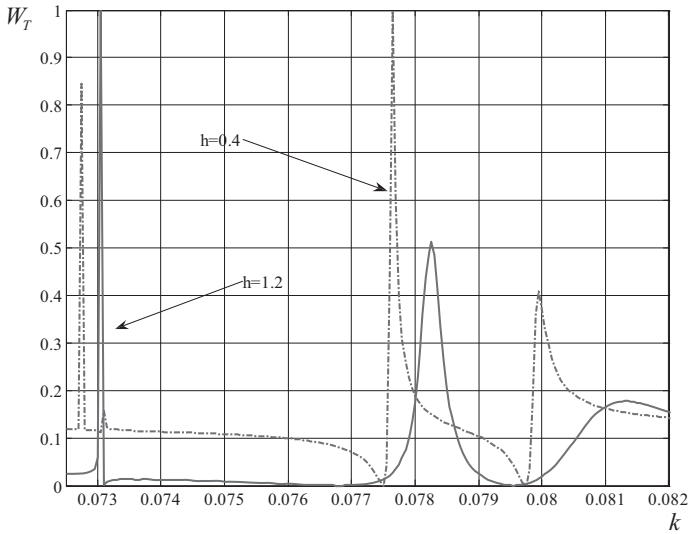

Figure 1.

Interface period is chosen equal to 2π, h is a depth of grooves. For the case illustrated by Fig. 1 within frequency range of interest the propagating harmonics in the space above the corrugated interface of artificial medium are forbidden. The energy may be carried only by harmonics inside the medium. In Fig. 1 we can see the pronounced resonant enhancement of the energy of the field excited inside material, but also the regions of nearly complete suppression of $W_T(k)$ within certain intervals of k. The larger h, the wider k interval. Such suppression of the scattered field appears due to the transformation of electromagnetic field of incident wave into the energy of eigen surface waves. The described situation exists in the case of double negative media and under conditions of coincidence of phase velocity of incident wave β with phase velocity of certain backward surface waves.

Local Transformation Leading to an Efficient Fourier Modal Method for Perfectly Conducting Gratings

Agnès Maurel[1], **Simon Félix**[2], **and Jean-François Mercier**[3]

[1]Institut Langevin, CNRS, ESPCI ParisTech, 1 rue Jussieu, Paris 75005, France
[2]LAUM, CNRS, Université du Maine, avenue Olivier Messiaen, Le Mans 72085, France
[3]CNRS, ENSTA ParisTech, INRIA, 828 boulevard des Maréchaux, Palaiseau 91762, France

Abstract— We present an efficient Fourier modal method for the wave scattering by perfectly conducting gratings (in the two polarizations). The method uses a geometrical transformation, similar to the one used in the C-method [1, 2], which transforms the grating surface into a at surface (Fig. 1(a)), thus avoiding to question the Rayleigh hypothesis. In addition, we use a geometrical, or optical, transformation which only affects a bounded inner region and naturally matches the outer region; this allows to apply a simple criterion to select the ingoing and outgoing waves. Otherwise, our proposed numerical scheme is similar to the Fourier Modal Method and it can be straightforwardly implemented.

A noticeable improvement of the presented method concerns the convergence, which is often not quantitatively reported in the literature. For penetrable gratings, the wavefield has a discontinuous gradient, which limits the convergence of the method to a power law $N^{-3/2}$, N being the truncation order of the Fourier series [3]. If the limit of perfectly conducting grating is considered, the error in the Fourier method is known to increase but the convergence in terms of power law is the same. Here, these limiting cases are directly treated as impenetrable gratings and this modifies drastically the convergence. Indeed, our geometrical transformation leads to a modified wave equation in a continuously varying medium, with space-dependent coefficients having the same regularity than the groove profile. For smooth profiles (described by a function of class C^∞), this produces a convergence with exponential rate, much better than the usual power laws. More results can be found in [4].

Vertical Mode Expansion Method for Applications in Plasmonics

Hualiang Shi and Ya Yan Lu
Department of Mathematics, City University of Hong Kong, Hong Kong, China

Abstract— Structures in plasmonics, such as metallic films with holes and metallic nanoparticles on a substrate, are often multiply-layered. A layered structure is a 1D structure for which the material properties depend only on one spatial variable z (assuming z is in the "vertical" direction). A multiply-layered structure is a 3D structure with a number of cylindrical regions where the material properties depend only on z in each region. General numerical methods can be used to analyze the scattering of light by a 3D multiply-layered structure, but it is possible to develop more efficient special methods. For structures involving circular cylinders, an efficient numerical method has been developed based on 1D vertical mode expansions and 2D horizontal cylindrical wave expansions [1–3]. In this paper, we consider multiply-layered structures where the cylindrical regions have arbitrary cross sections. An efficient method is developed by combining 1D vertical mode expansions and 2D boundary integral equations.

The vertical mode expansion process gives rise to a 2D Helmholtz equation for each mode. For each of these 2D equations, we calculate the so-called Neumann-to-Dirichlet (NtD) operator using a boundary integral equation (BIE) method. The BIEs are discretizd by Alpert's hybrid Gauss-trapezoidal quadrature rule. Notice that the NtD operators are calculated independent of each other. They are used to set up the final linear system of equations by matching tangential field components on the vertical walls of the cylindrical regions. We illustrate our method using examples in plasmonics.

Simulating the Linear and Nonlinear Response of 1D Nanostructures under a Focused Beam with a B-spline Modal Method

Patrick Bouchon[1, 2] and Patrick Bouchon[1]

[1]The French Aerospace Lab., ONERA, Palaiseau 91761, France
[2]Laboratoire de Photonique et Nanostructures, CNRS, Marcoussis 91460, France

Abstract— Focusing the light onto nanostructures thanks to spherical lenses is a first step to enhance the field, and is widely used in applications, in particular for enhancing non-linear effects like the second harmonic generation.

Nonetheless, the electromagnetic response of such nanostructures, which have subwavelength patterns, to a focused beam can not be described by the simple ray tracing formalism. Here, we present a method to compute the response to a focused beam, based on the B-spline modal method [1], which is known to be fast thanks to a non-uniform mesh and sparse matrices. The eigenmodes are computed in each layer for both polarizations in conical mounting, and are then combined for the computation of scattering matrices. The simulation of a gaussian focused beam is obtained thanks to a truncated decomposition on plane waves computed on a single period, which limits the computation burden [2].

Eventually, we develop a formalism to compute the second harmonic field under the undepleted pump approximation. The nonlinear polarization induced by a fundamental plane wave or a focused beam generates a source term at the doubled frequency. The latter is divided into a finite number of sub-sources and the second harmonic field is subsequently computed by integration of these subsources contributions [3].

Asymmetric Reciprocal Transmission through Double Metallic Gratings

M. Stolarek[1], **D. Yavorskiy**[1], **J. Łusakowski**[1], **C. Zapata-Rodríguez**[2], **and R. Kotyński**[1]

[1]Faculty of Physics, University of Warsaw, Pasteura 7, Warsaw 02-093, Poland
[2]Department of Optics, University of Valencia, Dr. Moliner 50, Burjassot 46100, Spain

Abstract— In this paper we analyse the propagation of sub-terahertz electromagnetic waves through double metallic gratings (DMG) with sub-wavelength slits. We demonstrate theoretically and experimentally the possibility of achieving directional transmission of electromagnetic radiation through the DMG structure in a planar geometry — for the TM polarisation, and in the cylindrical geometry — for the radially polarised field.

We optimise the overall system parameters in terms of the transmission efficiency, contrast and spectral range. The modelling is based on the finite-difference-time-domain method.

We provide structure parameters leading to the transmission of more than 50% and to a high transmission contrast in opposite directions for the wavelength range from 2.5 to 4 mm. The reciprocity of the system is maintained, and we prove that the unidirectional transmission in the zeroth diffraction order is not possible, therefore we do not classify our arrangement as an optical isolator [1]. In the planar geometry, the transmitted radiation propagates in the -1 and $+1$ diffraction orders. An analogues cylindrical grating led us to the design of an unidirectional diffractive lens [2]. The experimental set-up for the latter geometry requires to illuminate the structure with radial polarisation, which is obtained like in Ref. [3] by converting from the linear polarisation with modal selection in a tapered waveguide combined with the use of a discontinuous wave-retarder. A Gunn diode operating at 3 mm is used as the radiation source for both geometries. We have reached a good agreement between the experimental and modelling results.

Electromagnetic Methods for Some Gratings with Extreme Opto-geometrical Parameters

Evgeny Popov, Nadège Rassem, Yoann Brulé, Boris Gralak
Guillaume Demesy, and Anne-Laure Fehrembah
Aix-Marseille Université, Centrale Marseille, Institut Fresnel, CNRS UMR 7249, Marseille, France

Abstract— Several different electromagnetic spectral methods for modelling light diffraction by single or periodically arranged dielectric or metallic objects are compared in studying three systems having extreme optogeometrical parameters. The first system represents a three-segment dielectric diffraction grating having 1D periodicity, the middle segment is a resonant subwavelength grating acting as a narrow-band resonant reflection filter, the two outmost segments consist of Bragg grating used to reflect back the waveguide mode of the middle section. The entire length of the system contains several hundreds of wavelengths, and we demonstrate the capacity of two rigorous electromagnetic methods to correctly model the diffraction properties of the system, namely the Fourier modal method, and the Coupled dipole method. The results show an extreme flattening of the dispersion curve of the waveguide mode that can be explained by using a four-wave coupled mode approximate theory.

The second system represents a 2D grating made of arrays of metallic cones on a metallic substrate. The diffraction by the grating is modelled using the Coordinate transformation (C-) method and the Finite element method, and the results show a giant (10 000 fold) enhancement of the field intensity, compared to the incident field intensity.

The third example consists of a 1D echelette metallic grating made of negative-permittivity materials having simple- or hyper-singularity. We show the possibility of two electromagnetic methods (Integral method and C-method) to correctly predict the diffraction properties, when rounding of the corners is used. In the case of hypersingularity, the field varies with an increasing frequency and amplitude, as the radius of rounding is reduces, confirming the analytical theoretical predictions.

We compare the relative computation times for the different methods and they show similar duration for identical structures.

A New Approach to Diffraction in Volume Gratings and Holograms

David Brotherton-Ratcliffe
Centre for Ultra-realistic Imaging, Applied Science, Computing & Engineering,
Glyndŵr University, Mold Road, Wrexham, Wales LL1 2AW, UK

Abstract— Coupled wave theory has historically been successfully used to provide various analytic theories of optical diffraction in volume phase gratings. Here we develop a different approach based on a decomposition of the permittivity profile of the grating into an infinite array of infinitesimal discontinuities or step functions. By considering the corresponding elementary Fresnel solutions from each discontinuity, a first-order set of coupled partial differential equations can be derived, which are then solved in a rotated frame of reference to give analytical expressions for the diffraction efficiency of the general slanted grating at arbitrary angle of incidence. The underlying differential equations derived from the approach are a rigorous representation of Maxwell's equations for the case of the unslanted grating and few assumptions are required to provide highly accurate solutions for harmonic or quasi-harmonic permittivity distributions, even at large grating slant.

The method can be applied to either reflection or transmission geometry, although it is most accurate in the case of the reflection grating. It can also been extended to include finite absorption in phase gratings and to treat the cases of absorption and mixed absorption-phase gratings. It can also treat multi-chromatic gratings, spatially multiplexed gratings and holograms. Finally it can be used to provide accurate analytic expressions for gratings with variable fringe contrast profiles.

Comparison with rigorous numerical computations of Maxwell's equations show that the approach works somewhat better than simple coupled wave theory for most reflection gratings, whereas the coupled wave approach appears a little better in describing the transmission geometry.

The approach appears to offer a general approximate method for the analysis of electromagnetic, acoustic and other types of diffraction occurring in harmonic or quasi-harmonic structures.

Curvilinear Coordinate Generalized Source Method for Corrugated Gratings with Sharp Edges

A. A. Shcherbakov[1] and A. V. Tishchenko[2]

[1]Moscow Institute of Physics and Technology, Russia
[2]University of Lyon, France

Abstract— In this work we continue development of the fast and efficient methods for grating diffraction calculation. Recently we have proposed an extension [1, 2] of the previously developed Generalized Source Method [3]. The key novelty consisted in formulating the method in curvilinear coordinate system and introducing a concept of the generalized metric sources. Both standard and curvilinear formulations of the GSM were shown to possess near to linear numerical complexity and computer memory consumption relative to the number of Fourier orders. This allows for outperforming conventional Fourier space modal methods including the FMM and the C-method. Current talk will include a discussion of application of the curvilinear GSM to gratings with sharp edges, supported with demonstration of relevant numerical behavior. Treatment of sharp grating edges within the scope of the curvilinear GSM is done in a way similar to the treatment of continuous and discontinuous field components relative to grating corrugation interface (the analogous implementation for the C-method can be found in [4]).

The novel method reveals much better efficiency with respect to the standard GSM in modeling metallic gratings with complicated profiles.

Casimir-Lifshitz Force out of Thermal Equilibrium between Dielectric Gratings

Antonio Noto[1, 2], **Riccardo Messina**[1], **Brahim Guizal**[1], **and Mauro Antezza**[1, 3]

[1]Laboratoire Charles Coulomb (L2C), UMR 5221 CNRS, Université de Montpellier, Montpellier, France
[2]Dipartimento di Fisica e Chimica, Università degli Studi di Palermo and CNISM, Palermo, Italy
[3]Institut Universitaire de France, France

Abstract— We calculate the Casimir-Lifshitz pressure between two different 1D dielectric lamellar gratings in a system out of thermal equilibrium where the two gratings have different temperatures and are immersed in an environment having a third temperature. The calculation of the pressure is based on the scattering formalism and the needed scattering operators are deduced using the Fourier Modal Method. The behavior of the pressure is studied in detail varying many parameters of the system like the three temperatures involved as well as the geometrical parameters of the two gratings (period, filling factor, corrugation depth). We show that the interplay between non-equilibrium effects and geometrical periodicity offers a rich scenario for the manipulation of the force. In particular, we find regimes where the force can be strongly reduced close to zero for large ranges of temperatures. Moreover, a repulsive pressure can be obtained (purely non-equilibrium effect), whose features can be tuned by varying the temperatures as well as the several geometrical parameters associated with each grating. Remarkably, the transition distance between attraction and repulsion can be decreased with respect to the known case of two slabs, allowing one to obtain transition distances as low as 2.5 μm and implying an experimental interest for the observation of repulsion.

Analytical Regularization Method for Wave Diffraction by Grating of Resonant Cylindrical Screens

Yury A. Tuchkin, **Ali Şanlı**, **Emrah Sever**, **and Fatih Dikmen**
Electronics Engineering Department, Gebze Technical University, Kocaeli, Turkey

Abstract— The subject of our investigation is numerical modeling of diffraction by one-dimensionally periodical gratings formed by unclosed cylindrical screens of arbitrary smooth profiles, namely construction of numerically stable and efficient algorithm for solving the correspondent diffraction boundary value problems (BVP). The approach we suggest is based on Analytical Regularization Method (ARM) for such a class of BVPs. It essentially enforces the ideas and methods of [1–6]. We start with classic reducing of the problem to integral (or differential-integral) equation following with necessity from well-known Green's formulae technique. Integral equations such appearing are ones of the first kind in space $L_2(S)$, where S is a periodic set of closed or unclosed boundaries or contours of the obstacle. In particular, the Dirichlet BVP leads to the following integral equation $\int_S J(p)G(q,p)dS = u^i(q)$, $q \in S$. ARM principal idea is *analytical* (in closed form) construction of two-sided regularizer, i.e., a pair (R, L) of two invertible (possibly on corresponding dense sets only) operators R and L, such that $LAR = I + H$, where A is the operator of the BVP, I is the identity and H is a compact operators. Having such regularizer, one can reduce equation $Ax = b$ of the first kind to equation $(I + H)y = Lb$, y, $Lb \in l_2$ with new unknown $y = Rx$. The advantages of the equations of the second kind over ones of the first kind are well known.

Essential part of our approach plays algorithm of fast summation of the series representing Green's function for periodic gratings in the form $G_{gr}(q;\chi,\varphi) = (4\pi i)^{-1}\Sigma_{n=-\infty}^{\infty}\exp(\varphi_n x_q + \Gamma_n|y_q|)/\Gamma_n$, where $q(x_q, y_q) \in R^2$, $\varphi_n = n+\varphi$ and $\Gamma_n = (\chi^2 - \varphi_n^2)^{1/2}$ with $\mathrm{Re}(\Gamma_n) \geq 0$, $\mathrm{Im}(\Gamma_n) \geq 0$. The very slow convergence of this series is accelerated by means of rather sophisticated version of Kummer acceleration, which is essentially enforced in comparison with [2, 4].

Regular Coulomb Wave Function Method for Analysis of the Azimuthally Magnetized Circular Ferrite Waveguides

Mariana Nikolova Georgieva-Grosse[1] **and Georgi Nikolov Georgiev**[2]

[1]Consulting and Researcher in Physics and Computer Sciences, Gerlingen D-70839, Germany
[2]Faculty of Mathematics and Informatics
University of Veliko Tirnovo "St. St. Cyril and Methodius", Veliko Tirnovo BG-5000, Bulgaria

Abstract— The solution of the problems for normal TE_{0n} modes propagation in the circular waveguides, containing coaxially positioned ferrite cylinder or toroid of azimuthal magnetization faces serious obstacles of mathematical nature [1–12]. To overcome them different techniques have been proposed, allowing to reveal various aspects of microwave filed-anisotropic medium interaction: *i*) Bolle-Heller functions [1], *ii*) transverse network representation [2], *iii*) perturbation techniques [3], *iv*) variational calculus [4], *v*) confluent hypergeometric functions [6–10], *vi*) Coulomb wave functions [5, 11].

This paper presents the method of regular Coulomb wave function, applied to the problem for propagation of normal TE_{0n} modes along the circular waveguide, entirely filled with azimuthally magnetized ferrite. The magnetically dependent second-order ordinary differential equation for the H_z — component is reduced to the Coulomb wave equation [13, 14]. To apply the Coulomb wave functions $F_L(\eta, \rho)$ and $G_L(\eta, \rho)$ [13, 14] in the theory of waveguides, is an original idea by Georgiev and Georgieva [5, 11]. It is based on the Thompson and Barnett's proposal [15] to extend the definition of these functions, initailly introduced for real $\rho > 0$, real η and integer $L \geq 0$, for ρ, η and L — all complex, employing their link with the confluent hypergeometric functions [13, 14]. In contrast to Thompson and Barnett [15] who considered the computation of $F_L(\eta, \rho)$ and $G_L(\eta, \rho)$ through the latter, it is suggested to harness the representation of $F_L(\eta, \rho)$ in the Abramowitz form [14] and it is proved numerically that the same is applicable when L is a positive or negative factional number, as well. Here the regular Coulomb function is considered solely, since propagation in a single-connected waveguide cross-section is discussed. It is shown that the original series for $F_L(\eta, \rho)$ is much more rapidly convergent in the case mentioned and is preferable in the calculations. Graphs are depicted, showing the variation of the generalized function with ρ, provided $L = \pm 0.5$ and $\eta = 0$, ± 1, ± 5 and ± 10. A numerical investigation of dependence $F_L(\eta, \rho)$ on ρ is performed, too for the aforesaid values of L and $\eta = \pm\rho/2$. Tables of the zeros $o^L_{\eta,n}$ of $F_L(\eta, \rho)$ are also compiled. The phase characteristics, differential phase shift and the borderlines of the area of phase shifter operation of the configuration are computed through sophisticated iterative techniques and debated.

A Generalized Drude Model for Time-domain Simulations of Ferromagnetic Metals in Plasmonics

C. Wolff[1] **and K. Busch**[2, 3]

[1]School of Mathematical Sciences, University of Technology, Sydney (UTS), NSW 2007, Australia
[2]Institut für Physik, AG Theoretische Optik & Photonik
Humboldt-Universität zu Berlin, Newtonstraße 15, Berlin 12489, Germany
[3]Max Born Institute, Max-Born-Straße 2A, Berlin 12489, Germany

Abstract— Time-domain simulation techniques such as the finite-difference time domain method (FDTD) or the Discontinuous Galerkin time domain method (DGTD) are a key tool to investigating the broad-band and potentially the nonlinear response of plasmonic and other nano-optical structures. Within these method, the commonly used noble metals such as silver and gold are usually represented by a Drude model for the conduction electrons with additional Lorentz poles to account for inter-band transitions. However, this fails for non-noble transition metals, especially for the ferromagnetic metals iron, nickel and cobalt, which have recently gained some interest because their magneto-optic Kerr effect might provide an effective way to control the propagation of surface plasmons.

The failure of the common Drude-Lorentz description is due to the high degree of electron-electron correlation in ferromagnets and manifests itself in a different frequency dependence of the material loss compared to the conventional Drude model. We derive a generalized Drude model which includes the effect of such correlations to leading order. To this end, we introduce one new fit parameter that reflects the degree of correlation inside the electron system. In combination with two Lorentz poles, our model results in a very good reproduction of the experimentally measured permittivity of iron, nickel and cobalt into the ultra-violet.

The resulting equations can be easily formulated as auxiliary differential equations of very similar numerical effort compared to the conventional Drude-Lorentz. Additionally, we present an efficient way to include magneto-optic properties into time-domain frameworks by adding the Lorenz force to any polarization current. This avoids dispersive anisotropic material parameters, which lead to considerable overhead in FDTD simulations and pose serious problems to the formulation of DGTD. We check our implementation of the generalized Drude-Lorentz model including the magneto-optic terms against analytical expressions. Furthermore, we compare our method to numerical frequency-domain results and experimental data from the literature.

Undersampling to Regularize the Source Reconstruction Problem for an Electric Point Source

S. G. Sen
Electrical Electronics Engineering Department, Ataturk University, Turkey

Abstract— In this article, a source reconstruction problem is solved by sampling the tangential components of the electric field of an electric point source on the surface of a hemisphere the center of which is the location of the point source. The source reconstruction is performed by sampling the electric field at five different sampling rates. One of the sampling rate corresponds to the Nyquist rate, two of them are oversampling rates and the rest are undersampling rates. The problem is discretized into a matrix equation which is solved iteratively. For each of the solution iterate, the field components are reconstructed and the error with respect to the original fields are computed. It is shown that the error made is approximately the same for all the sampling rates. In addition, the fields are reconstructed on hemispheres outside the sampling hemisphere. The error made in this reconstruction is calculated and shown to be not too much varying among the five different sampling rates. By means of these two field reconstruction demonstrations, it is proven that the oversampling and Nyquist rate sampling do in fact provide redundant information for the source reconstruction since the oversampling and the Nyquist rate sampling do not increase the accuracy of the reconstructed fields. The current reconstruction is also made using the lowest sampling rate and it is indicated that the reconstructed current is close to the original current although the sampling rate is lowest. As a result, it is determined that undersampling regularizes the reconstruction problem by deleting the redundant information due to higher rate sampling.

A Novel Computational Method for Calculating Electrostatic Capacity and Screening in Conducting Objects of Arbitrary Shape

Beatriz A. Pazmiño Betancourt[1, 2] **and Jack F. Douglas**[1]

[1]Materials Science and Engineering Laboratory, NIST, Gaithersburg, MD 20879, USA
[2]Physics Department, Wesleyan University, Middletown, CT 06459, USA

Abstract— The calculation of the electrostatic capacity of an object relative to an electrode at infinity, the self-capacitance, involves the solution of Laplace's equation with a Dirichlet boundary condition. Although this problem is well known and well posed, its explicit analytic solution is notoriously difficult. Solution for even a cube is apparently impossible and there are only a handful of particle shapes that allow for exact solution. Finite element and boundary element methods are useful, but these methods are computational expensive and convergence problems exist when the shape of the object is irregular. Meshing in these calculations can be very time consuming and difficult to implement at all in some cases. We really need a versatile and accurate method suitable for particles having any shape. There has been recent progress in solving this type of problem by probabilistic potential theory where the solution is obtained numerically through path-integral sampling [PRE 64 061401], an approach that exploits a fundamental connection between long random walk paths and Laplace's equation. There is another probabilistic method to determining capacity using an ergodic theorem of Spitzer [Z. Wahr 3, 110]. This method consists on considering the volume swept out by a Brownian particle ('Wiener sausage') divided by the mean square displacement of the particle, a quantity that is proportional to the objects self-capacitance for objects having any shape. We use this formal mathematical construct to implement a simple computational algorithm for calculating capacity. This novel computational method takes advantage of current GPU technology which makes the computation rather fast. Capacity estimates obtained by this method are compared with estimates obtained by other methods. As a non-trivial application, we show that the minimization of the capacity of spherical objects and the electrostatic screening transition of spheres can be understood in a simple geometrical way form the shapes of Wiener sausages created by particles having different shapes. Thus, our method allows not only to determine the self-capacitance, put provides great practical intuition of understanding into how particle shape influences capacity. We also summarize many applications of capacity in applications outside the field of electrostatics.

Sparse Tensor Approximation for Uncertainty Quantification on 2D Periodic Gratings

G. Silva and C. Jerez-Hanckes
School of Engineering, Pontificia Universidad Católica de Chile, Santiago, Chile

Abstract— Grating structures have been considered in many applications, such as spectroscopy and energy conversion devices. Exhaustive theoretical and numerical analyses have been performed in order to design gratings optimally. However, real-life manufacturing processes can create random variations on the surface that greatly influence the properties of the gratings. In this work, we implement a numerical algorithm based on the Boundary Element Method (BEM) for randomly perturbed ideal surfaces, considering one dimensional gratings with Gaussian rough surfaces and satisfying Dirichlet boundary conditions. We calculate first and second statistical moments of the scattered field with a sparse tensorization and a discretization based on wavelets. Calculations are provided for different geometries and angles of incidence and show that our method converges significantly faster than taking Monte-Carlo (MC) simulations for BEM.

Abstract— A modified numeric procedure is applied to analyse the application of π circuits for representing distributed parameters. Numeric oscillations, which are associated usually with digital simulations associated with π circuits, are decreased. It is shown that these numeric oscillations, or Gibb's oscillations, are not related only to the mentioned associations. They are created by the application of the specific numeric integration methods for solving linear systems that describe the associations of π circuits. If the state equations are determined for each π circuit, then the proposed changes of the numeric routine for solving systems with π circuits lead to results with little influence on the numerical oscillations. This is confirmed using comparisons with results obtained from the Laplace transform and ATP software.

Searching for a simple representation of the cascade of π circuits, each unit is modelled individually. The influence of adjacent π circuit units are included by the differential relations among the state variables. Thus, the Gibb's oscillations are decreased significantly. Therefore, the limit for the increase in the number of π circuits is related to the best accuracy attained by the modified numeric routine for specific values of the applied parameters. The proposed numeric routine is more accurate than the numeric routine based on the application of only one matrix for representing the dynamics of π circuits. The results of the modified numeric routine are very close to those obtained using the Laplace transform method and ATP software.

Abstract— Exact absorbing conditions (EAC) are used in computational electrodynamics of nonsine waves for truncating the domain of computation when replacing the original open initial boundary value problem by a modified problem formulated in a bounded domain. In the opening sections of our communication we construct EAC as applied to the analysis of axially-symmetrical electrodynamic structures illuminated by the symmetrical pulsed TE- and TM-waves and prove the equivalency of the original (open) and modified (closed) initial boundary value problems. We present here the following results: The EAC for virtual boundaries in a cross-section of regular circular and coaxial waveguides and for an artificial spherical boundary in free space; the transport operators relating the near-zone and far-zone fields generated by compact waveguide inhomogeneities and obstacles in free space. We also prove the unique solvability of the modified closed problem and its equivalency to the initial open problem and solve the problem of extended and remote sources of pulsed waves giving grounds for rigorous theoretical justification of the EAC-method.

In the next sections, omitting technical details, we construct EAC as applied to the analysis of plane (2-D) electrodynamic structures illuminated by pulsed E- and H-polarized waves and EAC for 3-D vector initial boundary value problems describing spatial-temporal electromagnetic field transformations in open waveguide and compact resonators. Closing section is devoted to enhancement of efficiency of computation of the analytical results obtained in the previous sections.

The efficient limitation of the computational domain in open initial boundary value problems (i.e., the problems whose domain of analysis is infinite in one or more directions) is a vital issue in computational electrodynamics as well as in other physical disciplines using mathematical simulation and numerical experiments. Most of the well-known and extensively used heuristic and approximate solutions to this problem are based on the so-called absorbing boundary conditions (ABC) and perfectly matched layers (PML). The use of various modifications and improving techniques for respective methods yield good results in various specific physical situations. However, it appears that for certain problems associated with the resonant wave scattering, the numerical implementation of these methods may cause unpredictable growth of the computational error for large observation times.

The method utilizing the exact absorbing conditions for the artificial boundaries that truncate an unbounded domain of computation is outnumbered by the classical approximate approaches. However, the carefully computed testing data as well as a series of physical and applied results obtained with the help of this method, show its evident potential, especially, for obtaining reliable numerical data on space-time and space-frequency electromagnetic field transformations in open waveguide, periodic, and compact resonators.

Combining Boundary Element and Reduced Basis Methods for Fast Electromagnetic Field Computations

Yating Shi, **Xiuguo Chen**, **Chuanwei Zhang**, **Hao Jiang**, **Haiqing Wei**, **and Shiyuan Liu**

Abstract— Fast and efficient modeling of electromagnetic fields is highly desirable in the design, optimization, and optical measurement of nanostructures as one needs to repeatedly evaluate the distribution of electromagnetic field under variations of the frequency, the incident angle of the incident wave, and the nanostructure geometric parameters. Many numerical methods, such as the finite element method (FEM), the finite-difference time-domain method (FDTD), or the boundary element method (BEM) [1] have been proposed to simulate the electromagnetic fields scattered from aperiodic nanostructures. However, these numerical methods are quite computationally expensive. Recently, a numerical technique called the reduced basis method (RBM) has shown great potential in rapidly solving variable partial differential equations [2, 3] and has been widely applied in areas ranging from mechanics [4], fluid dynamics [5], to electromagnetics [6, 7]. In this work we focus on rapid and accurate calculations of electromagnetic scattering over dielectric nanostructures with varying parameters including the frequency, the incident angle, and the nanostructure geometric parameters. For solving problems with multiple homogeneous domains separated by predetermined boundaries, the BEM is probably the best candidate because it assigns and limits the unknown variables only on the boundaries. When further combined with the RBM, the enhanced performance can be expected for applications involving repeated calculations of electromagnetic scattering over an object which consists of multiple homogeneous regions separated by variable boundaries. In our combined BEM-RBM approach, we firstly select a number of so-called snapshots from the space of variable parameters, and establish offline a reduced basis space from BEM solutions corresponding to the snapshot parameters. By means of projecting both the electromagnetic field vectors and the BEM operators to the reduced basis space, the computationally large linear system of BEM is converted to a much smaller system that can be solved rapidly. The key to such a reduction is the affine decomposition of the BEM operator which divides the whole computation into a parameter-dependent time-consuming offline part and a parameter-independent computationally rapid online part. In this work, we will use the empirical interpolation method (EIM) to realize such affine decomposition. By varying the geometric parameters of the nanostructure, we are able to identify an affine mapping from a predetermined reference configuration to other actual configurations. Such mapping converts computation based on the actual configurations to the reference configuration, and hence avoids repeated meshing for different configurations. Practical numerical simulation shows that the efficiency of this BEM-RBM method is several ten times higher than that of the traditional BEM method.

Whistler Modes Guided by Enhanced Density Ducts in a Nonresonant Magnetoplasma

O. M. Ostafiychuk, **V. A. Es'kin**, **and A. V. Kudrin**
University of Nizhny Novgorod, Russia

Abstract— We consider axisymmetric waves guided by a cylindrical duct with enhanced plasma density in a magnetoplasma in the nonresonant region of the whistler frequency range. The overwhelming majority of theoretical studies on the subject deal with waves guided by density ducts in the resonant region of this range, which lies above the lower hybrid frequency and is characterized by the presence of an unbounded branch of the whistler-mode refractive index surface [1–3]. As to the whistler waves in the range below the lower hybrid frequency, when the magnetoplasma is nonresonant and the whistler-mode refractive index surface is closed, their guided propagation in density ducts has received little attention in the literature. Note that the interest in the behavior of whistler waves in the nonresonant magnetoplasma was stimulated in the past decade by experimental studies aimed at developing efficient methods of wave excitation in the indicated frequency interval [4].

We first consider a sharp-walled uniform cylindrical duct aligned with an external static magnetic field and surrounded by a homogeneous background plasma. Satisfying the continuity conditions for the tangential electric- and magnetic-field components at the duct surface, we obtain the dispersion relation that allows determining the propagation constants of the guided whistler modes. It is established that in the chosen frequency region, eigenmodes exist only in ducts with enhanced density. It is demonstrated that such eigenmodes allow a simplified description which significantly facilitates analysis of the features of their guided propagation. The description is based on that the corresponding modes have quasi-TE polarization. Using this fact, we have derived an approximate dispersion relation which gives mode propagation constants that are almost identical to those obtained from a rigorous dispersion relation. Then we analyze the propagation of axisymmetric whistler eigenmodes guided by a smooth-walled enhanced density duct in a nonresonant magnetoplasma. The possibility of a simplified description of these modes due to the extremely small value of the longitudinal component of their electric field inside and outside the duct has been demonstrated as well. It is shown that in this case, analytical results for the propagation constants and field structures of the eigenmodes can be obtained under certain conditions. The developed simplified description of the studied modes can assist in analysis of the features of their excitation by electromagnetic sources.

Application and Efficient Evaluation of Half-line Source Potentials and Their Derivatives

F. Turker Celepcikay[1], **D. R. Wilton**[2], **and D. R. Jackson**[2]

[1]Electrical and Electronics Engineering, Turgut Ozal University, Ankara, Turkey

Abstract— Recently, in many applications including microwaves, optics, metamaterials and nanostructures, one- or two-dimensional periodic structures in layered media are being utilized. For this reason, the fast and accurate evaluation of periodic mixed-potential Green's functions in layered-media has become a very important problem. A typical strategy for acceleration involves identifying and removing the asymptotic terms in the spectral sums that correspond to a periodic array of point sources in an infinite homogeneous medium. The removed terms are added back to the spectral sums after utilizing the Ewald transformation which results in a Gaussian decay. This extraction not only accelerates the convergence of the spectral sum, but also creates a "regularized" Green's function that is much smoother as a function of spatial coordinates, and hence is much easier to interpolate.

For some of the dyadic and scalar components of the Green's function the asymptotic extractions from the spectral sums correspond in the spatial domain to an infinite periodic array of half-line sources in a homogenous medium. The potentials from these sources may also be regularized within a unit cell by removing the contributions from the individual (non-periodic) half-line sources located at the corners of the unit cell. Another interpolation can then be applied to the "regularized extracted potential". Based on recent analysis, a speed-up factor of over 20 is observed when using interpolation, for which the major cost is the evaluation of the singular terms including the potential of the half-line source. Therefore, an efficient evaluation of the scalar Green's function (potential) due to a single half-line source is a key element in the efficient calculation of the periodic layered-media Green's function.

The half-line source is shown in Fig. 1, where it is assumed that the tip of the source is at $z = 0$. This potential depends only on two variables, $k\rho$ and kz, where $k = 2\pi/\lambda$, i.e., on the electrical distances from the source axis and source tip, respectively, as illustrated in Fig. 1.

The potential is given exactly as

$$G_z = \int_z^\infty \frac{e^{-jkR}}{4\pi R} dz'' = \int_0^\infty \frac{e^{-jkR}}{4\pi R} dz'' - \int_0^z \frac{e^{-jkR}}{4\pi R} dz'' = \frac{1}{8j} H_0^{(2)}(k\rho) - \int_0^z \frac{e^{-jkR}}{4\pi R} dz''. \qquad (1)$$

where $R = \sqrt{\rho^2 + (z - z')^2}$ and $z'' = z - z'$.

Methods and Results: The potential the half-line source expressed in Eq. (1) can be efficiently evaluated in various ways, with the efficiency of the method depending on the location of the observation point. In this research, we examine several different methods, and find that each one is more efficient than the others in a certain region of the (ρ, z) plane.

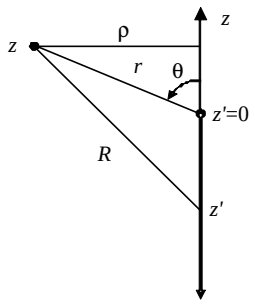

Figure 1: Half-line source that lies along the negative z axis, with the relevant coordinate system and geometrical parameters defined.

Hybrid TEM Wave Radiation from a Coaxial Waveguide with a Semi-infinite PEC Outer Cylinder and an Infinite Inner Cylinder Loaded with Partial Impedance

Abstract— The geometry of the problem is depicted in Fig. 1. The system consists of two coaxial cylinders the inner of which is infinite and has piecewise surface impedance while the outer cylinder is infinitely thin, semi-infinite and has a perfect electrical conductor surface. An incident TM_{00} (Hybrid TEM) mode travelling in the positive z direction is confined between the inner and the outer cylinders. The dimensions of the structure are chosen to satisfy the condition that only the dominant mode propagates inside the waveguide. The radius of the inner cylinder is a while the radius of the outer cylinder is b. For the sake of generality we assume that the sureface impedances of the inner cylinder where $z < 0$ and $z > 0$ are different from each other and denoted by $Z_1 = \eta_1 Z_0$ and $Z_2 = \eta_2 Z_0$, respectively, with Z_0 being the characteristic impedance of the free space. The aim of this work is to determine the effect of the relative surface impedances and the radii of the cylinders on the reflection coefficient and the radiated field. Being a very good model for long monopole antennas or traveling wave antennas, it important to analyze such structures.

The problem has been defined as a Wiener-Hopf equation by applying Fourier transformation to the scattered field and to the boundary conditions. The scattered field inside the waveguide has been expanded to series in terms of waveguide modes and the solution of the problem has been obtained by using the continuity conditions for the electromagnetic fields and transforming the problem into three sets of infinite algebraic equations containing three sets of infinite constants. The effects of the geometrical parameters and the impedances of the waveguide to the radiated field and the reflection coefficient has been observed.

One Way Speed of Light and Why Nothing Can Be Faster Than Light

V. N. Matveev and O. V. Matvejev
Homo Sapiens Publishers, Vilnius, Lithuania

Abstract— Einstein's theory of clock synchronization is based on an arbitrary assumption of the equality of the speed of light in opposite directions and on experimental data on the constancy of the average speed of light on the way "there and back". All experiments to measure the speed of light were conducted by measuring it with just one clock and calculating the time of signal propagation on the way to the reflector and back. All methods, including the method of astronomical observations used by Roemer, yield an average value of the speed of light in opposite directions.

Brillouin wrote: "... the rule says that signals propagating from east to west and from west to east have the same speeds, whereas Michelson's experiment only allows measuring the simple average of these two speeds ...".

Does it mean that the speed of light from west to east or reverse cannot be measured at all?

The fact that such measurement is possible and that it does not require prior synchronization of two spatially separated clocks may be deduced from the following.

Let us imagine that a short-wave radar is stationed close to the city of Quito, sending a narrow-angle signal in the east direction. Let us also imagine that all over the equator line a great number of reflectors are stationed in such a way that any of the adjacent reflectors is within the field of vision from another. Let the reflectors deflect the radar signal emitted in Quito in such a way that it, propagating zigzag-wise near the Earth's surface, circles the Earth along the equator, coming back to the radar in Quito from the west.

Knowing the length of the zigzag line along which the radar signal propagates and the time needed for signal to circle the Earth, an operator of a radio relay station can calculate the propagation speed of the signal circling the Earth from east to west or reverse. These speeds will not be identical to the constant C.

It is known that the velocities of material bodies cannot achieve the speed of light in a vacuum. Why does the speed of light, being finite, behave as if it is infinite and is therefore unattainable for materials bodies?

In our presentation a possible cause of the finiteness of the velocity of tangible objects is demonstrated without reference to the provisions of the special theory of relativity. A condition is formulated on the basis of which the assumption of the movement of tangible objects at any prescribed velocities proves to be self-contradictory in instances when the prescribed velocities of the objects exceed a certain value.

This condition consists of the presence of interaction signals and carrier particles in material bodies that are propagated at a velocity greater than any prescribed velocity of the material bodies. The condition does not contain a limitation of the velocity of tangible objects, but also does not contradict it. The condition is as follows: *"Massles signals and particles that are always present in material objects are propagated at a velocity, V, that is unattainable for physical objects and particles that do have mass, continuously initiate interactions and processes in these bodies".*

Experimental and Numerical Analyses of Leakage Flux Distribution in Core-type Voltage Transformers

Fevzi Kentli[1], **İsmail Bozkurt**[2], **and Nevzat Onat**[2]

[1]Faculty of Technology, Marmara University, Turkey
[2]Vocational School of Technical Studies, Marmara University, Turkey

Abstract— Recognition of the flux distribution in machines is required for three reasons: 1) for measurement of the inductances, 2) for measurements of the forces applied to the coils, and 3) for measurements of the additional losses that occur in the coils and steel parts. The analog form can be used to determine the flux distribution in the machines and the magnitudes related to the magnetic field. However, numerical methods for measuring these factors are desirable, as analog methods are difficult and inefficient. Today, several methods are used for field analysis. The finite different (FDM) and the finite element (FEM) methods are two of the main methods used in this area. This study is based on the leakage magnetic flux analysis of a core type transformer. The distributions obtained experimentally were verified with two-dimensional FDM and FEM calculation results to verify them. A special test assembly for obtaining actual measurements at different heights was installed. The experiment set included a voltage transformer and measurement coils that were used to determine leakage flux distribution around a transformer iron leg. With the solution of the matrix created by measuring the induced voltage, polynomial mathematical equations were obtained. The flux values were then calculated in accordance with the numerical methods. In order to compare the results, plotting of the flux distribution was the best solution, and for this purpose, the total flux lines were determined. In addition, the difference between the smallest and largest value of the vector potential was also determined. The voltage (potential difference) vector was calculated by dividing the difference between the flux lines. In the last step, the equipotential points were determined by adding to the minimum potential value. This process was repeated using eight different heights on the leg, and the two-dimensional coordinates of the equipotential point were determined at each height. By combining the same valuable points, flux distribution was obtained graphically. Finally, fluxes were drawn in line with the measurement and calculation results and were compared with each other. As a result, the leakage flux distribution of the voltage transformer was obtained, and it was observed that the FEM model succeeded in calculating closer values to the measurement results. According to the study results, the use of measurements from several points taken by means of magnetic field probes in the FEM model provides sufficient accuracy solutions. The degree of the polynomial used in the FEM method will increase the accuracy rate. By increasing the degree of the polynomial used in the FEM method, more accurate results can be achieved.

[4]Department of Applied Physics, Aalto University, Espoo, Finland

Abstract— Progress in present-day electromagnetics research happens very much on boundaries where other disciplines are encountered. Metamaterials, nano-optics, and plasmonics are some of the domains into which many classical electromagnetics experts focus their interest these days. Indeed, with traditional Maxwell-based mathematics and computational tools it is possible to analyze and understand very much of the fascinating physical phenomena that take place when light and electromagnetic radiation interacts with complex nanomaterial structures.

Volume plasmons in metals are oscillations of the electron cloud. The boundaries in discrete particles constrain these oscillations, resulting into various modes of localized particle plasmons [1]. In this presentation, we discuss the varieties how the properties of plasmonic resonances depend on the morphological and topological features of nanoparticles. It turns out that using fairly simple quasistatic analysis of the electric field interaction with a particle inclusion [2] whose dielectric function follows a Drude model, the main resonant features of these particles can be predicted satisfactorily for particles below 30 nm size. The material used in computations is silver [3], and the interesting physics happens within the optical wavelengths. Among these effects are redshifting (and sometimes also blue-shifting) of resonances, variation in their magnitudes, and differences in the behavior of scattering, absorption, and extinction efficiencies when the shape, structure, and dielectric contrast against environment varies. It is to be noted that the region of validity is of course bounded also from below: the classical description fails when the particle size goes down to a few nanometers where quantum effects can no longer be neglected.

For the analysis of larger and complex-form composite scatterers, we use other computational tools capable of full-wave simulation: surface- and volume-integral-equation, and discrete-dipole approximation based codes. This research is a result of the EXPECTS project within the framework of Aalto Energy Efficiency Research Programme.

Structured Metals Transparency for Ultrabroadband Electromagnetic Waves and Acoustic Waves

Ru-Wen Peng, **Ren-Hao Fan**, **Dong-Xiang Qi**, **Xiao-Ping Ren**, **and Mu Wang**
National Laboratory of Solid State Microstructures, Department of Physics
Nanjing University, Nanjing 210093, China

Abstract— In this talk, we present our recent work on making structured metals transparency for ultrabroadband electromagnetic waves and acoustic waves via surface excitations. First, we show that periodic, quasiperiodic, and disordered metallic gratings can become transparent and completely antireflective for extremely broadband electromagnetic waves at oblique incidence. Second, we significantly develop oblique metal gratings transparent for broadband electromagnetic waves (including optical waves and terahertz ones) under normal incidence. In the third, we present that the principles of broadband transparency for structured metals can be extended from one-dimensional metallic gratings to two-dimensional cases. Moreover, similar phenomena are found in sonic artificially metallic structures, which present the transparency for broadband acoustic waves. These investigations provide guidelines to develop novel broadband metamaterials, and have potential applications on transparent conducting panels, antireflective conducting solar cells, broadband acoustic imaging and sensing, and so on.

Properties of Optical Cavities Made of Metamaterials

Haitao Jiang, Yunhui Li, and Hong Chen
School of Physics, Tongji University, Shanghai 200092, China

Abstract— Metamaterials with engineered permittivity ε and permeability μ have attracted people's great interest due to their unique electromagnetic (EM) properties. In this talk we will discuss our recent studies on properties of optical cavities made of metamaterialssuch as the artificial medium with zero index (ZI) and with special dispersion coming from the classical analog of the electromagnetic induced transparency (EIT) phenomenon. It is known that an optical cavity is one of basic devices for light manipulation and novel properties are required for modern applications. For example, requirement of strong coupling in cavity quantum optics need to put a quantum dot right at the cavity field peak, which is very challenging for a cavity made of ordinary optical materials because of inhomogeneous distribution of the cavity field. To overcome this difficulty, we propose to get uniform field distribution in a cavity made of ZI metamaterilas, then realize experimentally position-independent quantum optics phenomenon such as Rabi splitting. On the other hand, in some applications, one needs an optical cavity with both high quality factor (Q) and high transmittance (T). In a conventional cavity, stronger confinement of the cavity field can boost Q, at the cost of T decreasing as stronger scattering loss is involved. To reduce scattering loss, a cavity made of an EIT-like metamaterial is introduced, where Q is enhanced by the mechanism of special EIT dispersion, instead of confinement effect. Enhancement of Q while keeping T unchanged is illustrated experimentally.

Effective Medium Approach to Compute Optical Stress

Wujiong Sun[1, 2], **Jack Ng**[3], **Lei Zhou**[2], **and C. T. Chan**[1, 4]

Abstract— Light can exert a force on material objects, which may be computed by a surface integral of the Maxwell stress tensor over a surface that encloses the entire object. However, it is also highly desirable to know the optical stress (e.g., to deform a cell). In principles, the stress can be given by the divergence of the stress tensor. Unfortunately, there are still controversies in what is the appropriate stress tensor inside a medium.

Consider an artificial effective medium, for example, consisting of a periodic or random array of dielectric cylinders with sub-wavelength cylinder size and lattice constant. The stress will be calculated by two methods. The first method is a rigorous but slow microscopic approach where the stress is defined as the force per unit area, and the force can be computed by Maxwell stress tensor. The second method is a very efficient effective medium approach where the cylinder array is treated as an effectively homogeneous medium and the stress for that effectively homogeneous medium is calculated directly using the divergence of three commonly employed stress tensors. It turns out that only the stress tensor derived from free energy, which takes into account the electrostriction, gives consistently correct results. In other words, MST and its "macroscopic generalization" have failed.

Situations other than dielectric cylinders will also be discussed. More examples with different composition and lattice structures will be considered.

Slowing Microwaves with Deeply Subwavelength 3D Printed Metamaterial Waveguides

N. Kaina[1], **A. Causier**[2], **M. Fink**[1], **T. Berthelot**[2], **and G. Lerosey**[1]

[1]Institut Langevin, ESPCI Paris Tech, France
[2]CEA Saclay, IRAMIS, NIMBE, LICSEN, UMR 3685, F-91191 Gif sur Yvette, France

Abstract— We study resonant wire media that are scaled at very subwavelength scales. We show that introducing local defects permits to guide the waves with a transverse confinement of the order of one period in any direction, independently of the spatial organization of the medium. We prove that the propagation within these waveguides exhibit a very low group velocity that can be tuned by modifying the geometrical and frequency parameters of the neighboring wires. We present simulation and experimental results of 3D printed polymer copper coated waveguides.

Slowing down the waves is one stake of time-signal processing, signal energy compressing, wave-matter interaction enhancements and device miniaturization. This can be achieved using strong material dispersion, for example very high index media, or with engineered systems such as photonic crystals waveguides (PCW) or coupled resonator optical waveguides (CROWS). If those are valid solutions for optical signals, photonic crystal based systems become very bulky for microwaves and telecommunication signals. In previous work [1], we demonstrated that is was possible to steer waves at scales independent of the wavelength in a deeply subwavelength wire-medium metamaterial by locally introducing defects whose frequency lie in the hybridization bandgap of the metamaterial. Whithin those waveguides, the wave tunnels from one defect to its neighbour thus providing a very low group velocity propagation as in photonic crystals. Contrarily to PCWs however, our waveguides can have arbitrarily small transverse dimensions, solely limited by the size the wires.

Using the 3D printing technology along with chemical copper plating process we were able to fabricate waveguides embedded in a wire medium with periodicities down to 2 mm ($\lambda_0/30$ at 5 GHz). We first show that our waveguides can exhibit an almost 0 dB transmission provided that an appropriate feeding is used. We then investigate the influence of the surrounding medium on the group velocity of a pulse propagating in the waveguide and as well as the shape of the dispersion relation within the transmission band (Fig. 1). We especially experimentally demonstrate that by decimating the medium density by a factor 3.5, the group index can be tuned from $n_g = 65$ up to $n_g = 230$.

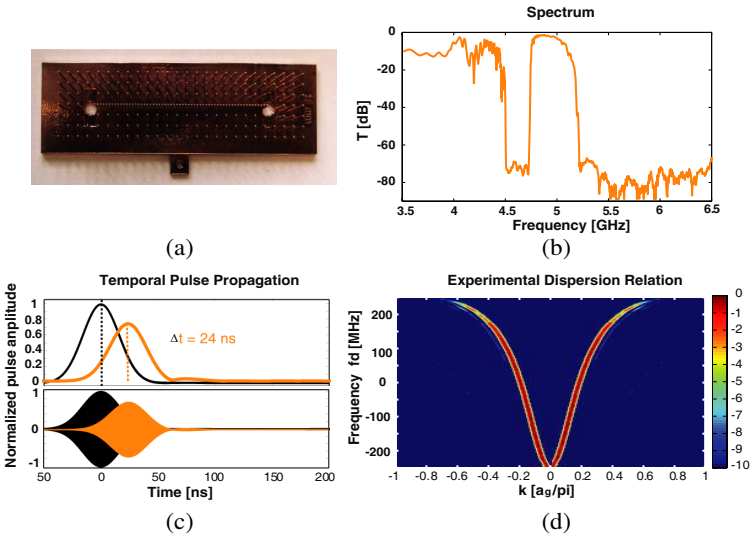

Figure 1: (a) 3D printed copper coated metamaterial waveguide. (b) Experimental spectral transmission (dB). (c) Temporal pulse emitted (black) and recieved after propagation (orange). (d) Experimental dispersion relation in the waveguiding transmission band.

We believe that our deeply subwavelength slow propagation waveguides in the microwave frequencies are promising candidates for the miniaturization of delay lines, filters, multiplexers as well as for more fondamental wave-matter enhancement studies.

Abstract— Light beams propagate along shortest paths by the Fermat principle, diffracting and broadening as described by the proper wave equation. The behavior of electromagnetic waves in static curved space is exactly analogues to that in inhomogeneous media, were the change in refractive index plays the role of the curvature. The space curvature affects the trajectories and the diffraction rate of light beams causing a unique behavior which can be emulated in an optical system by engineering the optical properties of a material. Here we experimentally demonstrate collimation of a beam in homogenous media for an order of magnitude more than the diffraction length, created after passing through a predesigned refractive index. The refractive index profile is analogues to a curvature of some massive star enabling observation of Einstein's Rings caused by the gravitational lensing as predicted by Einstein in 1936.

Effective Model for Plasmonic Coupling: Theory and Experiments

Meng Qiu, **Bin Xi**, **Shiyi Xiao**, **Hao Xu**, **Shulin Sun**, **Qiong He**, **and Lei Zhou**
State Key Laboratory of Surface Physics and Key Laboratory of Micro and Nano Photonic Structures
Fudan University, Shanghai, China

Abstract— Plasmonic couplings between nanoparticles generate fascinating physical phenomena, which can be utilized to realize certain applications [1, 2]. However, theoretical understandings on such problems are relatively behind experimental developments. Most theoretical efforts are based full wave simulations, which are not only computational complicated but also physically less transparent [3]. A complete effective model accounting for both electric and magnetic dipole terms in plasmonic nanoparticles, derived from a rigorous ground, is highly desired and is the key motivation of present work [4].

Based on the generalized tight-binding method for dispersive photonic media [5] and a multiple-expansion technique, we derived an analytical model for plasmonic coupling coefficient $t_{1,2}$ between two NPs, which includes all interacting terms between electric and magnetic dipoles of the NPs,

$$t_{1,2} = t_{pp} + t_{pp}^{rad} + t_{pm} + t_{mm} \tag{1}$$

where

$$t_{pp} = (f_0/8\pi\varepsilon_0 \langle\Phi|\Phi\rangle) \cdot \left[\vec{p}_1^{\,*} \cdot \vec{p}_2 - 3\left(\vec{p}_1^{\,*} \cdot \hat{d}\right)\left(\vec{p}_2 \cdot \hat{d}\right)\right]/d^3 \tag{2}$$

and

$$t_{mm} = (f_0\mu_0/8\pi \langle\Phi|\Phi\rangle) \cdot \left[\vec{m}_1^{\,*} \cdot \vec{m}_2 - 3\left(\vec{m}_1^{\,*} \cdot \hat{d}\right)\left(\vec{m}_2 \cdot \hat{d}\right)\right]/d^3 \tag{3}$$

are the standard dipolar interactions between electric and magnetic dipoles in different NPs.

$$t_{pp}^{rad} = -\left(f_0 \;/\; 16\pi\varepsilon_0 \langle\Phi|\Phi\rangle\right) \cdot (kd)^2 \cdot \left[\vec{p}_1^{\,*} \cdot \vec{p}_2 + \left(\vec{p}_1^{\,*} \cdot \hat{d}\right)\left(\vec{p}_2 \cdot \hat{d}\right)\right]/d^3 \tag{4}$$

is the electric dipolar interaction contributed from radiation effect.

$$t_{pm} = i\,(f_0/8\pi\varepsilon_0 c \langle\Phi|\Phi\rangle) \cdot kd \cdot \vec{p}_1^{\,*} \cdot \left(\vec{m}_2 \times \hat{d}\right)/d^3 \tag{5}$$

describes the interaction between electric and magnetic dipoles [4].

We performed extensive full-wave simulations [4] on particular plasmonic coupled systems to verify the effective model presented in Eqs. (1)–(5). Computations [4] show that our effective model can well describe the plasmonic coupling behaviors in general cases. In particular, when the NP is large enough so that a quasi-static approximation is no longer valid, one has to take the radiation correction term t_{pp}^{rad} into account (see Figs. 1(e)–(f)) to reasonably describe the plasmonic coupling behaviors, and the EM cross-interaction term t_{pm} is crucial to explain an intriguing mode-sequence reversal effect discovered in a particular coupled NP systems. In addition, we found that the coupling strength between certain plasmonic nanoparticles can be tuned through varying the orientations of NPs, leading to interesting phenomena such as ultra-slow-wave plasmon propagation. These intriguing phenomena have been experimentally verified in the microwave regime using split-ring-based resonators (see Fig. 1(i)) [6], and we will describe our latest THz experiments in the conference.

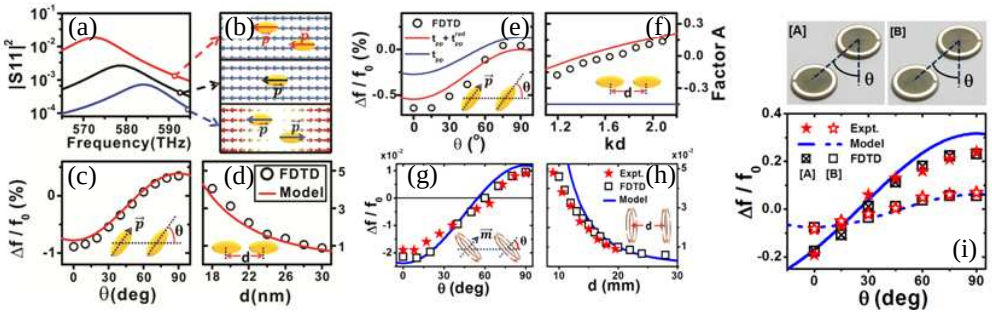

Figure 1: Simulation method to detect (a)–(b) the "Dark mode", and (c)–(i) comparisons between FDTD simulations, microwave experiments, and the effect model in different coupled systems.

Multi-layer Transmission of Spoof Surface Plasmon Polaritons

Bai Cao Pan, **Zui Tao**, **and Tie Jun Cui**
State Key Laboratory of Millimetre Waves, School of Information Science and Engineering
Southeast University, Nanjing 210096, China

Abstract— Spoof surface plasmon polaritons (SSPPs) show a low-pass transmission property with a remarkable stop frequency due to the asymptotic property of the dispersion relationship. A series of SSPPs waveguides and their applications have been reported such as high efficiency transmission, ultra-thin waveguides and active device researches. However, in order to show more potential in combining with the traditional integrated circuits and achieve new-type plasmonic circuits, the SSPPs signal needs to be transmitted between multiple layers efficiently. Here, we propose a method to transmit such surface modes from one side of the substrate to the other side efficiently. In our design, a metallic hole in layed inside the substrate is used to connect the traditional corrugated metallic strip waveguide on both sides of the substrate. The metallic hole could provide a decoupling effect near the transition parts between the two waveguide on different sides since the electromagnetic field distribution is remained. The simulation results show that our design could transmit the SSPPs wave from the top layer of the medium to the bottom layer without significant loss. On the other hand, through the modulation of the position of the metallic hole, a series of absorption peaks during the transmission frequency band appears because of the coupling in the superposition section of the two waveguides. It's simulated that such design could provide a broadband high-efficient multi-layer transmission with a controllable absorption and such absorption is only related to the superposition area of the corrugated metallic strip. Based on our design, SSPPs with ultra-short wavelength and high-confinement property are able to play a more important role in the plasmonic integrated circuits.

Electromagnetic Metamaterial Absorbers for High Temperature Applications

Wei Li[1], **Yi Wang**[1], **Urcan Guler**[2], **Wei Wang**[1], **Tianlong Wu**[1] **and Jianguo Guan**[1]

Abstract— Electromagnetic metamaterial absorbers exhibit distinct absorbing properties compared to the traditional electormagnetic absorbers, such as thin thickness, adjustable or even real-time controllable absorption, and circumstance responsible absorption [1]. These properties endow the metamaterials with important applications in sensing, stealth, electromagnetic compatibility and communications [2]. However, existing metamaterial absorbers are nearly all designed for room temperatures since they are mostly made of heat-vulnerable polymer dielectrics and low-melting-point metals such as copper, silver and gold.Those metamterials will be distructed or work improperly at temperatures no higher than 1000°C, which restricts their high temperature applications [3]. However, few research efforts are made on refractory metamaterials till now [4].

As a meaningful start, we reported a refractory metamaterial optical absorber for high temperature of more than 1000°C in solar thermophotovotaics. The broadband and polarization independent metamaterial absorber uses a plasmonic material of Titanium Nitride (TiN) instead of traditional noble metals. We measured an absorption of more than 95% in average over the entire visible spectrum (400–800 nm). The high temperature stability of the metamaterial is demonstrated experimentally. Our investigation suggests that TiN, which exhibits lower plasmonic resonant frequency and higher thermal stability than noble metals, and merges the benefits of better impedance match from bulk plasmon and losses caused by localized surface plasmon, is more favorable in broadband optical absorption.

In microwave regime, we proposed a rafractory metamaterial made of titanium boride (TiB_2) and alumina (Al_2O_3). Without the help of plasmonic resonance, the metamaterial absorber achieved a nearly perfect absorption through standing wave resonance at X band with a thickness of less than 1 mm at 1000°C. The absorption changes from around 40% to 99% with temperature rising from room temperature to 800°C. These features enable the metamaterial to be used in temperature sensing and hyper sonic aircraft stealth applications.

These two works extended the metamaterial research to high temperature and opened a path to the application of ultrathin broadband absorbers in various high temperature applications sincluding solar thermophotovoltaics (STPV).

Enhancement of Polarizabilities of Cylinders with Cylinder-slab Resonances

Meng Xiao[1], **Xueqin Huang**[1], **H. Liu**[1, 2], **and C. T. Chan**[1]

Abstract— If an object is very small in size compared with the wavelength of light, it does not scatter light efficiently. It is hence difficult to detect a very small object with light. Meanwhile, a superlens type metamaterial slab is impedance matched with background, so it is also difficult to detect with light. However, the effective polarizability of a small cylinder can be greatly enhanced by coupling it with a superlens type metamaterial slab and this is shownusing analytic theory as well as full wave numerical calculations. This kind of enhancement is not due to the individual resonance of the metamaterial slab, nor due to that of the object, but is caused by a collective resonant mode of the cylinder and the slab. The enhancement ratio is limited by factors such as the absorption of the metamaterial slab and the cylinder, and the radius of the cylinder relative to the wavelength of light. The condition of this hybrid resonance mode is derived using an analytic model where we only consider the monopole moment of the cylinder. The analytically derived condition is confirmed with full wave simulations. We find that this type of particle-slab resonance is actually closely related to the reverse effect known in the literature as "cloaking by anomalous resonance" which can make a small cylinder undetectable. We also show that the enhancement of effective polarizability of the cylinder can lead to strongly enhanced electromagnetic forces that can be attractive or repulsive, depending on the material properties of the cylinder.As the force enhancement is quite strong (four orders of magnitude) at the resonance condition, the system can behave as a light-enabled "force shield", where the energy barrier as the particle approach (or recede from) the slab is significant.

Quantum Dot Optical Frequency Comb Laser (QD-FCL) for Simultaneous Multiple-wavelength Peak Generation

Naokatsu Yamamoto, Kouichi Akahane, Toshimasa Umezawa, and Tetsuya Kawanishi
National Institute of Information and Communications Technology
4-2-1 Nukui-Kita, Koganei, Tokyo 184-8795, Japan

Abstract— High-capacity and high-speed photonic networking and device technologies are essential for constructing advanced metro/access network systems. Additionally, radio-over-fiber (RoF) systems and short-reach interconnections and/or data center networks require a large number of channels for their many port-to-port connections. Solutions that satisfy these requirements incorporate two technical components to increase the operational optical frequency range: alternative wavebands and ultrabroadband photonic devices and materials. As an alternative waveband application, we have proposed the use of T and O bands (T band: 1000–1260 nm; O band: 1260–1360 nm) because large optical frequency resources (> 70 THz) can be employed to obtain many wavelength channels in these wavebands. A semiconductor quantum dot (QD) structure is a potential candidate as an optical gain material for high-performance and ultrabroadband photonic ICT devices. The QD nanostructures also have interesting optical gain properties based on the discrete energy state of carriers, which are confined in the QDs, as shown in Fig. 1(a). By using these discrete optical gain properties of QDs, we successfully developed a QD optical frequency comb laser (QD-FCL) as a novel functional wavelength division multiplexing (WDM) light source, as shown in Fig. 1(b), for stable generation of multiple-wavelength peaks from single and compact QD gain chips. Fig. 1(c) shows typical multiple-wavelength peak generation in the T + O band with a stable optical power characteristic. It is clearly demonstrated that five-wavelength peaks can be obtained from a single QD device. We also successfully demonstrated error-free optical data transmissions using the developed QD-FCL as a multiple-wavelength optical carrier generator.

Broadband High Efficiency Asymmetric Transmission of Achiral Metamaterials

Jinwei Shi, Dahe Liu, and Wenjun Fan
Applied Optics Beijing Area Major Laboratory, Department of Physics
Beijing Normal University, Beijing 100875, China

Abstract— Asymmetric transmission (AT) effect has attracted great interest in recent years, due to its potential application in integrated photonics from GHz to optical frequency. To realize AT effect, numerous metamaterials have been proposed, mainly based on the chirality of the structure. In this paper, we demonstrate that achiral metamaterials can also have AT effect. Furthermore, it is shown that modal conversion is more essential than chirality to achieve AT effect. In particular, we have proposed a mirror symmetric metamaterial with broadband high efficiency AT effect for circular polarization wave operating at THz region. With further optimization of the unit cell, $> 80\%$ of the central frequency bandwidth and average 74.05 (maximum 150) transmission ratio can be obtained. The idea demonstrated here can also be applied to other frequency regions and the development of linear polarization devices.

Analysis of EM Shielding Effectiveness of CNT Films Based on TEM Cell Electric and Magnetic Coupling Fields

[2]Electronics and Telecommunications Research Institute, Korea

Abstract— In this paper, we evaluated the electromagnetic (EM) shielding effectivenesses (SEs) on various CNT-based films which are prepared with deposits densities and thicknesses of the carbon nanotubes (CNTs) films. The test environment based on a TEM cell is adapted for a comparison of the standard ASTM test and the near-field test using electric and magnetic coupling fields and differences of CNT films' SEs on electric field and magnetic field according to near end or far-end tests by the rotations of a microstrip patch antenna as a DUT. In addition, the effect of CNT's composites and their film thickness on the SEs are investigated with TEM cell electric and magnetic field coupling to the DUT.

Figure 1 shows the test environment and measured EM SEs according to composites and thicknesses of CNT films. The antenna as an EM source is devised with a 2-layers PCB and the test repeats four times in the 0, 90, 180, and 270 degrees. The SEs are calculated with the equations as follows, $\mathrm{SE}\,[\mathrm{dB}] = P_1\,[\mathrm{dBm}] - P_2\,[\mathrm{dBm}]$ where P_1 and P_2 mean the transmitted power without and with that of CNT-film shielding, respectively. Measured SEs shows that EM powers are more reduced with increasing CNT composites than film thickness. Also a comparison of the standard ASTM test and the near-field test at the antenna rotation of 90 degree shows similar measured results. The tests with 0 or 180 degrees, however, show the different results between those of ASTM tests and the near-field test. The measured SEs of CNT films at 0 and 180 degrees are very lower levels than those of 90 and 270 degrees because the eddy currents on CNT films give the additional magnetic coupling effect. The 4 rotated test results can be explained as CNT films don't effectively prevent magnetic fields but CNT films can reduce electric fields. Also, the SE characteristics of CNT films are changed according to CNT composites and maximized SE peak points moves low frequency to high frequency as the CNT composites are increasing. The SE levels are changed, but the maximized SE peak doesn't change according to thicknesses of CNT films.

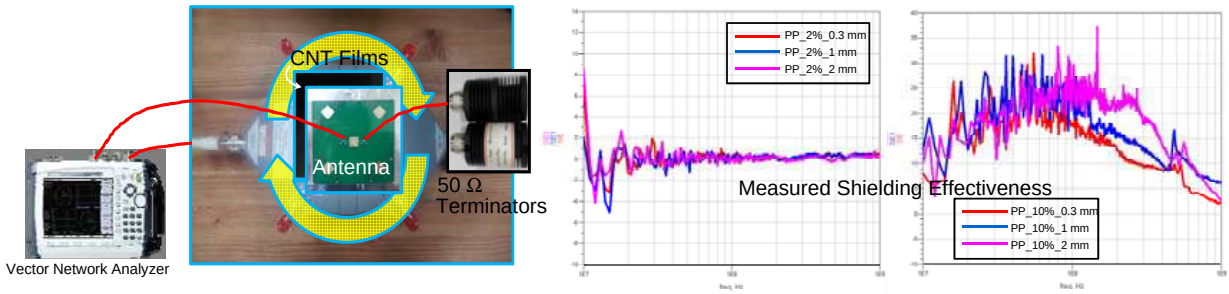

Figure 1: Test Environrmnt and measured EM SEs according to densities and thicknesses of CNT films at antenna rotation of 90 degree..

Manipulating Electromagnetic Waves Based on Magnetic Plasmonic Gradient Metasurface

Abstract— Molding the electromagnetic features of spatially propagating waves or the propagating surface waves is considerable important due to its significant importance for scientific exploration and technological advancement. Photonic crystals and metamaterials are the typical candidates to tailor the photonic dispersions by introducing, respectively, the wavelength-scale periodic structures and the subwavelength resonant building blocks. A great quantity of exotic phenomena and potential applications are realized based on the concept of photnic crystals and metamaterials. Nonetheless, due to the size mismatch of the photonic crystals based circuits and the electronic integrated circuits, an inevitable deficiency comes into appearance for the integration compatibility of photonics and electronics. Although metamaterials can manipulate photons at subwavelength scale, the loss is still an inherent disadvantage owing to the resonating nature of the building blocks.

The recent emerging "flat optics" offers an alternative way in engineering optical components, which is capable of circumventing the essential issues obstructing the development of PCs and metamaterials such as strong loss, high cost, and even integration compatibility. It enables full control of the electromagnetic waves via engineering the amplitude, phase, and polarization of photons. In this presentation, we provide a newly designed gradient metasurface made of ferrite materials, quite different from the previous design with dielectric and metallic composite structures. Due to the time reversal symmetry breaking nature of the magnetic system under an external magnetic field, unidirectional magnetic surface plasmon can be excited, resulting in the construction of gradient magnetic plasmonic metasurfaces (GMPMS). We demonstrate that a remarkably enhanced unidirectional coupling of a Gaussian beam to the GMPMS with the coupling efficiency about 80 percent can be realized. The underlying physics lies in that the dispersion features can be tailored by optimizing the gradient of the GMPMSs, which strongly reinforces the interaction between the photons and GMPMSs, resulting in the excitation of unidirectionally guided edge states.

Thermal Imaging of RF Induced Heat Loss in a Microwave Metamaterial Absorber

Abstract— Metamaterial absorbers (MAs) play an important role in stealth technology in microwave bands. Although MAs absorbs incident RF power, they usually convert it into the heat which might be a disadvantage for counter-measurement against remote thermal imaging systems. In this study, we present the design, simulation, fabrication and RF/thermal imaging measurement of a narrowband MA absorber in the microwave region. MA consists of a two dimensional periodic array of a well-known metallic split ring resonator (SRR) and a ground plane separated by a dielectric layer. It is found that the RF simulation results are in good agreement with the measurements such that near-perfect absorption occurs at 4.75 GHz when the incident electric field vector is perpendicular to the SRR gaps. On the other hand, near-zero absorption is obtained when the incident electric field vector is parallel to the gaps. Thermal imaging of these two cases are carried out using a commercial thermal imager which has a longwave infrared sensor between 8–12 μm wavelengths. Surface temperature map of the MA are extracted from the recorded thermal images of the MA at these two cases. It is shown that a slight temperature difference happens with respect to the ambient temperature for the MA of the near-perfect absorption whereas the MA of the near-zero absorption has zero temperature difference. Physical mechanisms of the RF absorption and the RF induced heat loss are explained using further electromagnetic numerical simulations and heat transfer model. Results are going to be presented and discussed in the conference paper.

Plasmonic Switches

J. Leuthold, **A. Emboras**, **W. Heni**, **C. Hoessbacher**, **C. Haffner**, **Y. Salamin**, **P. Ma**, **Y. Fedoryshyn**, **and Christian Hafner**
Institute of Electromagnetic Fields (IEF), ETH Zurich, Zurich 8092, Switzerland

Abstract— Plasmonic modulators and switches have attracted considerable attention because they offer ultra-compact size in the order of a few micrometers, high speed with bandwidths in the order of THz and potentially low power consumption in the order of a few fJ/bit. However, the debate as of which concept is most efficient is ongoing and it ultimately might depend on the application as of what concept might be most advantageous. In this review we shed light on some of the recent findings and try to categorize the various mechanisms.

An ideal optical switch should feature a small footprint, offer high speed operation and operate with the least possible power consumption. However, to this day, optical switches have relatively large footprints compared to λ and are not really power efficient nor can they achieve THz bandwidths.

More recently, plasmonics has emerged as a potential solution to some of those issues [1–10]. Plasmonic waves can be confined to sub $100\,\mathrm{nm}^2$ dimensions, which offers a way to build devices with footprints of $\mu\mathrm{m}^2$ and to take advantage of strong nonlinearities that are a direct consequence of the ultra-compact confinement. More recently the first high-speed plasmonic devices have emerged [11, 12].

In this paper we review waveguide structures and concepts to build optical modulators. We will discuss plasmonic devices based on the thermo-plasmonic effect [1], the free carrier dispersion effect [8, 13, 14], the Pockels effect [11, 12, 15], the phase-change effect [16–18] and the electro-chemical metallization effect [19, 20]. We will then compare them with respect to speed, power efficiency and footprint.

Electromagnetically Induced Transparency Analogy of Metamaterial

Fuli Zhang, **Xuan He**, **and Yuancheng Fan**
Key Laboratory of Space Applied Physics and Chemistry
Ministry of Education and School of Science
Northwestern Polytechnical University, Xi'an 710072, China

Abstract— Recent research reveals that elaborately controlling microstructure coupling effect between neighboring elements enables metamaterial to exhibit not only frequency shift but also an analogy of electromagnetically induced transparency (EIT) of classical quantum effect of atomic system. To resemble classical quantum behaviour, various metamaterial based approaches including "trapped mode" and destructive interference between bright and dark (superradiant or subradiant) resonators were developed.

In the first part, we investigated coupling effect of asymmetric SRR metamaterial dimer whose elements differ from magnetic resonance frequency. An electromagnetically induced transparency (EIT)-like transmission spectrum with one transparency peak located between two dips is observed. Due to interplaying effect between asymmetric SRRs, a steep normal phase occurs, resulting in an enhancement of group delay with respect to SRR alone. Furthermore, local field demonstrates a suppressed mode formed by opposite local magnetic dipoles of two SRRs can explain the underlying physics.

To produce different dissipation loss between magnetic resonance elements, barium strontium titanate (BST) and calcium titanate ($CaTiO_3$) are chosen as the bright and dark EIT resonators, respectively, due to their different intrinsic dielectric loss. Under incident magnetic field excitation, dielectric metamaterial exhibits an EIT-type transparency window which is accompanied by abrupt change of transmission phase.

At last, instead of electromagnetically induced transparency, analogy effect of electromagnetically induced absorption (EIA) will be addressed. An EIA effect is observed inside a metal/dielectric hybrid microstructure. Meanwhile, an enhanced group delay of more than 20 ns for X band is verified experimentally and numerically.

Abstract— The acquisition of neural signals has received significant interest from the neuroscience research community very recently. Usually, the micro-electrode array is used to acquire electric signals from neurons and transmits them to multichannel micro-electronic recording systems for amplify, filter, and digitization. Since the number of the electrodes should be affirmatively much larger than the number of recording channels, the multiplexer is necessary in such systems. An analog integrated multiplexer and a bootstrapped switch as an indispensable element for the input analog interface of multi-channel neural signal recording system in a 0.5 μm CMOS process is presented in this situation. Considerable attention is paid to low distortion performance of the multiplexer as it is the importance part delivering the amplified neural signals to the analog to digital converters. However, most switches suffer from the distortion of passing signals from the non-ideality of the MOS transistor. Bootstrapped switch is attractive as a circuit technique to alleviate the poor conduction and varying on-resistance of many traditional switches such as single MOS transistor switch or complementary MOS transistors pair switch. In this article, the bootstrapped switch is improved to suit the specific environment, which satisfies the requirements of constant clock feed-through, constant charge injection, and compensation for body-effect. Meanwhile, the switch remains the practicability for less increase in complexity. An exemplary 4-channels analog multiplexer is constructed based on the proposed bootstrapped switch for verifying the effectiveness of the optimization. Analysis and discussion follows the simulation results, which show a higher linearity comparing the proposed switch to the conventional bootstrapped switches.

A 2 GSps 8 bit Folding & Interpolation ADC in 90 nm CMOS Technology

Abstract— High-speed (GSps), medium-resolution (6∼8 b) analog-to-digital converters (ADCs) are essential in realizing multi-Gbps communication systems. They are also required in some other applications, including radar, satellite, and test instruments. However, increased devices mismatch, decreased supply voltage prevent current GSps single-channel CMOS converters from being extended to 8-bit. Flash- and folding-ADCs are the primary candidates for GSps applications due to high conversion speed and low latency. As the flash architecture requires $2^N - 1$ comparators for N bits of resolution, resulting in area and power costs, folding-ADC becomes the best choice as it can simplify the circuit while maintaining the same conversion speed as flash.

A single channel 2 GSps, 8 bit folding and interpolation (F&I) ADC with digital assisted calibration designed in TSMC 90 nm CMOS technology was presented in this paper. The ADC utilized cascaded folding architecture, which incorporated an additional inter-stage sample-and-hold amplifier between the folding circuits to enhance the quantization time. A pipelined track-and-hold amplifier (THA) with bootstrapped switch was taken as the front-end THA. To improve the stability of THA's hold-mode voltage, the sub-threshold charging problem was found and the improved pre-amplifier was taken instead of the normal one. The foreground digital assisted calibration was also employed in this design to correct the error of zero-crossing point, thus to improve the linearity of the ADC. Chip area of the whole ADC including all pads is 930 µm × 930 µm. Post simulation results demonstrate that under a single supply of 1.2 Volts, the ADC costumes 210 mW. For the clock of 2 GHz, the signal to noise and distortion ratio (SNDR) is 45.93 dB for Nyquist input signal frequency.

10 bit 100 MS/s SAR ADC with Reduced Loop Delay

Dong Li[1], **Qiao Meng**[1], **Linfeng Wang**[1], **Yi Zhang**[2], **and Wenwei He**[1]

[1]Institute of RF- & OE-ICs, Southeast University, Nanjing, China

Nanjing University of Posts and Telecommunications, Nanjing, China

Abstract— This paper proposes a novel logic control scheme to reduce successive approximation (SA) loop delay of the successive approximation register (SAR) analog-to-digital (ADC). The propagation delay in the SA loop is one of the dominant speed limiting factors, it can be reduced to improve the conversion operation of the SAR ADC. The key path of the SA loop is from the start of the comparison to the completely settlement of the DAC. In the proposed SAR ADC, the regeneration of the comparator and the operation of the shift register and the switch-driving register (SDR) are simultaneous. When the comparator control clock (CLKC) triggers the comparator to be in regeneration phase, it also triggers the shift register to generate multi-phase clocks for SDR. Then the SDR is turned on. Thus, the comparison results of the comparator are directly transmitted to determine charging or discharging the DAC capacitor array before the next comparison without waiting for the completion of the comparison. Compared with the conventional SAR ADC, the valid signal of the proposed technique is only used to pull-down the corresponding-phase clock to low and is not in the key timing path. So the propagation delay of the key path of the SA loop is shortened in the proposed SAR ADC. In addition, a novel SDR is proposed to further improve the conversion speed. The input of the SDR is the output of the comparator. During the sample phase of the DAC, the output of the SDR is reset to low. The proposed SAR ADC is realized in 90 nm CMOS process. With the proposed logic control scheme and SDR, the proposed SAR ADC achieves high conversion rate, low power, leading to SNDR of 59 dB and SFDR of 72.6 dB at 100 MS/s with 49.7 MHz input. The figure-of-merit (FoM) is 39.1 fJ/conversion-rate at 100 MS/s with a power consumption of 2.87 mW.

High Speed Pipelined ADC Uses Loading-balanced Architecture

Linfeng Wang[1], **Qiao Meng**[1], **Dong Li**[1], **Yi Zhang**[2], **and Wenwei He**[1]

[1]Institute of RF- & OE-ICs, Southeast University, Nanjing, China

Abstract— Applications such as wireless sensor networks, image recognition and medical instrumentation require high-speed high resolution and low power consumption analog to digital converters (ADCs). Moreover the trend of system on a chip (SoC) based on advanced VLSI technology requires lower power consumption. Pipelined ADC has been widely used in these fields because it achieves a good compromise between speed, accuracy and power consumption. Pipelined ADC also has the advantage of much wider effective-bandwidth performance, because it can realize single-path sampling of the signal.

Because the speed and resolution of the pipelined ADC is in proportional to the hardware cost and power consumption, so many circuit techniques such as sample-and-hold Amplifier (SHA)-less front end, op-amp sharing, capacitor sharing and scaling down capacitor values through the pipeline have been developed in order to reduce the power consumption.

In this work, a prototype of 10 bit 200 MS/s pipelined ADC with loading-balance architecture is developed, the circuit consists of eight 1.5 bit stages and a 2 bit backend flash. It uses one op-amp less than the traditional ADC for using SHA-less architecture. The number of op-amp is reduced from 8 to 4 for op-amp sharing technique is used, the capacitor load of the first stage is reduced equal to the second stage for capacitor sharing technique, the non-standard inter-stage gain makes the feedback factor of the first stage increased equal to the second stage. So the load of op-amp shared by the first two stages is balanced. The load capacitor and feedback factor of the third and fourth stage are the same. The fifth to eight stage is the same as the third and fourth stage. From the system view, all the loads of the OTAs shared are balanced. The design power optimized.

The ADC is implemented in TSMC 0.18 μm 1P6M CMOS process. The power voltage is 1.8 V, The simulation results show 57.7 dB SNDR and 61.13 dB SFDR, ENOB = 9.3 with an 98 MHz input operating at a 200 MS/s sampling rate, the power consumption is 152 mV, the layout area is 1.2 mm × 1.2 mm.

A 30-GHz Low Phase Noise LC VCO and Frequency Divider in 90-nm CMOS Technology

Junliang Wang, **Zhigong Wang**, **Jian Xu**, **and Yan Wen**
Institute of RF- & OE-ICs, Southeast University, Sipailou 2, Nanjing 210096, China

Abstract— The large wide bandwidth around microwave frequency for high transmission data rate of multi gigabit per second is very attractive in both academic and industry. In China, the $59 \sim 64$ GHz frequency band was assigned for these applications, and recently a 45-GHz band of Q-band was developed to support both long-range and short range high data rate wireless communications. More and more up-coming frequency bands are posing the urgent needs and challenges of microwave chip designing.

In a typical double-conversion low intermediate frequency receiver architecture for the 45-GHz applications, considering a first intermediate frequency (IF) of 15 GHz and a low second intermediate frequency, two local oscillator (LO) signals can be generated by a 30-GHz LC voltage control oscillator (LC-VCO) and its divided-by-two frequency divider. This paper presents the design of a 30-GHz narrow-band VCO and its high speed divider using a standard 90-nm CMOS process. Two drain resistors are adopted in the VCO to suppress the flicker noise up-conversion.

For the 30-GHz LC-VCO, a single PMOS cross-coupled architecture is implemented. To suppress the flicker noise up-conversion, two small resistors are inserted in series to the drain of the cross-coupled MOSFETs. This method avoids the degradation of the start-up margin which is the start-up transconductance of the MOSFET, and makes the circuit reach remarkable phase noise suppression. Two sets of varators with different DC biasing are adopted in the VCO to make the K_{VCO} more linear. The simulated tuning range of the VCO covers from 28.7 to 32.4 GHz in four tuning curves. The simulated output phase noise at offsets of 10 kHz, 100 kHz and 1 MHz is -50, -78, and -104 dBc/Hz, respectively. The power consumption of the VCO is 9 mW under a 1.2 V power supply.

A current mode logic (CML) divide-by-two module is designed to operate at 28 to 32 GHz. The tail current is removed to make sure the divider can work under a 1.2 V power supply. The simulated operating range of the divider covers from 22 to 40 GHz and the self-resonant frequency is set to 32 GHz.

The layout area of the proposed schematics is $609 \times 497\,\mu\mathrm{m}^2$. The VCO operates at the supply voltage of 1.2 V and consumed an average current of 7.5 mA and the divider consumed an average current of 3.3 mA under the same supply voltage.

The paper is organized as follows: Section 1 is the introduction of the recent development of microwave wireless communications. Section 2 presents the VCO architecture and the phase noise enhanced technology. The CML based divider structure and its operation are describe in Section 3. Simulation results and conclusion are provided in Sections 4, 5, along with a comparison of the presented work with other recent works.

A 45-GHz CMOS Low-power LNA Using Active Feedback

Li Ma, **Zhigong Wang**, **Jian Xu**, **and Xixi Chen**
Institution of RF-&OE-ICs, Southeast University, Sipailou 2, Nanjing 210096, China

Abstract— In recent years, millimeter-wave (MMW) circuits have been studied widely for its capability of high data rate communication. Q-LINKPAN which has been included in IEEE 802.11aj (45 GHz) Task Group is a newly proposed communication standard working within the 40∼50 GHz. A low noise amplifier (LNA) that provides good noise performance, good matching and enough gain is necessary in MMW receiver.

The development of deep submicrometer CMOS process makes it possible to implement a CMOS MMW LNA. Therefore, a 45 GHz low power MMW low noise amplifier (LNA) using a 40-nm CMOS process is presented in this paper. The resistive feedback and active feedback structures are widely used in wideband LNA. The transconductance of the transistor in resistive feedback LNA is restricted to 20 mS which is not large enough for better noise performance. So the active feedback structure for excellent input matching is adopted in the first stage of the proposed 3-stage LNA. The output matching employs an L-type matching network and a cascode structure is adopted in the third stage for better reverse isolation.

Simulations have been carried out using Cadence Spectre®. It shows that both S_{11} and S_{22} are less than −18 dB at 45 GHz. The die area of the layout is 0.78 mm × 0.7 mm. The LNA consumes 18.7 mW under a 1.1-V voltage supply, achieving an maximum S_{21} of 17.9 dB through the −3 dB frequency band of 41.5∼49 GHz. Compared to several recently published MMW LNAs, this work consumes the least power. The minimum NF is 5.7 dB at 42.5 GHz. The simulation results show that the proposed LNA is promising for the Q-LINKPAN application.

Microwave-rectification RFI Response in MOSFET Valid in All Operation Regions

Clovis Pouant[1, 2], **Jérémy Raoult**[2], **Patrick Hoffmann**[1], **and Sylvie Jarrix**[2]

Abstract— When Radio Frequency (RF) interference is superimposed at the terminals of the Metal Oxide Semiconductor (MOS) transistor, various susceptibility effects take place depending on RF power level, frequency and the operation region of the transistor. Due to the nonlinearity of the MOS current-voltage characteristics, RF excitations cause distorted drain current waveform which leads to a bias point shift. This modification of the average of the drain current called the rectification effect is discussed. An analytic formulation of the bias point shift has initially been proposed by Richardson, but only for a saturation region of the transistor. This paper presents a global study of the rectification effect for all transistor regions of inversion (saturation, nonsaturation and linear).

Traditionally, the semi-empiric modeling procedure is based on a one variable Taylor series expansion of the gate voltage-drain current characteristic $I_D = f(V_{GS})$, when the transistor is in the saturated operating mode. If a microwave voltage is applied at the gate there is a small increase in drain current. In this operating mode the increase in drain current is proportional to the variation in transconductance with gate voltage, and the square of the microwave voltage amplitude. The average of the drain current is given by: $\Delta I_D = \frac{V_{GS}^2}{4} \frac{\partial g_m}{\partial V_{GS}}$.

When the transistor is in the nonsaturation and linear operating modes, a one variable Taylor series expansion is not enough to predict the drain current rectification. The output conductance becomes an important nonlinear source and must be included in the calculation of the rectified current. So we use a two variables Taylor series expansion of the gate voltage-drain current and the drain voltage-drain current characteristics $I_D = f(V_{GS}, V_{DS})$. In these operating modes if a microwave voltage is applied at the gate there is a small decrease in drain current and its average value can be expressed as: $\Delta I_D = \frac{V_{GS}^2}{4} \frac{\partial g_m}{\partial V_{GS}} + \frac{V_{DS}^2}{4} \frac{\partial g_d}{\partial V_{GS}} + \frac{1}{2} V_{GS} V_{DS} g_{md} \cos\varphi$. The transconductance, the conductance and the cross terms were extracted experimentally from the characteristics $I_D = f(V_{GS})$ and $I_D = f(V_{DS})$. The derivatives of these terms are then computed numerically. Our semi-empiric model which predicts the average drain current under RFI (Radio Frequency Interference) takes into account of the transconductance and conductance nonlinearity. In fact in the linear or nonsaturation regions of the transistor, the conductance can vary strongly with bias voltages (V_{GS}, V_{DS}). Our model is limited by the RF voltage amplitude applied at the gate and the frequency of the RFI. Experiments on a commercial MOS transistor have been conducted. Drain current shifts in all transistor regions of inversion have been measured and calculated. Theirs comparisons have shown a very good agreement until RF voltage amplitudes about 4 V and RFI frequencies of 500 MHz.

Finally this model could be used to predict effects of high-power microwave (HPM) coupling on digital MOS circuit.

A Broadband E-band Vertical Transition from Substrate Integrated Waveguide to Rectangular Waveguide

Elnaz Abaei[1] and Alireza Shamsafar[2]

[1]Facultad de Informatica y Electronica
Escuela Superior Politécnica de Chimborazo, Riobamba, Ecuador
[2]Dipartimento di Ingegneria Informatica Modellistica, Elettronica e Sistemistica
Università della Calabria, Rende, CS 87036, Italy

Abstract— In this paper, a compact wideband vertical transition from substrate integrated waveguide (SIW) to WR12 rectangular waveguide at E-band (77 GHz) is presented. SIW, as a planar and low profile type of waveguide, has received much attention in recent years and various kinds of microwave and millimeter-wave integrated circuits such as antenna, couplers and filters have been realized in this structure. The advantages of SIW are low-loss, low radiation, low profile, simple fabrication, small size, and compactness compared to standard air filled waveguide. However, classical waveguide (RWG), which has better power handling compared with SIW techniques, is still an important transmission line in microwave and millimeter wave circuit design, and a large number of commercial and existing products are in waveguide format. Moreover, RWD is especially more suitable for building complicated 3D feeding structure and is more rigid. So, it is necessary to develop various kind of transition between planar SIW and rectangular waveguides.

In the vertical transition which is designed in this work, a rectangular cavity resonator with closely metalized via holes is used to connect the SIW and WR12 waveguide. The energy between SIW and RW12 is coupled through the slot window etched on the board wall of the rectangular SIW cavity resonator. In this transition, the substrate of SIW can be easily surface-mounted to the standard flange of the waveguide; so the proposed component has a simple mechanical alignment. Moreover, the proposed SIW to RW transition can be easily realized and integrated with standard double-sided PCB technologies.

Commercial full-wave HFSS software is used for the design and simulation. The simulation results of designed transition show that the return loss remain below than −10 dB from 72 GHz to 83 GHz (more than 12%) while this value decrease to below than −15 dB from 73 GHz to 82 GHz. Insertion loss on the frequency band is always higher than −1.5 dB, which shows good electromagnetic power coupling from SIW to WR12. The simplicity and compact size of the designed transition is attractive for development of millimeter- wave circuits and measurements.

Development of a Radio Interferometer Operating at 12 GHz for Education and Research

Junghwan Han[1], **Bangwon Lee**[2], **Bi-Ho Jang**[3], **In-Woo Han**[3], **Sang-Eun Jung**[4], **Ji-Sung Ha**[4], **Seung-Soo Hong**[4], **Min-Ho Ka**[1], **and Yong-Sun Park**[2]

[4]National Youth Space Center, Korea

Abstract— A radio interferometer system operating at 12 GHz for educations and possibly for research is developed. The commercial components are usually used for satisfying a low cost strategy, and the driving system is made to resist the strong wind, because the installation site is located near the seaside. The interferometer system consists of three off-axis parabola antennas, whose diameter is 1.8 m. The baselines between antennas are about 4 m, 19 m, and 20 m, so about 4' resolution can be acquired. The baseline vectors are accurately measured by using a theodolite, a light wave distance measurement, and GPS (Global Positioning System). The center frequency of the receivers is 12.177 GHz, and the bandwidth is 6 MHz. The receiver is able to observe the methanol line (12.178 GHz) and continuum from the Sun, the Moon, and the Galactic plane. The signals of each receiver are sampled and quantized by the AD convertor, and then software correlation is conducted with the developed parallel process program. The used libraries for software correlation are Fastest Fourier Transform in the West (FFTW), CompuScope Software Development Kit (SDK) of Gage Instrument, and Open Multi-Processing (OpenMP). We succeeded in finding fringes toward the Sun, Moon, Crab Nebula, and Cassiopeia A. By using a Nobeyama solar radio image taken at 17 GHz with a bright spot at the center of solar disk, we tried to calibrate uncertainties involving signal cable length, but it was found to be only partially successful. In order to make images of celestial objects, more careful treatment seems necessary with the use of phase calibrators or with a method similar to self-calibration without the phase calibrator.

Abstract— Broadband wireless access communication systems are undergoing a rapid expanding growth. Such systems employ RF filters in their transceivers. Therefore, there is an increasing demand for low cost and compact size filters. Tunability of these filters is a required feature in these multi-standard communication systems, as it allows them to tune to several frequencies and operate for different applications.

A simple tunable microstrip band pass filter is presented in this paper. The basic configuration of this filter is shown in Fig. 1. A simple microstrip line is designed on a 40 mm × 20 mm Rogers RO3203 substrate with dielectric constant of 3.02 and thickness $h = 1.6$ mm over a full ground plane. The filter is based on a T-shaped slot incorporated in the microstrip line between a pair of gaps. The slot itself has bandstop characteristics, but the two gaps which act as capacitors transform the bandstop into bandpass operation. The designed filter operates in the frequency band from 1.8 to 3 GHz. Frequency tunability is obtained by inserting a varactor in the design as indicated in Fig. 1 and modifying its capacitance using the shown DC bias lines. The size of the varactor is compatible with the design and its capacitance ranges between 0.6 and 71 pF.

Figure 2 shows the reflection coefficient plots for different capacitance values of the varactor. As shown, frequency tunability is achieved and the filter can operate on different frequencies in the 1.8–3 GHz band corresponding to different applications such as LTE, UMTS, WiFi, and others. Detailed and verified results will be included in the full paper.

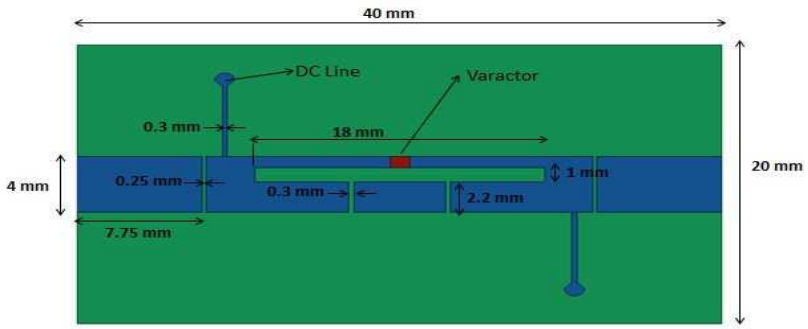

Figure 1: Microstrip filter configuration.

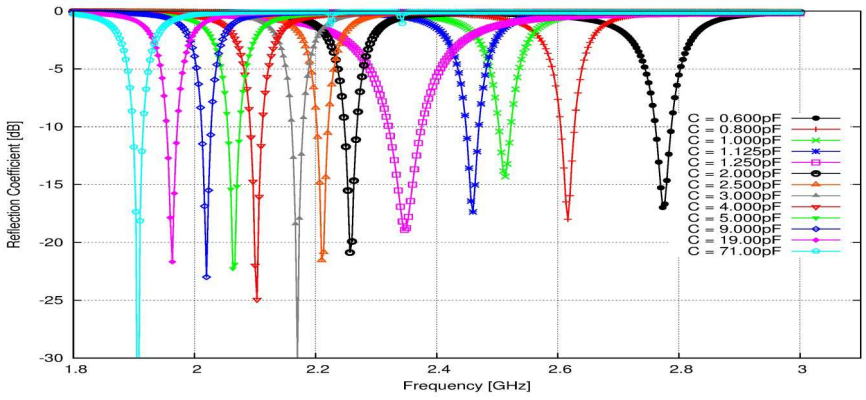

Figure 2: Simulated reflection coefficients for different capacitance values.

A Simple Digital Predistortion Architecture for Beamforming Transmitter

Abstract— Beamforming (BF) signal transmission using SHF band is a promising scheme for enhancing the bandwidth and capacity of 5G mobile communications. Since antenna elements are smaller for SHF, a BF antenna can be composed of a large number of antenna elements. Although it realizes high performance, the same numbers of power amplifiers (PAs) are necessary. In order to suppress outband radiation caused by nonlinear distortion of PAs, a digital predistortion (DPD) technique should be employed. This paper proposes a simple DPD architecture for beamforming transmitters that uses only one common digital predistorter for multiple PAs. Fig. 1 shows the proposed DPD architecture. The predistorter output is divided into necessary numbers for beam forming and they are modulated by different phases and then input to PAs. The multiple feedback paths from PA outputs are combined after removing the phase shifts for beam forming and then digitized by single analog-digital converter (ADC). The concern about the architecture is sensitivity against deviations of PA nonlinearity characteristics. The following Saleh's PA behavior model has been employed for analyzing this issue.

$$y = \frac{ax}{\sqrt{1+b|x|^2}} \exp\left(j\frac{c|x|^2}{\sqrt{1+d|x|^2}}\right) \tag{1}$$

By shifting parameters *a, b, c, d* in the model, sensitivity of the proposed DPD architecture has been simulated. Fig. 2 shows AM-AM conversion characteristics of four antenna BF transmitter when the linear gain parameter *a* is deviated among four PAs. With the DPD, AM-AM characteristics for all PAs are successfully linearized. On the other hand, when the phase conversion

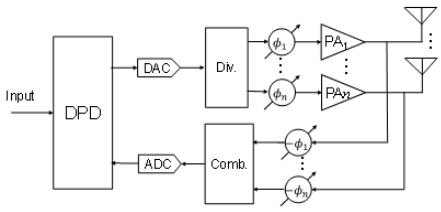

Figure 1: Proposed BF DPD architecture.

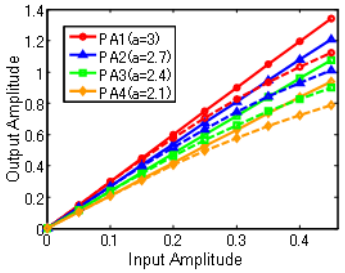

Figure 2: Input/output conversion characteristics when the linear gain has a deviation.

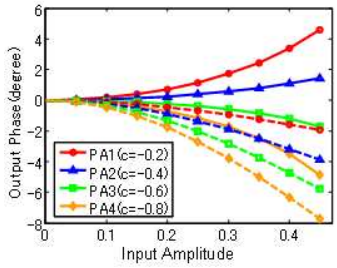

Figure 3: Input/output conversion characteristics when the phase shift gain has a deviation.

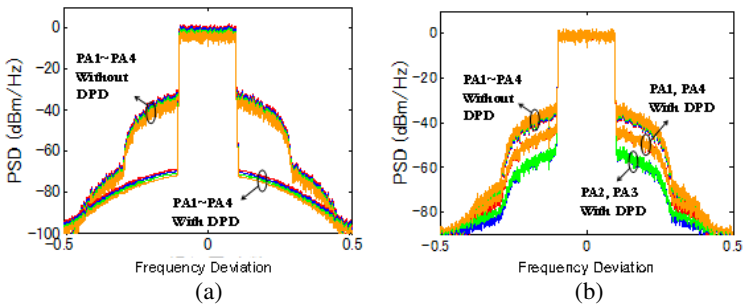

Figure 4: PA output spectra with deviation of PA parameter for (a) linear gain deviation, (b) phase shift gain deviation.

gain parameter c is deviated, only the average phase shift among four PAs is compensated as shown in Fig. 3. The corresponding power spectra output from PAs are presented in Figs. 4(a) and (b). Outband radiation is perfectly suppressed when the parameter a is deviated. However, outband radiation is not perfect when the parameter c is deviated.

In conclusion, the proposed DPD architecture is effective to linearize BF transmitter with reduced circuit size and cost, while the deviation of AM-PM conversion characteristics for PAs needs to be controlled.

An Optimized Opamp-sharing in 2nd Order ΔΣ Modulator Based on Changing the Stages Output Capacitance Timing Strategy

Abstract—

Application of ΔΣ Modulators in Power Electronics: An application of delta-sigma modulators is the Control loop of the DC-DC Switching Converters that tabernacle with PWM generators and decreases the ripple and noise of the DC-DC converters [1].

The Proposed Opamp-sharing Idea: In this paper, an opamp-sharing technic discussed that made the delta-sigma modulator with two loop-filters and one opamp. In this structure, the opamp moved from stage1 (loop filter1) to stage2 (loop filter2) and conversely. Furthermore one opamp saved that causes power dissipation and area is minimized by factor2. In phase1, opamp presented in the integrator1 (stage1) and in phase2, the opamp presented in other integrator. In the loop filter1, noise once shaped and in loop filter2, noise twice shaped than the stage2 requires fewer output capacitance in the switch capacitor integrator structure and it must have been less pulse-width (i.e., phase2 pulse-width according to Fig. 1) rather than stage1. Therefore, the sampling frequency is maximized and the harmonic distortion is minimized with this technic. Since the pulse-width designed according to integrator output capacitance and opamp conditions in two stages not changed, the harmonic distortion is minimized.

According to Fig. 1, the pulse-width dedicated to stage2 is less than stage1 and the phases are madding from the clock signal with very high frequency rather than two phases.

The proposed integrator structure shown in Fig. 2. In this structure, the opamp only required in one phase and it can move to other stages. According to Fig. 2 based on [2], in the phase Φ_{1a}, the integrator sampled the input signal on the sampling capacitor (C_S) and in the phase Φ_{1b}, the integrator transfer the electric load from sampling capacitor to integrator capacitor (C_f) and conversely. Therefore the opamp not require been in the integrator structure at phase2 and moved to other integrator.

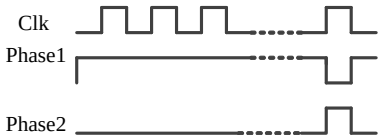

Figure 1: Proposed switch-capacitor delta-sigma modulator timing diagram.

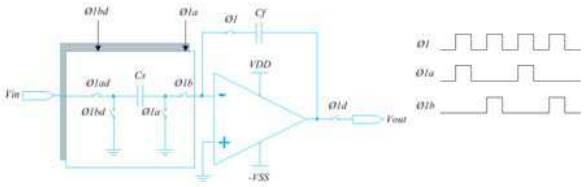

Figure 2: Proposed switch-capacitor integrator in phase1 (Φ_1).

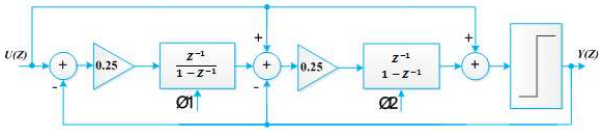

Figure 3: Proposed 2nd order delta-sigma modulator block diagram.

Table 1: Simulation results for the proposed 2nd order ΔΣ at 1.2 v power supply.

f_{BW} (Hz)	SNDR(dB)	Power (μw)	FoM (fJ/s-c)
10 k	80.7	69.2	392.2

Table 2: Simulation results for the proposed 2nd order $\Delta\Sigma$ at different process corners.

Parameters	$\boldsymbol{T \cdot T}$	$\boldsymbol{S \cdot S}$	$\boldsymbol{S \cdot F}$	$\boldsymbol{F \cdot S}$	$\boldsymbol{F \cdot F}$
f_{BW} (Hz)	10 k	10 k	10 k	10 k	10 k
SNDR (dB)	80.66	81.85	78.70	80.21	78.23
ENOB (bit)	13.11	13.30	12.78	13.03	12.70
FoM (fJ/s-c)	392.25	295.79	540.16	385.39	648.44

Simulation Results: In this paper, the proposed block diagram in Fig. 3 is simulated. According to Fig. 3, the opamp has been in stage1 at phase1 (Φ_1) and the opamp has been in the other stage at phase2 (Φ_2). The output capacitance of the stage1 is about six times than stage2. Therefore, the pulse-width for stage1 is about six times other stage.

The Proposed idea simulated at the 130 nm CMOS model and the simulation results presented at the Table 1. Also, Table 2 shows the simulation results in the process corners.

Abstract—

Application of Comparator in Power Electronics:

An application of comparators is in the Control loop of the DC-DC Switching Converters. In the loop of DC-DC Switching Converters, PWM generators uses comparator that compare Triangular wave with the difference DC-DC output voltage and reference voltage.

Proposed Dynamic Comparator:

A. Structure:

The comparator is consists of two parts that namely pre-amplifier and latch These parts operate in the same phase. Therefore, comparator can pull the latch. The pre-amplifier output nodes up to the power supply voltage level in the second phase. Also in this phase, the comparator offset can be cancelled [1, 2]. Consequently in this paper, the comparator offset effect has not been considered. Fig. 1 shows the Schematics of circuit diagram that has been used in simulations and has been obtained from [3] with adding Q2 and Q4, thus a dual rail pre-amplifier is achieved. Two CMOS inverters have been used to supply capacitive loads for decreasing the loading effect on the comparator output. The comparator consumes dynamic power Because the comparator consists of dynamic latch and pre-amplifier [4].

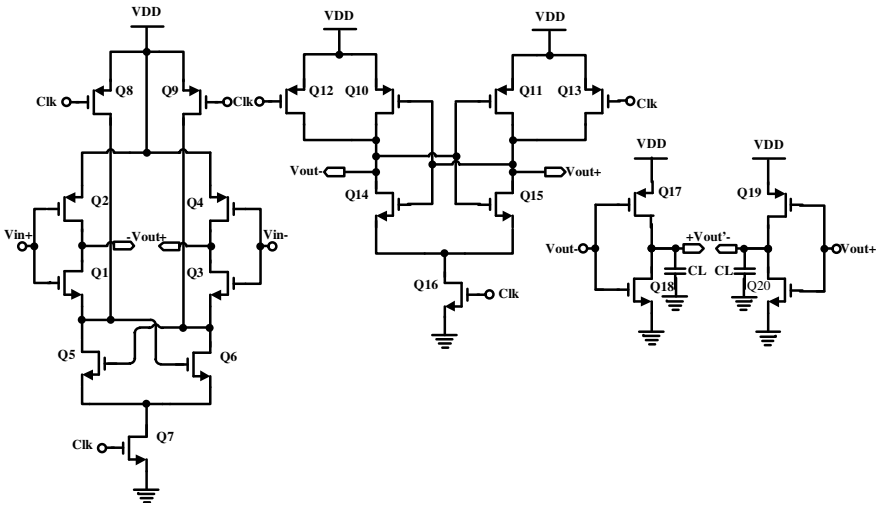

Figure 1: Schematics of the dynamic comparator and CMOS inverters.

B. Transient Behavior:

Figure 2 shows the sketch map of the transient behavior of the dynamic comparator in the comparison phase. By the switching transistors Q8, Q9, Q12, and Q13 during the reset phase, the output terminals and the drain side voltages of Q5 and Q6 are all pulled high to VDD, respectively. The comparison phase begins by turning on the two tail transistors Q7 and Q16. Therefore, the CMOS input stage transfers the differential small signal to the cross coupled stage. When the input common mode is lower than the Q1 or Q3 threshold voltage, Q2, Q4 are activating. Therefore, the dual-rail differential input obtain since they are supplies the preamplifier output. Based on [5], the comparison transition can be divided into phase 1 to phase 3. During the phase 1, the output terminals are pulled down by two tail transistors Q7 and Q16. Until one of the two output terminal voltages decreases to (V_{DD}-V_{thp}), the p-channel transistors Q10 and Q11

remain cut-off. When the cross-coupled stage composed from Q1, Q3, Q5 and Q6 cannot start, the Q2 and Q4 activate. Therefore, the speed of proposed idea is more than paper [3]. In order to enhance the voltage difference between the output terminals, the cross-coupled inverters provide strong positive feedback in the phase 2. The transition state changes from phase 2 into phase 3 when one of the transistors Q14 and Q15 is cut-off. There is no static power dissipation since the current flows through these n-channel MOSFETs stop automatically after the transition.

Therefore, the strong positive feedback provided by these two cross-coupled inverters separates the output voltages. Against paper [3], this design aren't use from p-wells, thus the cost of comparator chip is lower.

C. Simulation Results:

In this paper, the proposed comparator (Fig. 1) is simulated and for simulation reliability, the Post-Layout Simulation (PLS) for layouts in the Fig. 3 is adopted.

The Proposed idea simulated at the 180 nm CMOS model. The post-layout simulation results versus Sampling Frequency presented at the Table 1.

Theoretical and Experimental Study of Tunneling-induced Optoelectronic Effects in Plasmonic Nanoantennas with Ultra-narrow Gaps

R. Esteban and J. Aizpurua
Donostia International Physics Center DIPC and Materials Physics Center CSIC-UPV/EHU
Paseo Manuel de Lardizabal 4, 20018 Donostia-San Sebastián, Spain

Abstract— Coulomb coupling between two or more metallic nanoparticles separated by a narrow gap introduces great possibilities to tune and optimize the optical response of the whole system. When the distance between the different elements of such an optical nanoantenna becomes nanometric or even subnanometric, however, the well-understood classical behavior is modified by quantum effects [1–3] such as nonlocal correlations of the electron gas, the spill-out of the electrons at the metal interface and the electron tunneling current across the gap. In the case of small systems, these effects can be studied within Time-Dependent Density Functional Theory (TDDFT). We recently developed a Quantum Corrected Model (QCM) that allows treating quantum effects also in large systems [4].

Using TDDFT and the QCM, together with experimental results for subnanometric gaps, we demonstrate and analyze how electron tunneling can completely modify the optical response of a plasmonic system, an optoelectronic effect occurring at extreme fast speed and in a nanometric volume [2, 4, 5]. For gaps limited by spherical surfaces, the charge transfer due to tunneling leads, already before contact is established, to a gradual transition from the Bonding Modes to the Charge Transfer Plasmons, strongly modifying the far field response. The charge transfer also quenches strongly the local fields at the gap. Electron tunneling alters the optical response of modes of both electric and magnetic nature. The latter has not been studied in the context of quantum effects.

We discuss these effects for two different experimental systems for which subnanometric gaps are well controlled (Figure 1). Furthermore, we demonstrate that the morphology of the gaps needs to be considered to understand the effect of tunneling on the optical response [6]. Notably, while quenching of the near fields at the gap appears to be a general trend, our calculations for flat gaps defined by two large planar surfaces predict the inhibition of tunneling-induced optical far-field effects, in contrast to the results of spherical gap terminations. This difference between flat and spherical gaps can be critical when trying to identify quantum effects from the experimental far-field response. Our study thus demonstrates the intriguing properties of plasmonic systems at the limit, with potential future applications in nanooptics and optoelectronics.

Binary Mixtures of Chiral Gases

C. Presilla[1, 2] **and G. Jona-Lasinio**[1, 2]

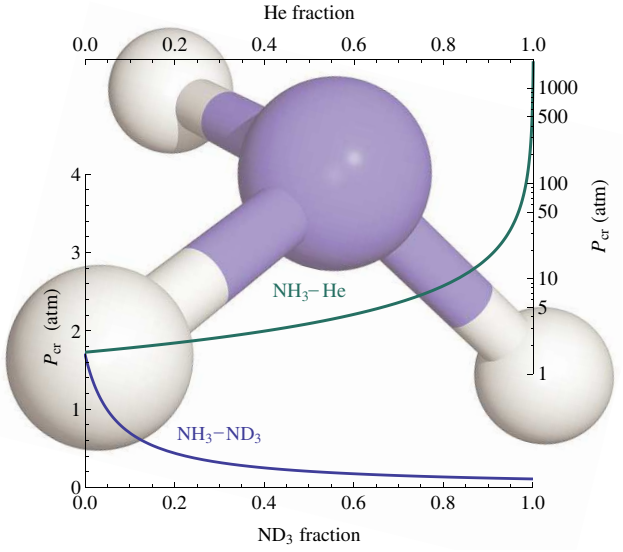
[1]Sapienza Università di Roma, Italy
[2]Istituto Nazionale di Fisica Nucleare, Italy

Abstract— According to quantum mechanics chiral molecules, that is molecules that rotate the polarization of light, should not exist. The simplest molecules which can be chiral have four or more atoms with two arrangements of minimal potential energy that are equivalent up to a parity operation. Chiral molecules correspond to states localized in one potential energy minimum and can not be stationary states of the Schrödinger equation. A possible solution of the paradox can be founded on the idea of spontaneous symmetry breaking. This idea was behind work we did previously involving a localization phase transition: at low pressure the molecules are delocalized between the two minima of the potential energy while at higher pressure they become localized in one minimum due to the intermolecular dipole-dipole interactions. Evidence for such a transition is provided by measurements of the inversion spectrum of ammonia and deuterated ammonia at different pressures. A previously proposed model gives a satisfactory account of the empirical results without free parameters. In the present paper, we extend this model to gas mixtures. The main results are as follows.

i. Also in the case of mixtures there is a quantum phase transition between a delocalized (or achiral, or nonpolar) phase and a localized (or chiral, or polar) phase. At fixed temperature, the crossover between the two phases is determined by a properly defined critical pressure.

ii. We derive formulas expressing the critical pressure of the mixture in terms of the doublet splittings of the isolated chiral molecules and of the fraction of the constituents. Different formulas are derived for mixtures made up of one chiral species and several non polar gases or several chiral species. In both cases, the inverse critical pressure of the mixture is the fraction-weighted average of the inverse critical pressures of its components.

iii. We derive formulas giving the dependence of the inversion frequencies on the pressure. These results are susceptible to experimental tests.



On the Application of Group Theory to Understand the Optical Response of a Chiral Nanostructured Surface

Xuezhi Zheng[1], **Guy A. E. Vandenbosch**[1], **and Victor V. Moshchalkov**[2]

[2]Institute for Nanoscale Physics and Chemistry (INPAC), KU Leuven, Belgium

Abstract— Symmetry holds a prominent position in defining the electromagnetic response of a chiral nanostructured metasurface [1, 2]. In this talk, we base our discussion [3] on a powerful mathematical tool, group representation theory [4], and combine it with the eigenvalue problem of Volumetric Integral Equations (VIE) [5] that models the light-nanoantenna interaction. We illustrate how the symmetry allows or forbids the coupling between the metasurface's eigenmodes and an incident left/right polarized light and, which leads to so-called circular dichroism (CD). Further, the effects of symmetry on the energetic coupling (i.e., interference) between the eigenmodes will be discussed. Specifically, we start our demonstration with a metasurface whose unit cell is a symmetric cross (which has a D_2 group, See Fig. 1(a)). Then, the mirror symmetry of the cross is removed to form two chiral structures with different handedness (See Figs. 1(b)–(c)). The eigenmodes of the above structures are extracted with their mutual coupling and their coupling to left/right circularly polarized light discussed in detail. We believe that the present work enhances the fundamental understanding of the modes in a chiral metasurface and thus allows the engineering of a metasurface's spectrum.

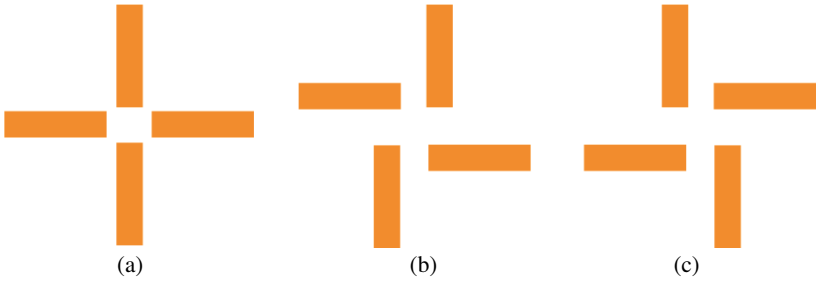

Figure 1: Illustration of the topologies studied in this talk (a) symmetric cross and crosses with (b) left- and (c) right-handedness.

Abstract— The development of precise nanofabrication methods has enabled the study and engineering of the optical properties of nanostructured media, i.e., optical metamaterials, which may display unconventional properties, such as negative index of refraction. The properties often arise from the geometry of the nanostructure rather than the atomistic composition.

Noble metal nanoparticles display resonances of the electron gas. These, so-called plasmon resonances, can enhance the local electric field near the surface of a particle, which can then amplify nonlinear optical effects, such as second-harmonic generation (SHG). Consequently, nonlinear optical metamaterials hold promise for many practical applications.

As the fabrication of nanostructures is slow and expensive, there is a call for accurate and versatile numerical simulation of their electromagnetic response. For plasmonic materials, this can be especially demanding due to the presence of resonances. Frequency-domain boundary element method (BEM), especially the Poggio-Miller-Chang-Harrington-Wu-Tsai formulation (PMCHWT) with vector basis functions, has been found suitable for such demands [1]. We have extended the PMCHWT BEM for the modeling of surface SHG in the undepleted-pump approximation from individual plasmonic particles [2] and it has been further extended by others for the modeling of periodic structures [3] and the nonlocal bulk response [4].

One advantage of the use of BEM in frequency domain is that the use of focused Gaussian beams with unconventional polarization states is straight-forward. We have developed algorithms for the fast simulation of scanning a focused beam over a nanoparticle while collecting the SHG in reflection by the focusing lens [5, 6]. We have also recently shown that the modeling of SHG from a periodic metasurface by BEM yields unprecedented agreement with measurements, thus validating the method in practice [7]. Our recent work also details how geometrical symmetry can be utilized in BEM to decrease the memory requirements and computation time for both linear and weak nonlinear response [8].

In addition to modeling the response of a nanostructure to an incident field, it is often of interest to understand the possible outcomes of the system without the specification of an incident field; the resonances and modes are properties of the structure. We have proposed an approch based on boundary integral operators for the characterization of resonances and the study of eigenmodes in the time-harmonic setting [9]. The modes are defined over the compact surface of the scatterer, thus avoiding many inconveniences associated with direct analysis of Maxwell's partial differential equations. We show that the approach is fully compatible with the Mie theory for spheres and with a previously studied quasistatic limit. We also calculated the complex resonance frequencies and eigenmodes of structures that are elementary, but comparable in size to the vacuum wavelength.

Effective Dielectric Tensor of Optically Thick Chiral Composite Layers

A. A. Shcherbakov[1], **A. A. Ushkov**[1], **and A. V. Tishchenko**[2]

[1]Moscow Institute of Physics and Technology, Russia
[2]University of Lyon, France

Abstract— Composite 2D and 3D periodic media are promising candidates for replacing natural materials since they provide benefits of engineering specific macroscopic anisotropic properties. Currently there exist reliable technological methods of fabrication and characterization of complex 2D and 3D periodic chiral artificial structures at macroscale [1]. These methods should be supported by powerful computational techniques being are able to predict and optimize artificial media optical properties, and there is still a need in research towards better numerical methods.

In this work we continue development of a method for composite 3D protonic crystal homogenization [2]. The method is based on the Fourier space formulation of the Maxwell's equations with source terms. Being reduced to a linear algebraic equation system they provide a response to a given excitation that can be found in linear time relative to the total number of Fourier harmonics. An efficient resonant analysis of the obtained response provides propagation constants and propagating mode amplitudes with quite high accuracy.

First part of the talk will cover the formulation of the method with correct treatment of the electromagnetic boundary conditions in the Fourier space, which results in the following linear equations system for electromagnetic response:

$$\mathbf{E} = \left[\frac{\varepsilon_b}{\varepsilon}\right]\left(\left[\frac{\varepsilon_b}{\varepsilon}\right] - \mathrm{K}\left\{\left(\left[\frac{\varepsilon}{\varepsilon_b}\right] - \mathrm{I}\right)\left[\frac{\varepsilon_b}{\varepsilon}\right] + \left(1 - \left[\frac{\varepsilon}{\varepsilon_b}\right]\left[\frac{\varepsilon_b}{\varepsilon}\right]\right)\Gamma\right\}\right)^{-1}\mathbf{E}^{inc}$$

where $\mathbf{E}$ is unknown vector of the electric field components Fourier images, $\mathbf{E}^{inc}$ is the corresponding excitation vector; matrices $[\varepsilon/\varepsilon_b]$ and $[\varepsilon_b/\varepsilon]$ are the Fourier matrices of microscopic dielectric permittivity and inverse permittivity in a protonic crystal unit cell with ε_b being some constant; matrix K is composed of spatial wavevector components; and matrix Γ contains spatial Fourier images of normal vector components to microscopic interfaces between different media provided that normal vector functions are appropriately continued to a whole unit cell. Second part of the talk will include demonstration of the method numerical behavior as well as examples of chiral composite layers simulation.

Abstract— Nonlinear frequency conversion is in the core of the modern world of nonlinear optics. For efficient generation of harmonics, phase matching conditions must be satisfied, to ensure constructive interferences of the generated signal over the entire interaction length. So far, three main techniques were employed to achieve phase matching: one is the use of birefringence, when, e.g., an ordinary wave at fundamental frequency and an extraordinary wave at second harmonic have the same refractive index. This option, however, is only available for a limited range of nonlinear crystals. The other technique relies on periodic poling of nonlinear crystal, which is also not universally available. More recently, the advent of metamaterials enabled dispersion engineering, such as for bi-resonant systems, however this track is barely suitable at optical frequencies. We propose to make use of hyperbolic dispersion, which recently became accessible in layered metal-dielectric metamaterials (Fig. 1). Hyperbolic media support, in principle, arbitrary k-vectors, promising novel opportunities for phase matching. Taking second harmonic generation as an example, we systematically analyse all the possible combinations of the dispersion types at the two relevant frequencies, and find several configurations appropriate for nonconventional phase matching (Fig. 2). We analyse the arising possibilities with the available material parameters, and point out some specific examples, presenting a parametric analysis on the range of fill fractions, incident angles and frequencies (Fig. 3). Importantly, this novel approach yields a possibility to run phase-matched nonlinear processes with materials where conventional birefringent phase matching is not available. With the rapid progress in fabrication techniques for hyperbolic metamaterials, we trust the proposed approach will be soon available for practical applications.

Abstract— Optical activity is a phenomenon which is widely observed across both natural and artificially chiral structures. Microscopically, the presence of optical activity in a system is conventionally understood in terms of the coupling of excited, co-aligned electric and magnetic dipoles [1]. Whilst combinations of electric dipoles with higher-order multipoles can also contribute to optical activity, such effects are frequently considered to be negligible. Metamaterial engineering however, allows for the design of structures where conventional microscopic multipole responses are suppressed in favour of more unusual excitations, including the elusive toroidal dipole.

First considered by Zel'dovich in 1958 [2], the toroidal dipole has recently been identified as an integral component in the excitations of metamaterial structures [3]. As the toroidal dipole radiates as an electric multipole [4], it is anticipated that it could contribute to optical activity in the same manner as an electric dipole. Here, we report on the first observation of optical activity in a structurally-chiral metamaterial that cannot be attributed to conventional multipoles, and can only be accounted for by the inclusion of the toroidal dipole in the multipole expansion.

The metamaterial unit cell studied consists of four split-ring resonators embedded in a low-loss dielectric, with the unit cells arranged such that the material has a structural chirality. The metamaterial is studied experimentally in a microwave chamber and computationally using a commerical Maxwell's equation solver. By extracting the microscopic multipole response, we confirm that at resonance a non-negligible toroidal dipole is excited and contributes to the observed circular dichroism in the metamaterial's transmission spectrum. This is corroborated by an examination of the material's polarisation eigenstates and how they vary upon removal of multipole excitations from the metamaterial's response.

Natural Chiral Photonic Structures: Morphology, Self-assembly and Optical Properties

Silvia Vignolini
Department of Chemistry, University of Cambridge, Cambridge, UK

Abstract— Nature provides a multitude of nanostructures that have been finely tuned by natural selection and produce structural coloration that play a role in many biological functions such as mating, signalling or camouflage [1–3]. A recurring design that is found both in the animal and plant kingdoms is the helicoidal structure, i.e., a multi-layer structure where adjacent layers rotate along a helical screw [4], see Figure 1(a).

Examples of such structures have been found in different plant tissues [5], in algae, and also in fish and insects. Two example of photonic chiral structures in insect and plants are reported in Figures 1(b) and (c), respectively.

In this talk I will review some example of chiral structures in nature, their optical response. I will discusses on how their common morphology suggests convergent evolution of optimized, left-handed multilayered structure. Finally, I will present a bio-inspired approach to replicate such chiral optical response found in natural structures, using the same materials as nature: cellulose [4, 5].

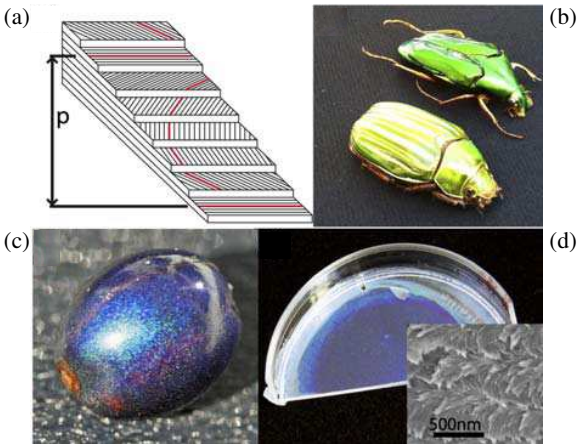

Figure 1: (a) Schematic diagram showing a wedge of a left-handed helicoid structures (adapted from [2]). (b), (c) Picture of beetle and *Pollia* fruit, respectively. (d) Camera picture of cellulose structurally coloured film obtained by cellulose nanocrystals self assembly, in the inset a cross sectional SEM of the structure, showing the twisting of the nanocrystals.

Chiral Reflectors of Circularly-polarised Light in Scarab Beetles of the Genus *Chrysina*

Ewan D. Finlayson, Luke T. McDonald, and Pete Vukusic
Department of Physics and Astronomy, University of Exeter, EX4 4QL, UK

Abstract— Certain species of jewel scarab beetle of the genus *Chrysina* exhibit a highly-reflective vivid metallic appearance to the human eye. This specular reflectance is accompanied by the anomalous preservation of the handedness of circularly polarised (CP) light upon reflection. Both of these properties result from the elaborate lamellar structure of the insect cuticle, in which planes of anisotropic chitin-based microfibrils are orientated parallel to the surface and are assembled such that their azimuth rotates continuously through the outer exocuticle layer The resulting helicoidal construction forms a chiral dielectric multilayer optical reflector. In this work we study natural structures that achieve broadband CP reflectance of silver or gold appearance by means of their helicoidal pitch being chirped. The CP-specific reflectance magnitudes of the insect elytra are measured experimentally at normal incidence for human-visible and near-infrared wavelengths. A scattering matrix technique based on the Berreman 4×4 matrix method for simulating anisotropic multilayers is used to model the optical behaviour. The model is informed by the experimental quantification of the physical dimensions of the chiral multilayer configurations using transmission electron microscopy (TEM) performed on the specimens, while refractive index values are selected from the literature. The origin of the broadband reflectance is elucidated by the simulations in terms of the role of the helicoidal pitch distribution and its arrangement in forming the chirped multilayer reflector. A quantitative comparison is made between the simulations and the reflectance measurements in order to gauge the applicability of the selected refractive index data to the species studied. The future goal of the realisation of novel optical devices containing synthetic biomimetic analogues of these natural structures is served by the development of an understanding of the observed optical behaviour.

Giant Broadband Chiral Response in Three-dimensional Shell-like Plasmonic Nanostructures

Dang Yuan Lei[1, 2]

[1]Department of Applied Physics, the Hong Kong Polytechnic University, Hong Kong, China
[2]Shenzhen Research Institute, the Hong Kong Polytechnic University, Shenzhen, China

Abstract— Continuous breaking of the mirror symmetry in a symmetric metal nanoshell can result in the formation of a new class of three-dimensional shell-like chiral structures (SLCSs). Here we demonstrate a record chiral response from a large-area plasmonic SLCS sample prepared through a two-step glancing angle deposition of different metals on a self-assembled microsphere array. A circular dichroism signal, defined as the ratio of the transmission intensity difference and sum of the right- and left-circularly polarized lights, of ~ 0.4 and a chiral parameter of $k_{\text{chiral}} > 0.09$ are achieved over the whole visible spectral range. Full-wave electromagnetic simulations reveal that the giant broadband chiroptical effect results from the weighted average of chirality over many microscopic domains in the plasmonic SLCS samples and the removal of the disorder arrangement of the microsphere array in long range.

Surface Enhanced Raman Scattering Induced by Periodic Gratings with Random Gold Particles

Chongjun Jin
State Key Laboratory of Optoelectronic Materials and Technologies
School of Physics and Engineering, Sun Yat-Sen University, Guangzhou 510275, China

Abstract— Raman scattering is the fingerprint of a molecular, which is very important for identifying the composition of materials, especially in polymer, food and biological sciences. However, the signal of the Raman scattering is very weak. Fortunately, the signal of the Raman can be enhanced by the metal nanoparticles and nanostructures, such as gold and silver nano particles. This enhanced Raman scattering is named as Surface enhanced Raman scattering (SERS). SERS has enormous applications in many areas of chemical and biological sensing, including single molecule detection, non-intrusive study of reaction dynamics, and identification of trace amounts of dangerous chemical species in foods. In the presentation, we propose a novel method to increase the signal of SERS via periodic grating with random gold particles. The experimental results show that, compared with the random gold particles on a flat surface, if the particles are sprayed on the periodic gratings, the signal of SERS will be further increased by a factor of over 10. We also explain this phenomenon via FDTD simulation and the interaction of different resonant modes.

Chiral Metasurfaces

Abstract— Two dimensional chiral surfaces exhibit interesting polarization properties and can, by virtue of their additional symmetry-breaking, give rise to additional second harmonic generation signals. Here, we describe arrays of chiral nanostructures that form metasurfaces with dense sub-wavelength features, which can simultaneously exhibit multiple properties, including plasmonic enhancement and very strong optical activities. These chiral metasurfaces are based on a parallel fabrication scheme we have recently developed that allows shape-control at the nanoscale [1]. We have grown arrays of chiral helices that predominately contain silver, gold, copper, or oxides to name but a few of the materials. However, it is also possible to grow hybrid structures as well as alloys or magnetic materials. The scalability of the technique is unique as it permits the rapid structuring of nanophotonic elements at the wafer-scale.

Chiroptical responses in transmission (optical rotation) and absorption (circular dichroism) are typically small effects. The chiroptical signal may be enhanced using amplification schemes, including weak value amplification [2], or by increasing the multipolar light-matter interaction itself. The latter is possible when the chiral object has a size that approaches the wavelength of light. Since we can fabricate structures that are of a similar length-scale as the wavelength of visible light, whilst being small enough to minimize scattering, large chiroptical signals can be recorded even in films that are only about a 100nm thick [1]. We show chiroptical measurements conducted on transparent substrates of wafer-scale metasurfaces [3–5]. In addition it is possible to study the same chiral nanostructures as a colloidal suspension, a "metafluid". Dynamic alignment of the chiral nanocolloids permits spectral discrimination between those effects that arise in the chiral signal due to their orientation on a chiral metasurface and those that arise in the isotropic state.

Abstract— Cavity polaritons are formed when a confined optical mode within a high Q cavity strongly couples with exciton within the same cavity. A reversible exchange of energy between excitons and photons results in new allowed energy eigenstates of the system manifesting as a mixture of the uncoupled photon and exciton energies while exhibiting an anticrossing at the point of exciton-photon resonance. Strong coupling regime has been observed in microcavity structures incorporating both inorganic quantum wells (QWs) as well as organic materials such as J-aggregates, molecular crystals and polymers [1].

In this work we study hybrid exciton-polaritons that arise from mixing of two different organic-inorganic excitonic species with the resonant photon mode [2]. A planar microcavity structure consists of GaAs QWs and Jaggregate molecular dye assembled together in a multi-layered stack to form the active region. Angle-resolved photoluminescence at 80 K, when the system is excited almost-resonantly by a low repetition laser pulse at 780 nm reveals clear anticrossing. The complete structure containing both species exhibits large Rabi splitting of ∼68 meV shown in Figure 1(a), consistent with the presence of large oscillator strength J-aggregate Frenkel excitons. The measured polariton dispersion relations can be fitted well using coupled harmonic oscillator model in which both Wannier-Mott and Frenkel excitons couple to cavity photon. Furthermore, through power dependent measurements we demonstrate for the first time strong nonlinear emission and onset of hybrid polariton lasing regime with simultaneous line narrowing and interaction induced energy blueshift shown in Figure 1(b).

Such hybrid excitonic system presents an ideal playground for engineering nonlinear interactions and at the same time offers concrete possibilities for optoelectronics application. For example, laser diode designs combining high electrical conductivity of inorganic semiconductors with exciton robustness of organic compounds to maintain strong coupling regime at room temperature could provide efficient means to achieve electrically pumped organic polariton lasers.

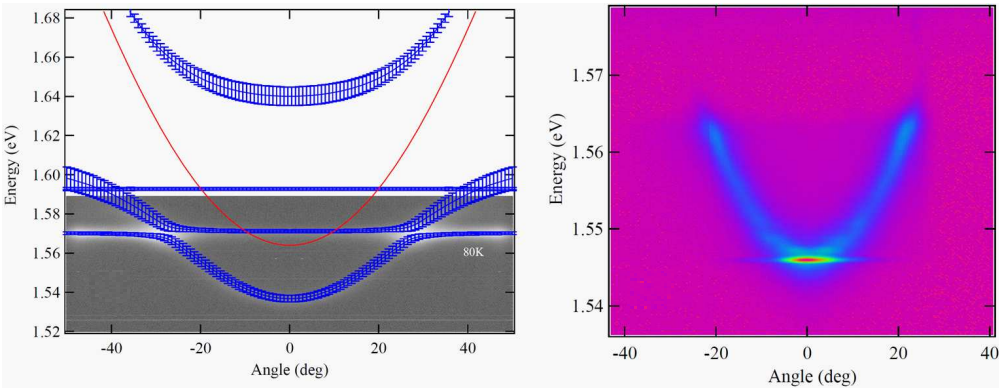

Figure 1: PL images recorded with Fourier plane projection technic. In Figure 1(a), clear polariton dispersion is revealed at 80 K while in Figure 1(b), clear polariton lasing obtained in similar detuning at 20 K.

Local Optical Activity in Metal Nanostructures Visualized by Near-field Circular Dichroism Microscopy

Hiromi Okamoto
Institute for Molecular Science, Myodaiji, Okazaki, Aichi 444-8585, Japan

Abstract— Confinement and enhancement of optical fields due to plasmons in metal nanostructures have great potentials in high-sensitivity spectroscopy, enhanced photochemical reactions, and so forth. In the past decade, our research group has made efforts to visualize the nanoscale optical fields in the periphery of the nanostructures, based on near-field optical imaging [1, 2]. Recently, optical activities of chiral nanostructures and chiral optical fields in the periphery of metal nanostructures have attracted attention of researchers. We are extending the near-field imaging study of nanoscale optical fields to local chiral optical fields generated by metal nanostructures [2].

For this purpose, we developed a near-field circular dichroism (CD) microscope [3]. The sample was irradiated by light for observation, which was modulated between left- and right-handed circular polarizations. The response field near the metal structure was picked up by an apertured near-field probe, and the CD signal was obtained by lock-in detection of the response field intensity, to construct the sub-wavelength CD image.

We prepared two-dimensional chiral gold nanostructures such as "S" and its enantiomeric mirrored structure, and recorded the CD images [3, 4]. Even though the far-field CD signal at the same observation wavelength was found to be small (10^{-3} level in absorbance unit) for this sample, *large local CD signal (10^{-1} level) was observed* on the nanostructure. The CD signals were not uniform in the nanostructures and CD signals of both positive and negative signs were observed at the same time in single nanostructures. An average of the local CD signal over the nanostructure yields a CD signal level similar to that observed with macroscopic CD measurements. This finding implies that metal nanostructures in general give locally enhanced CD signals even if they do not show strong optical activity macroscopically. In fact, we found that *even highly symmetric gold nanorectangles, which gave null macroscopic CD, showed strong local CD signals* [5]. This result is important in view of the selection rule of CD measurements of materials. The conventional macroscopic CD selection rule that only chiral materials are CD active is no longer valid for the local optical activity, because it reflects the *local symmetry* of the material.

To get information on the origin of local optical activity, we prepared a series of gold nanostructures composed of two "C" structures with various distances between their ends (it corresponds to "S" at zero distance between the two partial structures), and measured the near-field CD images [6]. The local CD signal at the connecting region of the associating structure was enhanced when the two partial structures were close enough (approx. 300 nm or less), and connection of the two partial structures was not necessary to get locally enhanced CD. This indicates that *the local CD of the two-dimensional metal nanostructure originates mainly from long-range electromagnetic interaction* and not from electronic exchange between the partial structures.

The method proposed here and the information obtained may serve as a basis for design and control of chiral optical fields, which is indispensable to applications of chiral fields to analytical purposes, optical devices, and so forth.

Transport and Harvesting of Excitons Mediated by Strong Coupling

Johannes Feist[1], **Carlos Gonzalez-Ballestero**[1],

Abstract— The transport of excitons (bound electron-hole pairs) is a fundamental process that plays a crucial rule both in natural phenomena such as photosynthesis, where energy has to be transported to a reaction center, and in artificial devices such as organic solar cells, whose power conversion efficiency can be improved significantly when the exciton diffusion length is increased. Similarly, excitons can play an important role in heat transport, and understanding and manipulating their role has possible applications ranging from thermoelectric effects to heat-voltage converters, nanoscale refrigerators, and even thermal logic gates. However, most systems composed of organic molecules are disordered and possess relatively large dissipation and dephasing rates, such that exciton transport typically is inefficient.

Very recently, an increase of the *electrical* conductance of an organic material was shown under strong coupling of the excitons to a cavity mode [1]. Strong coupling is achieved when the energy exchange rate between exciton and electromagnetic field modes becomes faster than the decay and decoherence rates of either constituent. Inspired by this result, we demonstrate that exciton conductance in organic materials can be enhanced by several orders of magnitude when the molecules are strongly coupled to an electromagnetic mode. Using a 1D model system, we show how the formation of a collective strongly coupled mode (a polariton) allows excitons to bypass the disordered array of molecules and jump directly from one end of the structure to the other [2].

We furthermore show that by designing the electric field profile of the electromagnetic mode that provides the strong coupling, the transport properties can be tuned to achieve exciton harvesting and funneling, i.e., to guide excitons from a collection area to a specific location. We demonstrate this effect using the localized plasmon resonances of a single metallic nanosphere and a three-sphere structure. The latter provides pronounced *hot spots* where the electric field is strongly concentrated. We show that excitons are efficiently transported between these hot spots, bypassing the rest of the system.

Abstract— We study energy transport efficiency in 2-D and 3-D configurations of two-level atoms (real or artificial ones). We show that, if the atomic system is embedded in a common blackbody radiation, the transport efficiency can be greatly increased with respect to the case $T = 0$. To understand this phenomenon we exploited the exact knowledge of field self-correlations, and showed that excitations can travel along the atomic system due to two alternative physical effects: in addition to the standard excitation hopping thanks to the atomic dipole interactions, atoms can affect each other's internal energy also by collective dissipation induced by non-local self-correlations of the electromagnetic field. This latter term has been neglected in previous phenomenological approaches since its effect has been assumed to be negligible. Although this assumption is well justified for regular systems where the hopping dominates, it breaks down in more general, non-regular configurations. By using a fully microscopic analysis of atomic dynamics, we show that these non-local terms, triggered by the thermal noise induced by the blackbody radiation, play a fundamental role in atomic energy transport. This generates a counter-intuitive temperature-dependence of the transport efficiency, which does not monotonically decrease as in the case of pure hopping, and gets instead amplified in a certain range of temperatures. By this effect excitations can travel along paths where hopping is forbidden with efficiencies remarkably higher than 100%.

Photonic Heat Transfer and Electronic Cooling in Hybrid Superconducting Nanostructures

H. Courtois[1], **C. B. Winkelmann**[1], **and F. W. J. Hekking**[2]

[1]Institut Néel, CNRS and Université Grenoble Alpes, Grenoble, France
[2]LPMMC, CNRS and Université Grenoble Alpes, Grenoble, France

Abstract— Electron thermodynamics at the nano-scale is a fast developing topic, in particular in superconductor-based hybrid devices. For instance, a simple Normal metal-Insulator-Superconductor (NIS) tunnel junction, when biased at a voltage just below the energy gap of the superconductor, enables only electrons with a higher energy to flow through. This selective evaporation process makes the normal metal electronic population as a whole to cool down. Electronic cooling is limited by electron-phonon coupling in the normal metal and by heat conduction. In a superconductor, electrons are paired into Cooper pairs so the electron-phonon coupling is vanishing, just as the electronic heat conductance. Therefore, only photons contribute to the heat conduction at very low temperature.

With a good matching between source and drain, the conductance of a superconducting transmission line is equal to the thermal conductance quantum: $K_Q = k_B^2 T\pi/6$ hbar. An inductance can also be present in some realistic configurations, due to the wiring geometry. We investigate the photonic heat transfer through a reactive impedance, i.e., a linear coupling circuit that contains a capacitor, an inductance, a resonant circuit or a transmission line. We follow a simple circuit approach, valid at low temperatures when the relevant photons have wavelengths larger than the size of the typical circuit element. The metallic parts can then be treated as lumped elements characterized by an electrical impedance. We present a quantitative analysis, enabling us to establish design rules for useful devices, including phonon thermometers or electron coolers. The photonic channel for heat transfer can in principle couple metallic systems that are galvanically isolated, e.g., through a capacitor. This effect can be detrimental when one wants to maintain two electronic populations at different quasi-equilibrium temperatures, but also beneficial in several cases.

Optomechanics at Microwave Frequencies: Mechanical Resonators Coupled to Microwave Cavities and Superconducting Qubits

Abstract— Micromechanical resonators affected by radiation pressure forces allow to address fundamental questions on quantum properties of mechanical objects, or, to explore quantum limits in measurement and amplification. A new setup for the purpose is an on-chip microwave cavity coupled to a mechanical resonator (Fig. 1(a)). Under blue sideband irradiation, we demonstrate the possibility of building a mechanical microwave amplifier [1], with noise properties approaching the quantum regime. On the red sideband side, we show how one can couple mechanical resonators via the cavity bus, while simultaneously cooling the mechanical modes very close to the ground state of motion [2]. A recent development in linear optomechanics is the coupling of graphene membranes to microwave-frequency cavities. Here, we observe radiation pressure back-action on the motion of graphene.

One can add intriguing features to the basic optomechanics setup by including a superconducting qubit made with Josephson junctions. The nonlinearity of the two-level system allows for much more rich physics than is possible with linear cavities. We have realized a superconducting transmon qubit interacting with a micromechanical resonator [3]. We operate the qubit in the circuit cavity quantum electrodynamics (circuit QED) architecture, where the qubit is coupled also to a microwave cavity. Hence, the combined setup represents an artificial atom coupled to two different cavities (Fig. 1(b)). We measure the phonon Stark shift, splitting of the qubit spectral line into motional sidebands, and coherent sideband Rabi oscillations. Another motivation the tripartite system owes from the challenges to increase the single-quantum coupling strength to exceed the cavity dissipation rate. Motivated by this goal, we present a new design of the circuit optomechanical experiment, where the on-chip microwave cavity includes a Josephson charge qubit [4]. The cavity is coupled to a micromechanical resonator whose motion is visible as charge, and hence affects the cavity frequency. This way we were able to boost the coupling in the setup by six orders of magnitude up to the MHz regime.

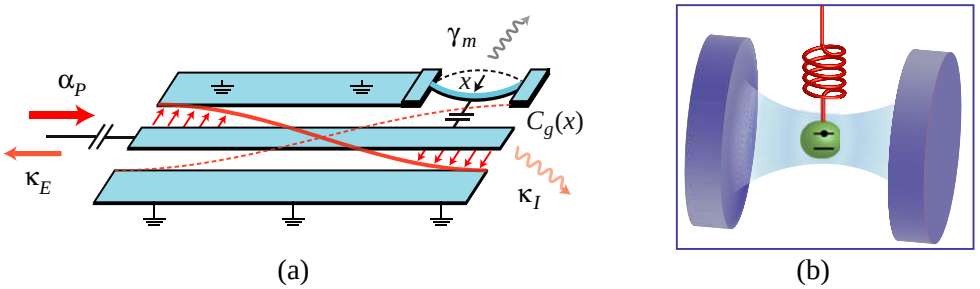

Figure 1: (a) A microwave resonator can be coupled capacitively to an arbitrary number of mechanical resonators. (b) Idea of introducing nonlinearity in optomechanics. Inside the cavity (blue) there is a quantum two-level system (green) which is mechanically compliant (red).

Light-matter Interface for Probing Quantum Gases

Gabriele De Chiara
Queen's University Belfast, UK

Abstract— I propose a scheme to probe many-body quantum states of ultracold gases using a light-matter interface based on the quantum Faraday effect. The polarisation fluctuations of light interacting with an atomic ensemble or atoms in optical lattices bear signatures of the many-body state. These fluctuations, observed with a quantum non-demolition measurement, allow one to reconstruct the phase diagram of a variety of Bose-Hubbard and spin models. In particular, I show how the critical point of the Mott insulator to superfluid phase transition can be accurately extracted from the light measurement [1]. Moreover, I propose a scheme, based on the same interface, to measure work and heat fluctuation relations, including the famous Jarzynski equality in ultracold quantum gases. This result opens the way to the exploration of mesoscopic quantum thermodynamics with cold atoms towards the realisation of quantum engines [2].

Thermal Emission by a Subwavelength Aperture

K. Joulain, **Y. Ezzahri**, **and J. Drevillon**
Institut Pprime, CNRS, Université de Poiters, ENSMA, Poitiers, France

Abstract— We calculate, by means of fluctuational electrodynamics, the thermal emission of an aperture filled by vacuum or a material at temperature T. We show that thermal emission is very different whether the aperture size is large or small compared to the thermal wavelength. Subwavelength apertures filled with vacuum (subwavelength blackbody) have their thermal emission strongly decreased compared to classical blackbodies. A simple expression of their emissivity can be calculated and their total emittance scales as T^6 instead of T^4 for large apertures. Subwavelength apertures filled with an opaque material have generally a similar behavior. However, if the material support surface waves or exhibit resonances, thermally excited evanescent resonant modes are scattered by the aperture. In this case, the thermal emission tends to be monochromatic and is strongly enhanced in comparison to the Planck theory. We think this behavior could open the way to very useful applications such as very narrowband passive source.

Thermal Emission of a Hyperbolic Blackbody

Abstract— The blackbody theory of Planck [1] is revisited in the case of thermal electromagnetic fields inside uniaxial anisotropic media in thermal equilibrium with a heat bath using the fluctuation dissipation theorem [2, 3]. When these media are hyperbolic, we show that the spectral energy density of these fields radically differs from that predicted by Planck's blackbody theory. We demonstrate that the maximum of their spectral energy density is shifted towards frequencies smaller than Wien's frequency making these media look colder than classical blackbodies for a given temperature. Finally, using Rytov's fluctuational electrodynamics we derive Stefan-Boltzmann's law for hyperbolic media which becomes a quadratic function of the heat bath temperature. We discuss direct consequences for heat transport through vacuum [4] and through a hyperbolic medium [5].

Measurements of the Heat Transfer in Near Field Regime

J. Chevrier and P. J. van Zwol
Institut Néel, CNRS and Universite Joseph Fourier Grenoble
BP 166 38042, Grenoble Cedex 9, France

Abstract— Heat can be exchanged between two surfaces through emission and absorption of thermal radiation. For distances smaller than the peak wavelength of the black body spectrum, radiative heat transfer can be increased by the contribution of evanescent waves. This contribution can be viewed as energy tunnelling through the gap between the surfaces. On the basis of results published in [1], we shall here present a detailed quantitative comparison between theory and experiments in the nanometre range. We shall describe an experimental setup that allows measurement of conductance for gaps varying between 30 nm and 2.5 µm. We shall then show how the systematic use of this machine has enabled us to measure the heat transfer in near field regime for different materials including VO2 which presents a prototypical metal insulator transition. Further we have investigated the change of the near field contribution to heat transfer when one surface is covered with graphene. Indeed owing to its two dimensional electronic structure, graphene exhibits many unique properties. One of them is a wave vector and temperature dependent plasmon in the infrared range. Theory predicts that due to these plasmons, graphene can be used as a universal material to enhance nanoscale radiative heat exchange for any dielectric substrate. Based on [2], we shall report on radiative heat transfer experiments between SiC and a SiO_2 sphere which have non matching phonon polariton frequencies, and thus only weakly exchange heat in near field. Heat flux contribution of graphene epitaxially grown on SiC will be shown to dominate at short distances. The influence of plasmons on radiative heat transfer is further supported with measurements for doped silicon. These results highlight graphene's strong potential in photonic near field and energy conversion devices.

Experiments on Giant Radiative Heat Flux at the Nanometer Scale

A. Kittel, K. Kloppstech, N. Könne, L. Worbes, and D. Hellmann
Institute of Physics, Carl-von-Ossietzky University of Oldenburg, D-26111 Oldenburg, Germany

Abstract— We report on a precise *in situ* procedure to calibrate the heat flux sensor of a near-field scanning thermal microscope. This calibration procedure is based on modulation technique and utilizes a hot wire method to build a metrologically accessible and controllable heat reservoir. This reservoir is coupled thermally via near-field interactions to our probe exactly in the same way as it is coupled in a actual measurement. Thus the sensor's conversion relation can be precisely determined which is the thermopower, generated in the sensor's coaxial thermocouple, in dependence on the thermal flux from reservoir through the sensor. The achieved accuracy is about 8%. With such a calibrated sensor we perform quantitative measurements of the heat flux between a gold coated near-field scanning thermal microscope tip and a planar gold sample at nanometer distances across a vacuum gap. We find an extraordinary large heat flux which is more than five orders of magnitude larger than black-body radiation and three orders of magnitude larger than the values predicted by conventional theory of fluctuational electrodynamics often used to describe near field effects of heat transfer. Furthermore, experiments show that this heat transfer can be drastically influenced by a thin layer of material on the surface. The findings demand modified, or even new models to describe the heat transfer across a vacuum gap at nanometer distances.

Casimir Actuation of MEMS between Real Materials

G. Palasantzas, M. Sedighi, W. H. Broer, V. B. Svetovoy, and J. Knoester
Zernike Institute for Advanced Materials, University of Groningen, Nijenborgh 4, The Netherlands

Abstract— Using the measured optical response and surface roughness topography as inputs, we perform realistic calculations of the combined effect of Casimir and electrostatic forces on the actuation dynamics of micro/nanoelectromechanical systems (MEMS/NEMS) using as input optical properties and surface roughness. Our findings play a principal role for the stability of micro/nanodevices such as vibration sensors, switches, and other related device architectures operating at distances below 200 nm. In contrast with the expectations, roughness can influence MEMS dynamics, even at distances between bodies significantly larger than the root-mean-square roughness. This effect is associated with statistically rare high asperities that can be locally close to the point of contact. It is found that even though surface roughness appears to have a detrimental effect on the availability of stable equilibria, it ensures that those equilibria can be reached more easily than in the case of flat surfaces. Moreover, it appears that surface roughness can suppress chaotic behavior towards stiction. In addition, the dependence of the Casimir force on the frequency dependent dielectric functions of interacting materials makes it possible to tailor the actuation dynamics of microactuators. The Casimir force is largest for metallic interacting systems due to the high absorption of conduction electrons in the far-infrared range. For less conductive systems, such as phase change materials or conductive silicon carbide, the reduced force offers the advantage of increased stable operation of MEMS devices against pull-in instabilities that lead to unwanted stiction. Bifurcation analysis with phase portraits has been used to compare the sensitivity of a model actuator when the optical properties are altered. Finally, computations using the Drude-Plasma models to model low optical frequencies show differencies that are strongly minimized for weakly conductive systems as are the doped insulators making actuation modeling more certain to predict.

Reducing the Casimir Force

S. A. R. Horsley and T. G. Philbin
Department of Physics and Astronomy, University of Exeter, Exeter, UK

Abstract— A considerable body of research has demonstrated that the Casimir force can be engineered to some extend. Theoretical and experimental work has shown that the choice of materials and the geometry of material samples can have a significant effect on the magnitude, and even the direction, of the Casimir force. This work has implications for future engineering on nanometre scales where the Casimir effect can play a significant role. Here we report on a theoretical study of artificially engineered non-reflecting coatings as a method of reducing the Casmir force. The use of artificial materials in Casimir manipulation has been limited by the need for broadband functioning, which is impossible with many designs based on "meta-atoms". The coatings we consider are inhomogeneous with specially chosen dispersion and absorption, but they do not have a "meta-atom" structure and can function as desired over a broad range of frequencies.

Photonic Forces on Magneto-dielectric Nanoparticles at Optical Wavelengths with Random Fields. Creating Optical Analogous of Van der Waals and Casimir Interactions and Beyond: Their Control and Design through the Spectrum and Spatial Coherence

Manuel Nieto Vesperinas[1] **and Juan Miguel Auñón**[2]

[1]Instituto de Ciencia de Materiales de Madrid, Consejo Superior de Investigaciones Científicas
Campus de Cantoblanco, Madrid 28049, Spain
[2]School of Physics and Astronomy, University of St. Andrews, North Haugh, Fife KY16, 9SS, Scotland

Abstract— At selected wavelengths, (visible and near-infrared), the Planck energy of optically produced random light is equivalent to that of the vacuum fluctuations; thus employing a quasi-monochromatic optical source, the forces on nanoparticles may be made analogous to Casimir-Polder and Van der Waals interactions.

We show how for some wavelengths, the contribution of the particle induced magnetic dipole predominates over that of the electric one, and how when Kerker conditions hold, (see [1] and references therein), the magnetic dipole can cancel to the purely dipole force, the interference being responsible for the mechanical action on the particle.

We derive new power-laws for the induced dipole forces. Further, we show how controlling the optical spectrum shape and bandwidth, as well as the degree of coherence of the emitted fields, one can tailor at will the electric and/or magnetic, conservative or non conservative, attractive or repulsive, nature of these forces, as well as their magnitude.

Fluctuation Induced Effects in Nanostructures

Lilia M. Woods
Department of Physics, University of South Florida
Tampa, Florida 33620, USA

Abstract— Fluctuations of observables can give rise to many types of interactions. Dipolar fluctuations are responsible for Casimir forces, which are of great importance for the operation of micro-machines and the stability of inert materials composites. Nanostructured materials, such as graphitic systems, offer a great opportunity to study such effects and discover unique functionalities. Near-field radiation, which can be characterized as Casimir-like phenomenon between systems at temperature gradient, is of particular relevance in graphene systems. In this presentation, we review how the thermo-plasmons tunability can be utilized in order to take advantage of the graphene transverse electric mode. Utilizing this phenomenon, one is able to find new ways for radiation control and probe the relaxation scattering times in graphene. In addition to dipolar fluctuations, charge fluctuations can also be responsible for Casimir-like forces. We show that such effects are of relevance to capacitor systems especially when nanostructured materials are involved. Our theory, which utilizes the quantum capacitance concept, demonstrates novel pathways for probing quantum mechanical and thermal fluctuations effects in materials with reduced dimensions.

Probing the Surface with Atoms

Ron Folman
Ben-Gurion University of the Negev, Israel

Abstract— As cold atoms are brought evermore closer to surfaces, they open a wide variety of possibilities of probing the surface. In this talk I will review past realizations of such experiments around the world, and the possibilities made available in the near future for probing the CP force, Johnson noise, the hypothesized short range fifth force, plasmons, and other surface effects.

Dispersion Interactions with Long-time Tails or Beyond Local Equilibrium

C. Henkel
Institute of Physics and Astronomy, University of Potsdam, Germany

Abstract— Dispersion forces out of thermal equilibrium can be understood as the rectification of electromagnetic fluctuations that arise from spatially separated sources (bodies). The forces are often observed on time scales much longer than the characteristic periods of thermal or zero-point radiation fields. Such a separation of time scales is a strong motivation for approximate treatments, assuming that the electromagnetic response of a body to an incident field is fast or that thermalization takes place rapidly. Many applications of radiative energy transfer on the nano-scale build on this picture (light harvesting, enhanced near-field heat transfer etc.).

The purpose of this contribution is twofold. (1) We take up the problem of the response time of the electromagnetic field or of a polarizable object in the extreme quantum limit (zero temperature). One finds in some cases correlation functions of the zero-point fields that are long range in time ('fat tails'), in distinction to the more familiar response (Green) functions. We discuss the relevance of these tails by focusing on a simple example: the electromagnetic drag force on a small polarizable particle (quantum friction). The corresponding field theory of photons and a few-level atom has been analyzed with the help of perturbation theory in Refs. [1, 2].

(2) A fictitious conversation is engaged to scratch for the foundations of dispersion forces in *local* thermodynamic equilibrium (LTE). Our focus is on suitable validity criteria and on potential observations that would illustrate non-LTE physics. As a concrete example, we address radiative heat transport across the interface between two transparent dielectrics, as discussed in Refs. [3–6].

The Coherent Effects of the Casimir-Polder Interaction on Driven Atoms and the Quasi-resonant Van Der Waals Interaction between Non-identical Atoms

Manuel Donaire and Astrid Lambrecht
Laboratoire Kastler-Brossel, UPMC-Sorbonnes Universités, CNRS, ENS-PSL Research University
Collège de France, 4, Place Jussieu, F-75252 Paris, France

Abstract— In this talk we address several aspects of the Casimir-Polder (CP) and van der Waals (vdW) interactions which need a time-dependent approach. In the first part of this talk we will show that the CP interaction of an atom with a material surface may give rise to a renormalisation of the Rabi frequency of the atom when the atom is driven under the action of two Raman lasers [1]. Likewise, CP-induced Rabi oscillations may generate between two Zeeman sub-levels of a free atom in the vicinity of a reflecting surface [2].

In the second part of this talk we will present the vdW interaction between two non-identical atoms, one of which is prepared in an excited state [3]. Finally, we will give results for the quantum friction which an excited atom experiences as it moves at constant velocity parallel to a dilute atomic surface.

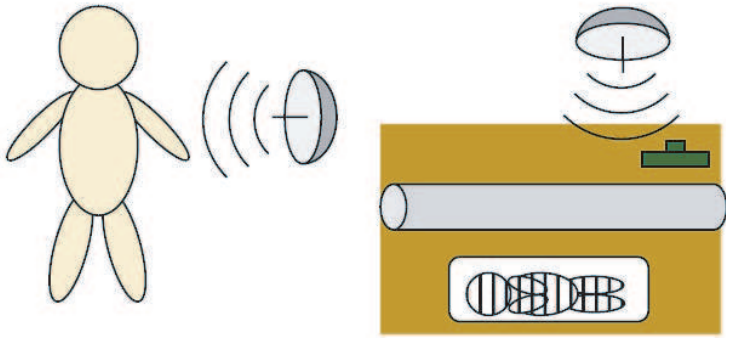
Calculation of Gain in a Lossy Medium

Takuichi Hirano, Jiro Hirokawa, and Makoto Ando
Tokyo Institute of Technology, Japan

Abstract— Characterization of propagation in a lossy medium is demanded in applications like ground penetrating radar (GPR), ultra wideband (UWB) radar for cancer detection and so on (see Fig. 1). This paper presents extension of Friis transmission equation [1] from a lossless medium to a lossy one.



(a) (b)

Figure 1: Friis transmission equation in a lossy medium. (a) UWB radar. (b) GPR.

When two antennas #1 and #2 are separately placed with distance r in a lossy medium as shown in Fig. 1, the extended Friis transmission equation becomes

$$\frac{P_r}{P_t} = G_1 G_2 \left(\frac{\lambda}{4\pi r}\right)^2 \exp(-2\alpha r) \tag{1}$$

where G_1 and G_2 are gains of the antenna #1 and #2, respectively. The $\lambda = 2\pi/\beta$ is the wavelength which is calculated from the phase constant β in the lossy medium. The α is the attenuation constant of the lossy medium. The factor $\exp(-2\alpha r)$ represents attenuation in the lossy medium, which does not appear in the conventional Friis transmission equation.

The authors developed the gain measurement algorithm [2], averaging method for the shortened far-field gain measurement technique, which is applicable for measurement and simulation.

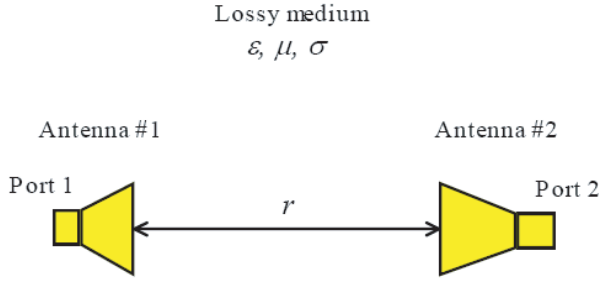


Figure 2: Friis transmission equation in a lossy medium.

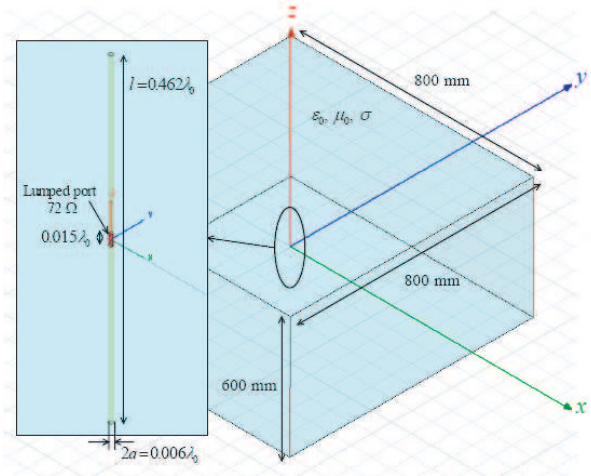

Figure 3: Simulation model of a half-wavelength dipole antenna.

For verification of the extended Friis transmission equation [1], the gain of a half-wavelength dipole antenna in a lossy medium is analyzed. Fig. 3 shows a simulation model of a half-wavelength dipole antenna. Ansys HFSS Ver.11 is used for the simulation. Table 1 shows calculated gain of the dipole antenna for several conductivities σ. The method in [2, 3] are used for the analysis of gain. The gain decreases as the conductivity σ increases. The result is verified by the simulation with two dipole antennas. Transmission coefficient S_{21} agrees well each other by that obtained by Eq. (1) ($P_r/P_t = |S_{21}|^2$).

Table 1: Calculated gain.

σ (S/m)	Gain (dBi)
0	2.22
0.001	2.08
0.01	0.86

A Novel Ka-band Spatial Combiner Amplifier: Global Design and Modeling

Alberto Leggieri[1], **Davide Passi**[1], **Franco Di Paolo**[1], **Marco Bartocci**[2], **Antonio Tafuto**[2], **and Antonio Manna**[2]

[1]Department of Electronic Engineering, University of Rome Tor Vergata, Rome, Italy
[2]Elettronica SpA, Via Tiburtina Valeria Km. 13, Rome 7-00100, Italy

Abstract— This article describes the complete design of high performances Ka-Band small size Spatial Power Combiner (SPC) Amplifier. Several multiple physics aspects are treated in the proposed study as electromagnetic behavior and thermo-mechanical features, in order to drive the active devices at full power. The combiner consists of quadruple Fin lines to microstrip (FLuS) (Figure 1) transitions inserted into a WR28 waveguide T-junction (Figure 2). In this structure, 16 Monolithic Microwave Integrated Circuit (MMIC) Solid State Power Amplifiers (SSPA's) are integrated.

When devices operate in high efficiency regime, thermal expansion of materials may induce significant stresses and strains with consequent displacement of the guiding and combining structures, resulting in an undesired modification of the electromagnetic behavior of the device. For this reason, thermal exposition has been controlled by an opportune heat-sinker subjected to a cooling air flow (Figure 3).

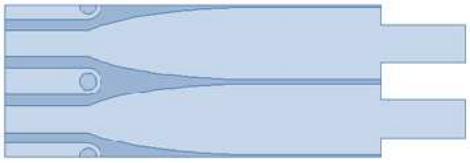

Figure 1: Quadruple FLuS employing the innovative dielectric Parallel QWT.

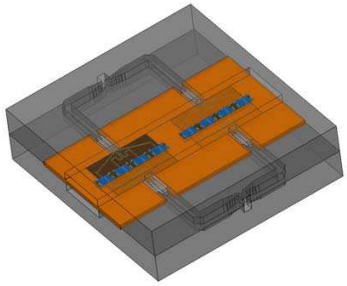

Figure 2: The complete Ka-band SPC Amplifier.

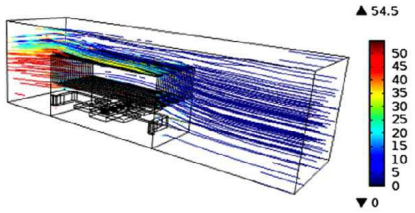

Figure 3: SPC subjected to the cooling airflow with temperature distribution (°C). Since the device has two symmetry planes, only a quarter of the SPC structure has been employed for the modeling by introducing opportune boundary conditions.

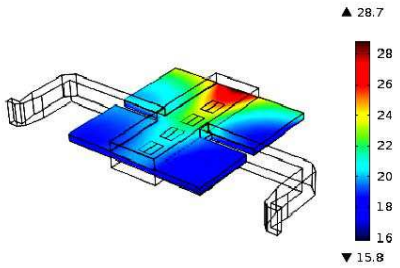

Figure 4: Maximum displacement on MMIC and carrier (μm). Thermal expansion induces a maximum displacement of 28.7 μm on the carrier.

Thermodynamic and Fluid-Dynamic analysis coupled to structural mechanics computation have been employed in order to study the effect of these critical factors. A main design has been followed by FEM simulation using Ansys-Ansoft HFSS and Comsol Multiphysics.

Scattering parameters, stresses and strains have been computed together with the temperature and airflow distributions. While operating at maximum power, the transistors present a maximum displacement of 28.7 μm (Figure 4) caused by the thermal expansion of the material due to a

channel temperature of 125°C (Figure 5). In such condition, a mean insertion loss of 2 dB for the passive SPC is achieved with a return loss better the 10 dB in the 31–37 GHz bandwidth (Figure 6).

In order to allow for the heat dissipation without mismatch between coefficients of thermal expansion (CTE) for GaAs and conductors, MMIC's are brazed onto CuMo heat spreader and the whole assembly is brazed onto copper carriers.

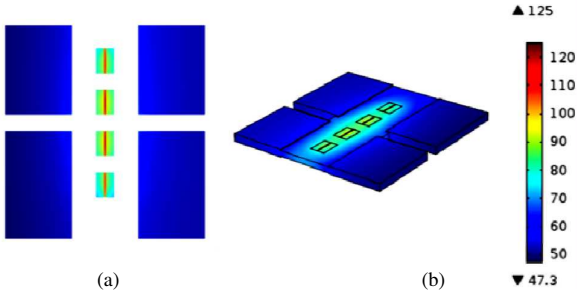

Figure 5: Temperature distribution (°C) on carrier and MMIC in (a) plane section and (b) 3D view. When the active devices operate at full power, the channels reach a maximum temperature of 125°C (below maximum rating).

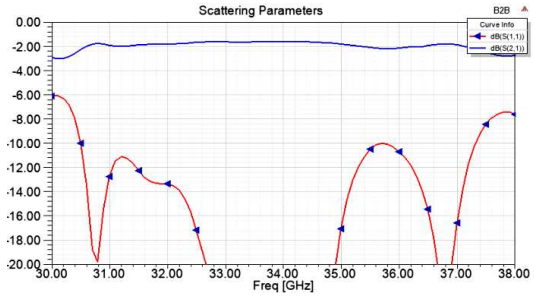

Figure 6: SPC insertion loss and return loss in dB.

Analysis of Bandpass Filters Consisting of Air Holes in Post-wall Waveguides

Ken'ichiro Yashiro[1] and Ning Guan[2]

[1]Chiba University, 1-33, Yayoi-cho, Inage-ku, Chiba 263-8522, Japan
[2]Fujikura Ltd., 1440, Matsuzaki, Sakura 285-8550, Japan

Abstract— A post wall waveguide is a promising candidate for the development of low cost circuits in the millimetre-wave region. The post wall waveguide consists of metallized dielectric substrate and arrays of metallic posts. If some air holes are set up in the post-wall waveguige, they have a filtering function. It is prospected to fabricate air holes easier than post-wall waveguide itself.

In this paper, we analyse the air-hole bandpass filter shown in Fig. 1. To do so, we developed the technique based on the method of moments. In order to treat the penetrating circular cylinders such as dielectric cylinders in the same way as perfect conductive cylinders, we assume the equivalent surface currents on the surface of each cylinder. By using Green function, that is a Hankel function of 0-th order, the scattered fields are given in the integral form in terms of the equivalent surface currents. The surface current density on each cylinder is expanded into a series of global basis functions in the local polar coordinate system. The global basis functions were used to reduce the number of unknowns per cylinder and the necessary computer memory is also reduced. The integrals for the scattered fields are calculated analyticaly by using Graf's addition theorem. We introduce the surface impedance so that the boudary condition is imposed at the surfaces of all of cylinders in the unified manner, Furthermore, the Galerkin method was used to obtain a sytem of linear equations. That is, the global basis functions were also used as weighting functions. When the field point and the source point locate on the different cylinders, the Graf's addition theorem was used again to evaluate the elements of the coefficient matrix analytically.

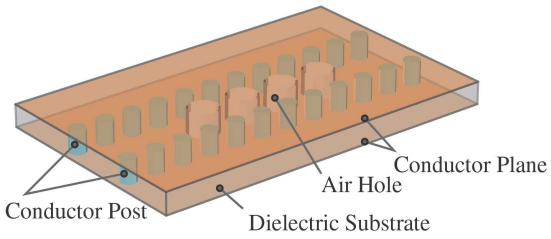

Figure 1: Air-holes in post-wall waveguide.

Several filters with the different number of air holes were analyzed and the frequency characteristics of them will be given. Furthermore, the electric field distributions are given for both cases of passband and stopband.

Bending-loss Improvement of Subwavelength Grating Waveguides by Using a Modified Structure

Hung-Hsuan Chen and Chin-Ping Yu
Department of Photonics, National Sun Yat-Sen University, Kaohsiung 80424, Taiwan

Abstract— Silicon on insulator (SOI) structures with high index contrast can efficiently reduce the device sizes to realize highly integrated optical circuits. However, due to their high confinement of lightwave, optical devices based on SOI structures suffer serious scattering losses resulted from the rough surfaces. In addition, the coupling effects and sensing abilities of SOI devices are relatively small due to only a few light field extended into the cladding regions. Recently, subwavelength grating (SWG) waveguides formed by periodically interlacing silicon segments at the subwavelength scale have been proposed to guide light in the SOI structures with larger extended filed in the cladding regions. In addition, it has been demonstrated that the propagation loss of SWG waveguides can be as low as 2.1 dB/cm for their delocalized mode field can reduce the scattering losses caused by the roughness of the vertical walls. However, the delocalization of mode filed in SWG waveguides may result in high bending losses, which limits the applications of SWG waveguides. In this study, we propose a modified bending SWG waveguide to reduce the bending losses. Along the bending, the rectangular segments are replaced by trapezoid segments with their bases are a and m, respectively. The numerical results obtained ny a 2-D finite element method (FEM) demonstrate that the larger base m can concentrate more field along the inner side of bending to prevent radiation losses as light propagates along the bending waveguide. We will also discuss the bending losses of our modified bending SWG waveguide for variant bending radii to help the development of optical devices based on SWGs.

Power Evaluation of a Metal Disc-shaped Terahertz Surface Wave Splitter

J. Shibayama, **D. Kusunoki**, **J. Yamauchi**, **and H. Nakano**
Faculty of Science and Engineering, Hosei University, Tokyo 184-8584, Japan

Abstract— Surface plasmon polaritons (SPPs) propagate along a metal-insulator interface at optical frequencies. At terahertz (THz) frequencies, however, SPPs cannot be supported along the metal-dielectric interface owing to negligible penetration of the electromagnetic fields. This is because THz frequencies are far below the plasma frequency of metal. Note, at THz frequencies, that spoof SPPs are supported on a metal surface with an array of holes, the sizes of which are much smaller than the THz wavelength [1]. For spoof SPP waves, bi- and multi-directional frequency splitters consisting of metal gratings with finite thickness have been studied numerically and experimentally [2]. The grating structures have also been investigated for slow wave devices [3].

Very recently, we have proposed novel splitters consisting of metal discs with a center hole and radially placed gratings [4, 5]. It has been shown that the discs act as frequency splitters at two, three and four frequencies. However, we have not evaluated the power propagating in each direction. In this presentation, we calculate the power based on the Poynting vector to investigate the splitting characteristics in detail. In addition, we illustrate the spoof SPP waves propagating along the disc, paying attention to the frequency splitting behavior.

Formation of One-dimensional Image by Pulsed Light Diffraction on Running Sound Wave

Victor Petrov[1] **and Roman Kijan**[2]

[1]St.-Petersburg Politechnical University, St.-Petersburg, Russia
[2]Laser Zentrum Hannover e.V., Hannover, Germany

Abstract— The advanced system for formation of a TV image on a projection screen is an acoustooptic system that relies on the principle of exposure of the entire TV 1D image by one laser radiation pulse and further deflection of 1D images across the frame will be presented. A general solution of the integral equation for a diffracted field for the case of wide-band anisotropic light diffraction by a slow shear elastic wave near the optical axis of an acoustooptic modulator (AOM) made from a crystal of paratellurite TeO_2 was found by us. We will discuss the solution for the diffracted field and consider the problem of formation of the image of an amplitude-modulated 1D image that fills the AOM aperture on the projection screen. For the practical realization a light source, a copper-vapor laser with wavelength $\lambda_0 = 0.5106\,\mu$m and generation pulse duration $\tau_0 = 10\,$ns was used.

In the approximation of a low diffraction efficiency, a two-dimensional field distribution in the (+1)st diffraction order in the focal plane of the input cylindrical lens and also time-average distribution of intensity of light from a pulsed coherent source in the image plane have been calculated. Calculations of the modulation-transfer function of the acoustooptic system for the 1D image formation including a pulsed copper-vapor laser and AOM from a paratellurite crystal (TeO_2) for different light pulse durations, carrier frequencies of ultrasound, acoustooptic interaction lengths, and also cones of angles of light incidence on the AOM in the plane orthogonal to the scattering plane have been carried out.

Numerical calculations have shown that an increase in the light pulse duration leads to a decrease in the contrast in transfer of amplitude-modulated signals at high frequencies. An increase in the contrast at high frequencies results from a decrease in the piezotransducer width and decrease in the carrier frequency of ultrasound. It approaches the frequency of two-phonon interaction.

It has been shown that in the case of incidence of a plane light wave on the input cylindrical lens, a dip of intensity associated with specific features of interference of diffracted elliptically-polarized light beams that propagate at different angles $\pm\alpha_0$ to the optical axis of the gyrotropic TeO_2 crystal is observed at the centre of the light intensity distribution along the y coordinate. When a light beam with angular divergence is incident on the input lens, the dip in the transverse distribution of intensity becomes less pronounced.

Requirements to the choice of the parameters of the optical components and AOM for the used geometry have been formulated.

Multi-physics Simulation for Evaluating High-density Magnetic Recording Methods

Abstract— High-density magnetic recording is an indispensable technology to develop storage devices for current big data demand. Some kinds of energy-assisted schemes using recording media with high magnetic anisotropy have become recent trend. In this presentation, we will discuss magnetization reversal process of high anisotropy recording media using micromagnetic and electromagnetic simulation and numerically verify a high-density recording method with assisted microwave irradiation. To evaluate exchange and magnetic dipole interactions efficiently, a fast computational method will be proposed and the effect of assisted microwave will be clarified.

We will also discuss another novel method, all-optical magnetic switching (AOS) with circularly polarized light, which has been recently discovered by one of the authors [1]. To localize the polarized light for triggering AOS beyond the diffraction limit, the higher density over 2 Tbit/inch^2 can be achieved [2–4]. Using FDTD electromagnetic simulation with the auxiliary motion equation of electrons, robust and efficient plasmonic antennas to generate the localized light will be designed. The surfaces of antennas are assumed to be perturbed considering nano-fabrication process. Characteristics of antennas are evaluated in terms of the Stokes parameters.

Abstract— Interaction of light with the metallic nanostructures and nanoparticles gives rise to various unique and surprising effects in photonics and optoelectronics [1]. The surface plasmons characterize the unique response in collective motions of electrons on a metal-dielectric interface, which is allowed when the permittivity of the metal is negative for the wavelength of excitation. Recently, much attention has been paid to the light scattering from *metal-dielectric* layered structures, because of their novel applications in sensors, super-scattering and invisible cloaking. Surface plasmons are accompanied by localized enhancement of the electromagnetic field. This leads to developing metallic nanostructures that can control light at the nanoscale in direct analogy to traditional optical components such as lens, mirrors and waveguides. Many of these applications rely on a planar geometry in practice.

An alternative of the planar configuration is a cylindrical configuration. In this regard, in the manuscript we investigate the light scattering by metal (silver)-coated dielectric nanocylinders periodically distributed along the cylindrical surface. The rigorous formulation uses T-matrix of a circular scatterer in isolation and it is taking into account all cylindrical Floquet modes and their interactions through the scattering between the nanocylinders periodically distributed along the circular ring [2]. The structure is under our interest from the viewpoint of its practical applications as plasmonic waveguides, plasmonic lasers and plasmonic ring resonators.

We investigate up to four metal (silver)-coated dielectric nanocylinders periodically located along the circular ring in a free space. Firstly, the scattering and absorption cross sections of three and four metal (silver)-coated nanocylinders are studied at various distances between the nanocylinders keeping their radii the same. The resonances appearing in the short wavelength region correspond to the plasmon resonances of metal-coated nanocylinders in isolation and the resonance wavelengths does not change by changing the separation distance between the nanocylinders. The spectral responses show some interesting profile characterizing the cylindrical configuration of the nanocylinders. When a separation distance between the nanocylinders is small (the nanocylinders are located very close, but not touching each other), there appear resonance peaks in the long wavelength region for both scattering and absorption cross sections. These resonances are characterized as the resonances intrinsic to the cylindrically periodic system. Other resonances appearing in the intermediate wavelength region describe the resonant coupling of the surface plasmon fields in the multiple nanocylinders systems.

Based on the analyses of the spectral responses, the near field distributions are calculated at the particular wavelengths corresponding to the resonance wavelengths. A deep physical insight is given to **a)** enhancement of the near fields at the inner (metal-dielectric) and outer (metal-free space) interfaces (corresponding to the resonances in the short wavelength region); **b)** localization of the excited field in the gap region between the nanocylinders through the coupled plasmon resonance (corresponding to the resonances in the intermediate wavelength region); **c)** strong confinement of the field inside the cylindrical structure (corresponding to the resonances in the long wavelength region). The latter uniquely characterizes the cylindrical configuration of the nanocylinders.

Comparative Study on Boundary Conditions for Terminating Photonic Crystal Waveguides

Zhen Hu[1] and Ya Yan Lu[2]

[1]Department of Mathematics, Hohai University, Nanjing, China
[2]Department of Mathematics, City University of Hong Kong, Hong Kong, China

Abstract— Photonic crystal (PhC) devices often use PhC waveguides as input and output ports. These periodic waveguides create a significant problem for numerical simulations of PhC devices, since they cannot be easily truncated to obtain a finite computation domain. The perfectly matched layer (PML) technique is extremely powerful for truncating unbounded homogeneous media in numerical simulations of waves [1], and it has been tried on PhC waveguides [2], but it fails to accurately simulate outgoing Bloch modes in PhC waveguides [3]. On the other hand, it is possible to numerically calculate a rigorous boundary condition for terminating a PhC waveguide. Joly et al. first applied the so-called limiting absorption principle [4] to calculate such a boundary condition. We have used Bloch mode expansions to find the same boundary condition [5]. The rigorous boundary condition can be used arbitrarily close to the main part of the device, but it is nonlocal, and is rather expensive for slab-based PhC devices. In [6], we developed a simpler and approximate boundary condition that models the outgoing Bloch modes accurately, but assumes that the evanescent modes and other radiating field can be ignored. In this paper, we compare different methods for truncating PhC waveguides, analyze the limitations of various methods in terms of accuracy or computational cost. The results are illustrated by numerical examples.

Abstract— Recently, the importance of silicon photonic integrated circuits has been widely recognized, especially in silicon-on-insulator (SOI) platform due to its advantage of hight-index-contrast and CMOS-compatible processing. However, the polarization dependent characteristics limit the application of silicon photonics devices. To overcome this problem, polarization diversity scheme is often used, where polarization converters (PCs) are the fundamental components. Photonic crystal fibers (PCFs), also known as holey fibers (HFs), which consisting of single material with periodical array of air holes around the fiber core, have attracted a lot of attention in the last two decades due to their flexible structure and the special properties that cannot be obtained by the conventional fibers. In recent years, elliptical-hole core circular-hole holey fiber (EC-CHF), a novel single-polarized holey fiber with a core filled with elliptical-holes, has been proposed for achieving the single polarization transmission easily [1]. In this research, we propose a novel PC using square lattice EC-CHFs with a short conversion length and a simple structure distribution. In addition, we combine the PC with a polarization splitter which we have proposed [2] to achieve the polarization separation and conversion at the same time.

In this research, we introduced elliptical-holes whose major axis rotated 45° counterclockwise against x-axis into the core region to achieve the polarization conversion. The ellipticity is set to $d_{\mathrm{major}}/d_{\mathrm{minor}} = 2$, and the holes in cladding is circular air holes. Since the large birefringence can be realized in the core region by using ellipses, our proposed PC has a short conversion length which consists of only two kinds of air holes. The air hole size dependence of conversion length has been discussed by using full-vector finite-element method (FV-FEM). From the analysis results, we note that if the diameter of cladding hole is set to be a constant, the conversion length has a minimum value with the variation of ellipses in core region. The shortest conversion length can be up to 31.7 μm. The propagation behaviors by using full-vector finite-element beam propagation method (FEBPM) shown that an x-polarized incident light can be completely converted into a y-polarized light through our proposed PC. Moreover, we demonstrated that the polarization splitter in [2] can completely divide an arbitrarily polarized light beam into two orthogonal polarization states based on square lattice EC-CHFs. In the future, we consider a kind of polarization splitter and converter based on square lattice EC-CHFs to achieve the polarization separation and conversion at the same time.

Broadband Line Imaging with Subwavelength Resolution Using Plasmonic Waveguides

Nina Podoliak[1], **Peter Horak**[1], **Jord C. Prangsma**[2], **and Pepijn W. H. Pinkse**[2]

[1]Optoelectronics Research Centre, University of Southampton, Southampton SO17 1BJ, United Kingdom

P. O. Box 217, 7500 AE Enschede, The Netherlands

Abstract— In this paper we design a high-resolution line imaging device allowing for broadband operation at near-infrared wavelengths ranging from 1 µm to 2 µm utilizing the advantage of subwavelength light confinement in plasmonic waveguides. The device consists of an array of air-guided plasmonic waveguides in gold with fanned-out geometry (see Fig. 1(a)) [1]. In the main part of the device the separation between waveguides increases gradually from the input towards the output. High resolution is achieved on the input side by tapering down the periodicity between channels to 150 nm, while simultaneously maintaining propagation losses of a few dB. The proposed design also minimizes optical cross-coupling between waveguides; each channel thus transmits optical fields independently allowing for high signal-to-noise ratio imaging. At the low-resolution side properly tailored output couplers are designed to enhance optical coupling to free space. This is also shown to be an effective method to reduce back reflection, thus minimizing Fabry-Pérot effects in the waveguides and allowing for broadband operation.

The imaging capacity of the device is demonstrated using finite-element simulations (see Fig. 1(a)). The numerical model shows that up to 90% of the light from two closely spaced point dipole emitters can be coupled into the corresponding waveguides on the high-resolution side and can be transmitted to the low-resolution side with moderate losses and low cross talk. Thus, two point dipole sources separated by 150 nm can be effectively distinguished by such a device. Moreover, consistent operation in the whole wavelength range from approximately 1 µm to above 2 µm is demonstrated. Fig. 1(b) shows total losses of each channel calculated for a set of wavelengths. At wavelengths near 1 µm the loss increase is caused by gold material absorption, while at wavelengths above 2 µm cross-coupling between channels limits the device performance. For the proposed device dimensions (shown in the inset in Fig. 1(b)), the array can contain up to 19 channels, which is limited by cross-coupling and losses caused by sharp channel bending.

Exhibiting large coupling efficiency and moderate transmission losses, the device allows for imaging of weak sources with a resolution of 150 nm over a broad bandwidth in the near-infrared range. This device can be effectively applied as a high-resolution linear image detector or, by operating in the reverse, for high-resolution optical writing.

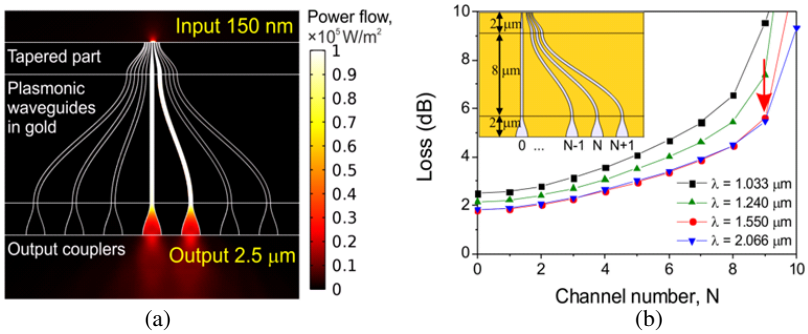

Figure 1: (a) Optical power flow inside the plasmonic waveguides excited by two incoherent point dipole sources emitting at 1.55 µm and separated by 150 nm. (b) Propagating loss of each channel for wavelengths between 1 µm and 2 µm. Inset shows the device dimensions.

Surface Plasmon Resonance Sensing in the THz Regime

J. Shibayama, **K. Shimizu**, **J. Yamauchi**, **and H. Nakano**
Faculty of Science and Engineering, Hosei University, Tokyo 184-8584, Japan

Abstract— The characteristics of surface plasmon polaritons (SPPs) are quite sensitive to the property of a dielectric material on a thin metal layer. Using these characteristics, surface plasmon resonance (SPR) sensors have widely been investigated [1] and already been made available commercially. Note that the SPPs are excited along a metal-dielectric interface at optical frequencies. On the other hand, at terahertz (THz) frequencies, InSb exhibits a negative permittivity as in metal at optical frequencies. In addition, an interesting feature of InSb is its permittivity varying with temperature. Recently, THz plasmonic filters and lenses consisting of InSb have been studied theoretically [2–4].

In this article, we investigate an SPR waveguide sensor with InSb at THz frequencies. The dispersion of InSb is efficiently taken into account using the frequency-dependent FDTD method based on the trapezoidal recursive convolution technique [5]. It is shown that the sensor exhibits an SPR response versus THz frequency, the peak frequency of which is around 1 THz. We also calculate the SPR curves with varying temperature, showing a possibility of realizing an SPR sensor in the THz regime.

RF Design of Input Cavity Structure of a Low Frequency, High Average Power IOT

Meenu Kaushik[1, 2] **and L. M. Joshi**[1, 2]

[1]CSIR-Central Electronics Engineering Research Institute (CEERI), Pilani, Rajasthan, India
[2]Academy of Scientific and Innovative Research (AcSIR), New Delhi, India

Abstract— Inductive Output Tube (IOT) is a vacuum electron tube device capable of amplifying RF power with very good efficiency. The major components of an IOT are electron gun, input/output cavities, input/output couplers, focussing magnet and collector.

IOT has been extensively used in TV services as UHF transmitters to amplify both audio and video signals. Its power gain, high efficiency and long life make it suitable for this application. Besides that, this tube has been proving its capability and reliability in scientific areas like in high energy particle accelerators and fusion plasma heating purposes.

The paper will present the RF design of input cavity of a low frequency IOT carried out at CSIR-CEERI. It is an important component of the device. The cavity should be smartly positioned so that the cathode-grid gap plays the role of cavity drift gap and contributes to the interaction between electron beam (emitting from the electron gun) and the input RF signal (applied at the cathode-grid gap). One key issue is that the cavity operates in grounded mode and in this case, the inner wall of the cavity is connected to the cathode and grid, having high negative potentials, hence proper isolation of the input circuit is mandatory for its successful operation. The simulation of the cavity has been carried out in CST and MAGIC2D codes. The CAD drawings have been prepared and the cavity structure has been fabricated. The details of design approach using CAD tools and cold test results shall be presented in this paper.

Quantum Optics with Solid-state Spins and Photons

Mete Atatüre
Cavendish Laboratory, University of Cambridge, JJ Thomson Avenue, Cambridge CB3 0HE, UK

Abstract— Spins confined in solids, such as quantum dots and atomic impurities provide interesting and rich physical systems. Their inherently mesoscopic nature leads to a multitude of interesting interaction mechanisms of confined spins with the solid state environment of spins, charges, vibrations and light. Implementing a high level of control on these constituents and their interactions with each other creates exciting opportunities for realizing stationary and flying qubits within the context of spin-based quantum information science. I will provide a snapshot of the progress and challenges for optically interconnected spins, as well as first steps towards hybrid distributed quantum networks involving other physical systems.

A Spin-photon Interface in the Solid State

[3]Département de Physique, Université Paris Diderot, Paris 7, Paris 75205, France

Abstract— A quantum-dot (QD) strongly-coupled to a cavity mode is an extremely sensitive device whose optical properties can be controlled with single incident photons. A key requirement in this context is the fabrication of state-of-the-art cavity-QED devices using micropillars: indeed, pillar cavities can demonstrate a maximized light-matter interaction (thanks to deterministic coupling techniques [1]) together with high coupling efficiencies and quality factors [2]. The optical properties of these devices can then be probed using high-resolution resonant spectroscopy techniques [3], and be exploited for various applications such as few-photon optical nonlinearity [4] or optical nanosensing [5].

In this presentation, we will focus on the development of a cavity-based spin-photon interface [6], making use of the rotation of optical polarization (Faraday or Kerr rotation) induced by a single spin in a cavity-QED device. This approach allows interfacing the spin with a photon generated by an external source, thus opening new possibilities in quantum optics. Up to now, however, Faraday/Kerr rotations induced by a single spin were reported only recently, with rotation angles in the few 10^{-3} degrees range.

Here, thanks to the cavity-QED enhancement of the spin-photon interaction, we report a huge amplification of the spin-photon interaction. As illustrated in Fig. 1(a), the reflected probe beam polarization is rotated clockwise or counter-clockwise depending on the spin state. Fig. 1(b) shows the Kerr rotation angle as a function of the probe energy: a macroscopic Kerr rotation of $\pm 6°$ (depending on the spin state) is demonstrated for the reflected probe beam, three orders of magnitude higher than the previous state of art [6].

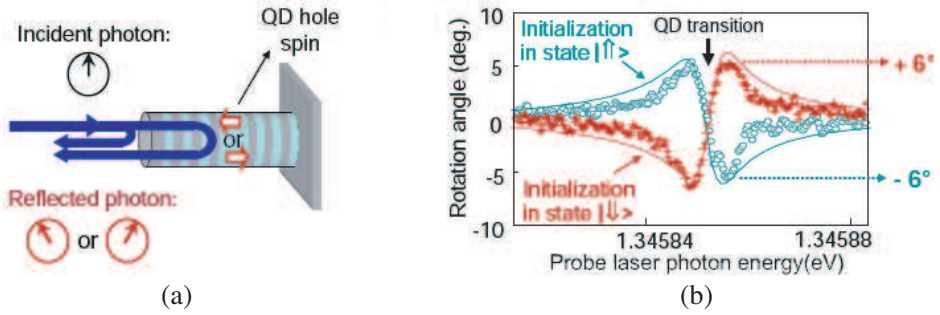

Figure 1: (a) Spin-dependent polarization rotation for the reflected probe beam. (b) Demonstration of giant Kerr rotation induced by a single spin. The spin state is pumped in the up or down state by a resonant pump beam, and a spin-dependent Kerr rotation up to $\pm 6°$ is observed.

In addition, cavity-QED calculations allow us to predict that an optimized device will be able to act as a spin-photon entangler with a unity-fidelity. It will also be possible to perform a perfect quantum non demolition measurement, projecting the spin qubit on either its up or down state, using a single photon detected by a photon counter. This novel way of interfacing a flying qubit and a solid-state quantum memory opens the road for a wide range of applications for quantum information processing and long-distance quantum communication.

Nitrogen-vacancy Defects in Diamond Coupled to Open Microcavities — Towards an Efficient Spin-photon Interface

S. Johnson, Y. C. Chen, L. Weng, P. R. Dolan, A. A. P. Trichet, and J. M. Smith
Department of Materials, University of Oxford, Oxford OX1 3PH, UK

Abstract— The realisation of an efficient spin-photon interface using the negatively charged nitrogen-vacancy centre (NV-) in diamond requires the resonant coupling of the zero phonon line (ZPL) of the centre to an optical microcavity [1]. The cavity serves to encourage emission into the ZPL in preference to the phonon sidebands, and potentially also to increase the homogeneous linewidth via a reduction of the lifetime (the Purcell effect) thus assisting in the generation of indistinguishable photons. Cavity coupling thus has potential to improve by orders of magnitude the speed with which entanglement can be created between spatially remote NV-centres [2], and to enable other mechanisms for realising spin-photon interfaces via non-demolition measurements [3]. Some previous demonstrations of ZPL coupling have been reported in monolithic cavities [4–6], but it is difficult to achieve optimal positioning of the emitter and resonant tuning in these structures.

Here we report on the coupling of ZPLs of single NV-centres to open microcavities at low temperature. The NV-centres are in nanodiamond produced by high pressure high temperature methods, while the open cavity is of a plano-concave design with the concave mirror substrate produced by the focused ion beam milling method [7]. The cavity has a mode volume around $2\,\mu m^3$ and a quality factor of about 1000. The cavity mirrors are mounted on piezoelectric actuators that enable tuning of the cavity mode wavelength and positioning of the nanodiamond in the confined cavity mode *in-situ*, whilst cooled to 77 K. We use registration marks on the planar mirror (onto which the nanodiamond is spin cast), to enable characterisation and recording of the positions of nanodiamonds of interest so that direct comparison can be made between the free-space and cavity-coupled behaviour of the same NV-centre, giving a direct measure of the effect of the cavity.

We will present data showing the change in fluorescence properties (spectrum, lifetime) as the cavity mode is tuned through resonance with an NV-centre ZPL. A significant enhancement of the emission into the cavity mode is observed on resonance. The ZPL is increased by about a factor of 10 relative to free-space emission as a result of the cavity coupling, so that it constitutes almost half of the total fluorescence and up to 15,000 photon counts/s on the detector. We will discuss the outlook for further enhancements and the prospects for realising a highly efficient quantum interface between the NV-spin state and an optical photon.

Abstract— The spontaneous emission rate of an emitter depends on the local photonic environment and can strongly be modified when the emitter is placed in the vicinity of a planar reflecting interface such as a silver mirror. By recording the spontaneous emission rate as function of the emitter mirror distance, information on the decay rate modification can be used, for instance, to determine the emitters dipole orientation, its intrinsic quantum efficiency, and to reveal higher order transition moments.

In this contribution we report on modifications of the spontaneous emission rate of nitrogen vacancy (NV) centers embedded in diamond crystals and placed in the vicinity of a planar silver mirror. The silver mirror was prepared on the end facet of a cleaved optical fiber and mounted on a piezo stage. At room temperature the emission spectrum of NV centers is characterized by a zero phonon line at 637 nm and a red shifted broad phonon sideband centered around 700 nm with a bandwidth of approximately 150 nm. When recording the decay rate as a function of NV center mirror distance we only observe small spontaneous emission rate modifications. These small modification we associate with the NV centers broad emission spectrum and averaging over the entire bandwidth. In contrast to the total decay rate, the broad emission spectrum is strongly modified in the vicinity of the mirror. To model our findings we use a rate equation approach taking into account scattering of photons on the broad phonon spectrum associated with the diamond lattice.

Infrared Counting and Imaging at Single-photon Frontier with Superconducting Nanowires

Alessandro Casaburi
University of Glasgow, UK

Abstract— Advances in materials growth and nanopatterning have enabled the creation of a new class of ultra-sensitive optical detector: the superconducting nanowire single-photon detector (SNSPD) [1]. These devices offer exquisite sensitivity and low noise at infrared wavelengths, far outperforming off-the-shelf alternatives such as semiconductor avalanche photodiodes and photomultiplier tubes [2]. The potential of SNSPDs has been demonstrated in a range of important scientific applications, including quantum cryptography [3], remote sensing [4] and laser-based cancer treatment [5]. Our efforts are focussed on the development of next generation SNSPDs employing state-of-the-art nanofabrication techniques, sensor configurations and innovative materials.We will review the results obtained with these innovative sensors in the recent years and describe how these devices can be modified to satisfy the stringent requirements of future applications. In this work, we will give a short overview on our recent results concerning direct detection of singlet oxygen luminescence [6], fibre Raman temperature sensing [7, 8] time-of-flight depth imaging [9]. We will also present results on the realization and characterization of a 2×2 SNSPDs array [10] to scale up the sensitive area of the detector at $60 \times 60\,\mu m^2$ for multimode fibre optical coupling on the perspectives for next future applications.

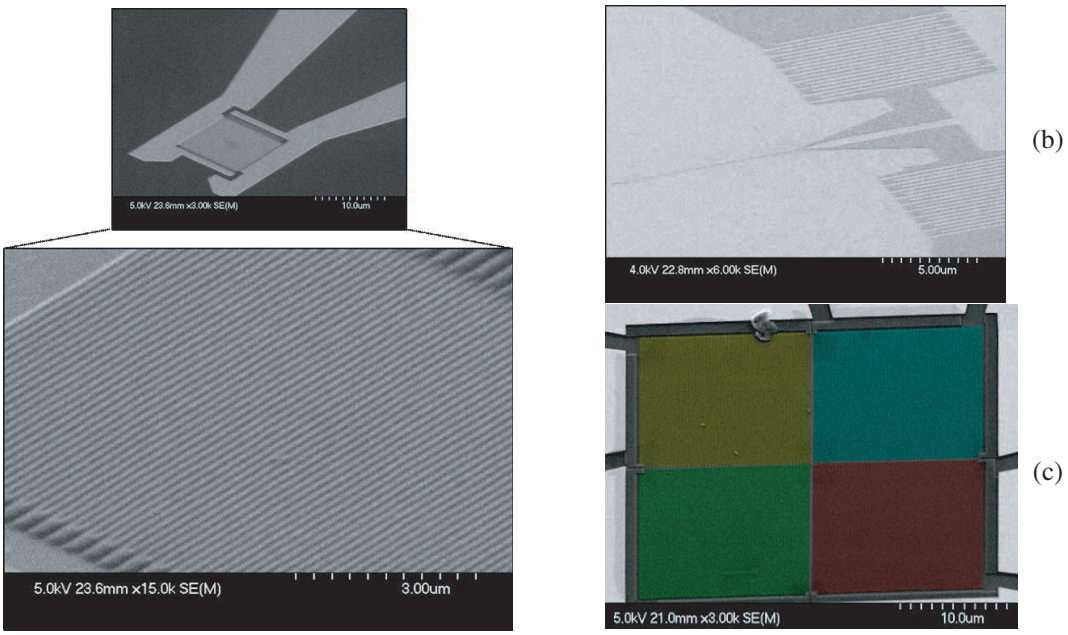

Figure 1: Next generation Superconducting Nanowire Single Photon Detectors (SNSPDs) under development at the University of Glasgow, UK. (a) Meander type single pixel (10 micrometre width) SNSPD. (b) Waveguide integrated SNSPD concept. (c) 2×2 SNSPD array ($30 \times 30\,\mu m^2$).

Abstract— Quantum dots (QDs) in photonic nanostructures open a promising route towards realizing all-solid-state scalable quantum networks for quantum-information processing [1]. In such networks single photons will serve as ying qubits, while the internal spin state of a single electron or hole trapped in the QD serves as the stationary qubit. For this vision to be realized it is necessary to create a spin-photon interface such that different spin states within quantum dots interact with orthogonal optical modes with near-unity efficiency. We have recently shown that photonic crystal waveguides (PCW) allow near-unity coupling efficiency, $\beta \sim 1$, with an embedded quantum dot [2]. However, interfacing different QD spin states with orthogonal modes with near-unity efficiency remains a challenge [3]. Here we show that by manipulating the geometry of a conventional PCW, we can design a new waveguide whose modes have a broadband in-plane circular polarization. Due to time reversal symmetry, $\mathbf{E}_{-\mathbf{k}}(\mathbf{r}) = \mathbf{E}^*_{\mathbf{k}}(\mathbf{r})$, and thus counter-propagating modes have orthogonal circular polarizations in this new design. In an external magnetic field, applied along the QD-growth direction, QDs have two orthogonal transition dipole moments with opposite circular polarizations. As illustrated schematically in Fig. 1(a) orthogonal circular dipoles couple to counter-propagating modes in the above discussed PCW, thus exhibiting *chiral light-matter interaction*. We demonstrate this experimentally in Fig. 1(b) where the emission spectra are simultaneously recorded from the two opposite ends of the waveguide. The QD emission is highly directional as can be seen by the two orthogonal transition dipoles, $QD_{+/-}$, coupling almost exclusively to counter-propagating modes [4]. We extract the average directionality factor, $F_{dir} = 91\%$. This quanties the likelihood that the emission from a given circular dipole into the waveguide, propagates into the direction indicated in the schematic of Fig. 1(a).

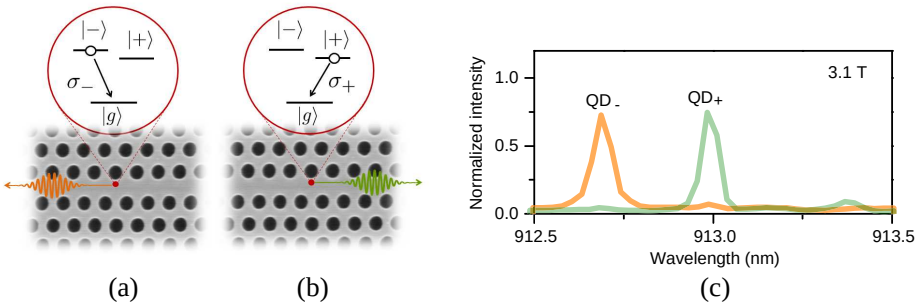

Figure 1: (a) Illustration of directional photon emission where the propagation direction of the single photon depends on the rotation direction of the circular transition dipole. The level structure of the quantum dot is shown schematically and the position of the quantum dot is indicated by the red spot. Single photons emitted from (a) the σ_--transition only couple to the left-propagating (orange) mode whereas photons emitted from (b) state σ_+-transition only couple to the right-propagating (green) mode. (c) Experimental verication of the directional photon emission [4]. The QD in this structure has highly directional emission as can be seen by QD_- and QD_+ coupling almost exclusively to counter-propagating modes, indicated by the two different colors.

Perhaps the most exciting aspect of the chiral light-matter interaction relates to the single photons scattering properties. The transmission coefficient for on-resonant narrowband photons is [5]

$$t_0 = 1 - 2\beta_{dir}, \tag{1}$$

where $\beta_{dir} = F_{dir}\beta$ is the fraction of photons channelled into the directional mode of interest, as opposed to all other modes. For $\beta_{dir} \to 1$, Eq. (1) implies a large transmission amplitude and a π phase shift, for a photon propagating to the left and on resonance with the σ_--transition, cf. Fig. 1(a). However, when reversing the propagation direction of the photon it does not interact with the emitter. This forms the basis of non-reciprocal photonic elements with applications in on-chip quantum information processing [4].

Tunable Narrow-linewidth Photonic Microwave Oscillators Using Optically Injected Semiconductor Lasers at Period-one Dynamics

Yu-Han Hung[1] **and Sheng-Kwang Hwang**[1, 2]

[1]Department of Photonics, National Cheng Kung University, Tainan, Taiwan
[2]Advanced Optoelectronic Technology Center, National Cheng Kung University, Tainan, Taiwan

Abstract— Period-one (P1) dynamics excited in an optically injected semiconductor laser have been widely investigated not only for academic interest in understanding nonlinear dynamics but also for practical interest for novel technological applications. Thanks to the self-sustained microwave oscillation of the laser intensity, P1 dynamics can be applied for photonic microwave generation. While the microwave frequency can be broadly tuned from a few to tens and even hundreds of gigahertz by simply adjusting the optical injection power and frequency, optical single-sideband modulation is so feasible as to mitigate microwave power fading over fiber distribution. However, owing to the inartistic laser noise, the linewidth of the photodetected microwaves is typically on the order of tens to hundreds of megahertz. To stabilize the photodetected microwaves, several stabilization schemes have been proposed, including direct modulation, optoelectronic feedback, and optical feedback. However, these proposed schemes suffer from either device bandwidth restriction or significant frequency jitter, limiting respectively the highest lockable microwave frequency, up to 25 GHz, or the lowest stabilized microwave linewidth, down to the order of kilohertz only. In this study, we propose to use modulation sideband injection locking scheme to stabilize the P1 dynamics. A 3-dB linewidth of 1 Hz is experimentally demonstrated for microwave generation up to 32 GHz using an electronic microwave reference at a small fraction, such as one-eights, of the generated microwave frequency. A higherfrequency microwave generation is feasible, such as 100 GHz or more, using devices of higher bandwidth.

Optical Fibre Limits: An Approach Using ASE Channel Estimation

N. Mac Suibhne, **M. E. McCarthy**, **S. T. Le**,
S. Sygletos, **F. M. Ferreira**, **and A. D. Ellis**

Abstract— In this talk we investigate the usage of spectrally shaped amplified spontaneous emission (ASE) in order to emulate highly dispersed wavelength division multiplexed (WDM) signals in an optical transmission system. Such a technique offers various simplifications to large scale WDM experiments. Not only does it offer a reduction in transmitter complexity, removing the need for multiple source lasers, it potentially reduces the test and measurement complexity by requiring only the centre channel of a WDM system to be measured in order to estimate WDM worst case performance.

The use of ASE as a test and measurement tool is well established in optical communication systems and several measurement techniques will be discussed [1, 2]. One of the most prevalent uses of ASE is in the measurement of receiver sensitivity where ASE is introduced in order to degrade the optical signal to noise ratio (OSNR) and measure the resulting bit error rate (BER) at the receiver. From an analytical point of view noise has been used to emulate system performance, the Gaussian Noise model is used as an estimate of highly dispersed signals and has had considerable interest [3]. The work to be presented here extends the use of ASE by using it as a metric to emulate highly dispersed WDM signals and in the process reduce WDM transmitter complexity and receiver measurement time in a lab environment. Results thus far have indicated [2] that such a transmitter configuration is consistent with an AWGN model for transmission, with modulation format complexity and nonlinearities playing a key role in estimating the performance of systems utilising the ASE channel emulation technique. We conclude this work by investigating techniques capable of characterising the nonlinear and damage limits of optical fibres and the resultant information capacity limits.

Impact of Phase Noise in High Capacity Optical Coherent Transmission Systems

Gunnar Jacobsen[1] **and Sergei Popov**[2]

[1]Acreo Swedish ICT, Box 1070, Kista SE-16425, Sweden
[2]Royal Institue of Technology, Stockholm SE-16440, Sweden

Abstract— Laser phase noise from the transmitter and Local Oscillator lasers strongly limits the performance of high capacity, high constellation coherent optical transmission systems. Using Digital Signal Processing techniques it is possible to mitigate the influence with specific form of the DSP for different modulation formats. In this paper we will present a number of possible mitigation techniques, applicable for such modulation schemes as N-level PSK and N-level QAM. It will specifically be shown that the circular QAM configuration has inherent significant added phase noise tolerance compared to the classical square configuration. The research has also been performed considering the so-called Equalization Enhanced Phase Noise, which appears as an added phase noise based impairment for coherent transmission systems with optically induced dispersion and digital (electrical) dispersion compensation. A novel understanding of the origin of EEPN and of straightforward mitigation techniques will be presented.

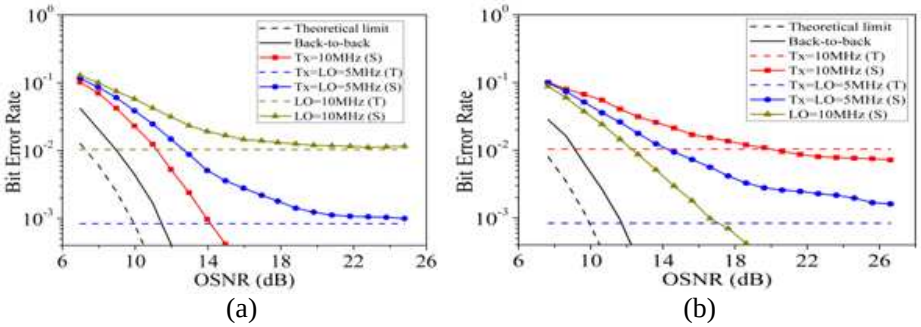

Figure 1: Bit Error Rate versus OSNR for a 28 GS/s DQPSK transmission system with (a) post- and (b) pre-compensation of chromatic dispersion influence (see [1, 2]). The transmission distance is 2000 km. It is observed that the phase noise influence of Tx and LO lasers is reversed for the pre- and post-compensation cases.

Higher-order Raman Amplification for Unrepeatered and Long-haul Super-channel Transmission

J. D. Ania-Castañón, G. Rizzelli, M. Camarasa-Gómez, and D. Hernangómez-Pérez
Instituto de Óptica "Daza de Valdés", IO-CSIC, Serrano 121, Madrid 28006, Spain

Abstract— Over the past 5 years, coherent super-channel transmission has become a comercial possibility, with companies announcing Tb/s capabilities and spectral efficiencies as high as 3.4 b/s/Hz [1]. In this context, distributed Raman amplification, and in particular higher-order solutions such as those based ultralong Raman fiber lasers [2], have shown great promise for super-channel communications, demonstrating full compatibility with super-channel techniques such Nyquist-WDM both in long-haul and unrepeatered schemes [3]. Still, the optimal amplification scheme configuration can be expected to depend strongly on the particular choice of super-channel implementation, desired system capacity, fiber base and distance requirements. In this paper we explore these and other dependencies for the optimal design of amplification solutions for super-channel transmission systems.

Channel Model and Lower Capacity Bound for the Transmission Based on Nonlinear Fourier Transform (Invited)

J. E. Prilepsky[1], **S. A. Derevyanko**[2], **and S. K. Turitsyn**[1]

[1]Aston Institute of Photonic Technologies, Aston University, Birmingham B4 7ET, UK
[2]Department of Physics of Complex Systems, Weizmann Institute of Science, Rehovot 76100, Israel

Abstract— The integrability of the nonlinear Schrödinger equation (NLSE) by the inverse scattering transform shown in a seminal work [1] gave an interesting opportunity to treat the corresponding nonlinear channel similar to a linear one by using the nonlinear Fourier transform. Integrability of the NLSE is in the background of the old idea of eigenvalue communications [2] that was resurrected in recent works [3–7]. In [6, 7] the new method for the coherent optical transmission employing the continuous nonlinear spectral data — nonlinear inverse synthesis — was introduced. It assumes the modulation and detection of data using directly the continuous part of nonlinear spectrum associated with an integrable transmission channel (the NLSE in the case considered). Although such a transmission method is inherently free from nonlinear impairments, the noisy signal corruptions, arising due to the amplifier spontaneous emission, inevitably degrade the optical system performance. We study properties of the noise-corrupted channel model in the nonlinear spectral domain attributed to NLSE. We derive the general stochastic equations governing the signal evolution inside the nonlinear spectral domain and elucidate the properties of the emerging nonlinear spectral noise using well-established methods of perturbation theory based on inverse scattering transform [8]. It is shown that in the presence of small noise the communication channel in the nonlinear domain is the additive Gaussian channel with memory and signal-dependent correlation matrix. We demonstrate that the effective spectral noise acquires "colouring", its autocorrelation function becomes slow decaying and non-diagonal as a function of "frequencies", and the noise loses its circular symmetry, becoming elliptically polarized. Then we derive a low bound for the spectral efficiency for such a channel. Our main result is that by using the nonlinear spectral techniques one can significantly increase the achievable spectral efficiency compared to the currently available methods [9].

Transoceanic Fibre-optic System Capacity with Electrical Power Constraints

Steve Desbruslais
Xtera Communications Ltd., UK

Abstract— Recent progress in maximising submarine optical fibre transmission capacity has benefited from significant gains using advanced coding techniques and coherent detection. The methods have not only allowed a dramatic increase in system capacity, but have enabled these gains to be made with little effect on the power requirements of the submarine plant. But now that these methodologies have been pushed close to their limit and demand is still increasing, we have to face the inevitable tenet that increasing transmission capacity requires an increase in total signal power. Each channel will have a modulation format dependent signal power requirement and so the more channels we implement, the greater the total optical power requirement will be. We can increase the system bandwidth, the number of transmission modes per fibre, the number of cores per fibre or else the number of fibres. We can also trade signal power with the type of modulation format. But no matter which of these methods we use the total signal power must inevitably increase. There is a direct relationship between the optical signal power and the electrical power required to generate it at the output of each repeater. But it is clear that we cannot increase the power delivered to the submarine plant without limit. The two approaches we can use to overcome this difficulty are to seek savings in energy conversion efficiency and seek improvements to the way the electrical power is delivered. Here we consider the latter.

We consider methods for maximizing the transmission capacity that is achievable in a system of given length subject to the constraints inherent in the powering of submarine repeaters. The way the power is distributed has a large bearing on the efficiency with which the available power can be utilised. Nevertheless, we come to the conclusion that the ultimate limits to long distance submarine transmission capacity are not optical nonlinearities or any other optical phenomena but rather electrical power constraints.

Machine Learning Approaches for Nonlinearity Mitigation and Component Characterization

D. Zibar and M. Piels
DTU Fotonik, Technical University of Denmark, Kgs. Lyngby DK-2800, Denmark

Abstract— Machine learning is an area of intelligent signal processing which uses advanced statistical and probabilistic methods to identify, learn, and track patterns about the underlying system from measured/observed data. The area of machine learning has, so far, had a great impact on our modern society. The Google search engine, for example, uses machine learning to predict the notably nonlinear behavior of internet users. There is a good reason to expect that machine learning can have similar impact on optical fibre communication. In this paper, we link powerful methods used in machine learning community to the future challenges in optical communication. Moreover, methods from machine learning can be used to learn the impairments from the observed data and built a probabilistic model of the impairment. One of the tools that we will consider in this paper is Bayesian filtering and parameter estimation using expectation maximization algorithm. Bayesian filtering allows for tracking of time-varying parameters such as amplitude and phase noise as well as self- and -cross phase modulation. The expectation maximization algorithm allows for maximum likelihood estimation of constant parameters. A significant advantage of Bayesian filtering is that it can be applied to nonlinear systems and account for non-white and also non-Gaussian noise. We will demonstrate how Bayesian filtering in combination with expectation maximization can be used for optical fibre channel nonlinearity mitigation and component characterization. Three special cases of Bayesian filtering are considered: particle filtering, extended Kalman filter (EKF) and extended Kalman smoother (EKS).

Predicting System Performance — An Art or Playing the Lottery?

André Richter and Hadrien Louchet
VPI Photonics, Carnotstrasse 6, Berlin 10587, Germany

Abstract— For many years, modeling and numerical simulation play an important role for characterizing equipment and dimensioning performance limitations of high-speed optical transmission systems. We try nothing less but to emulate in a computer environment what will happen in real life under real-world conditions, evaluate the performance of alternating transmission methods and corresponding technologies, and based on that make strategic decisions about the way to move forward.

How can modeling and numerical simulation actually address this challenging demand? Foremost, a good understanding of all relevant effects influencing the information transmission — from the initial digital (or analog) source to the corresponding sink — is required. If this is known and interactions are understood, one needs to determine, what it takes to emulate these effects realistically in a modeling environment and to obtain reliable measures predicting system performance. So, one needs to determine the required level of modeling abstraction as well as efficient and accurate means for implementing the emulation process.

Clearly, extensive numerical simulations should go hand-in-hand with equipment and system characterizations, and laboratory or field transmission experiments. Where possible, experimental data, either pre-recorded or measured live during simulation, can be integrated with numerical studies in order to deliver realistic and reliable performance predictions.

What characteristics should be evaluated in order to be able to draw the right conclusions? The range of options is large: optical spectra and required OSNR, (time-dependent) statistics of eye openings and constellation diagrams, symbol or bit error ratios, Q factor and EVM, or mutual information? And then, how should those characteristics be calculated/estimated/displayed?

When reviewing the evolution of technology over the past years, we see that the perspective changed significantly about what are important limitations and how should they be evaluated. Up to the end of the last century (dense) WDM transmission of $N \times 10\,\mathrm{Gbit/s}$ channels over dispersion-managed fiber links using OOK-based NRZ or (chirped) RZ modulation and direct detection receivers represented state-of-the-art. Optical loss and noise, CD and Kerr nonlinearities represented the main limiting effects. Soon after, channel rates of 40 Gbit/s using DPSK and later DQPSK modulation combined with balanced detection became popular. With this, limitations due to PMD and nonlinear phase noise became important. A few years later efficient means for IQ-modulation have been introduced and coherent optical detection has been rediscovered, which allowed using spectrally efficient modulation formats and moving key functionality for pulse shaping and mitigation of limiting performance effects to then available high-speed electronics. Nowadays, we develop systems with channel rates of 400 Gbit/s and more using many different types of single- or multi-carrier based two-dimensional and coded modulation formats, sophisticated multi-stage DSP and soft-decision FEC algorithms.

These developments made the task of reliably predicting system performance using modeling and numerical simulation a lot more challenging. With this paper we discuss numerical techniques for estimating the signal performance for high-speed optical transmission systems. We illustrate how the perspective about 'good methods' and 'reliable criterions' changed over the years with the advancement of technology. Further we highlight major challenges for estimating signal performance in today's transmission systems and discuss techniques to overcome them.

Interleaving to Reduce Code Overhead in DQPSK Systems

M. Y. Leong[1, 2], **K. J. Larsen**[3], **S. Popov**[2],
G. Jacobsen[1, 2], **D. Zibar**[3], **and S. Sergeyev**[4]

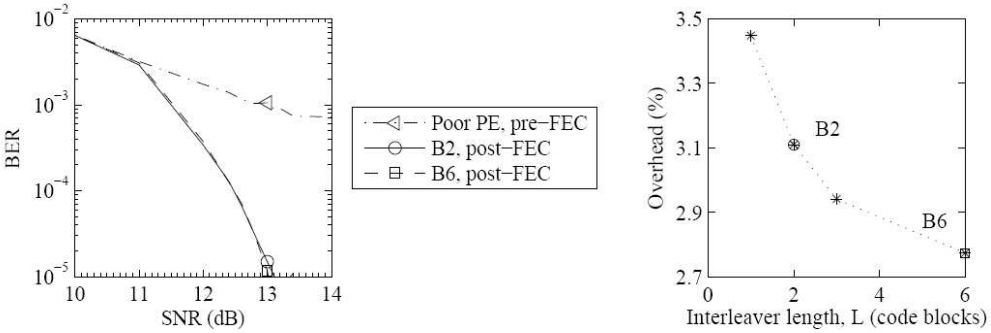
[3]Technical University of Denmark (DTU), Denmark
[4]Aston University, United Kingdom

Abstract— A method for selecting interleavers and BCH codes for systems with cycle slips.

Recently, both phase noise and Gaussian noise are considered in code design [1–3]. However, codes in [3] have high overheads due to correlation. We use interleaving to reduce overhead.

We add an interleaver of length L code blocks with $n_{B,S}$ bits/block after the Bose-Chaudhuri-Hocquenghem (BCH) encoder in [3]. It reorders the bits using randomly-generated permutations. A deinterleaver before the BCH decoder restores the bit order. We fit the probability density function (PDF) $\Pr(Y_G = y_G,\, Y_C = y_C)$ as in [3]. Let the random variable (RV) Y_A represent the number of bit errors in a code block, $\Pr(Y_A = y_A) = \sum_{(y_G,y_C):2y_G+y_C=y_A} \Pr(Y_G = y_G,\, Y_C = y_C)$. Let Y_L represent the number of bit errors in L blocks. $\Pr(Y_L = y_L)$ is the L-fold convolution of $\Pr(Y_A = y_A)$. After deinterleaving, the y_L bit errors are distributed randomly over L blocks. Let the RV Z_ℓ represent the number of bit errors in the ℓ-th block. $\Pr(Z_\ell = z_\ell | Y_L = y_L) = \binom{y_L}{z_\ell} (1/L)^{z_\ell} (1 - 1/L)^{y_L - z_\ell}$ if $z_\ell \le y_L$, and 0 otherwise. The PDF of Z_ℓ is $\Pr(Z_\ell = z_\ell) = \sum_{y_L=0}^{\infty} \Pr(Z_\ell = z_\ell | Y_L = y_L) \Pr(Y_L = y_L)$. A code corrects up to τ bit errors. Let X_ℓ be a RV that is 1 if $\tau + 1 \le Z_\ell \le \tau + 3$, and 0 otherwise. Let $X = \sum_{\ell=1}^{L} X_\ell$. The expectation of X is $E[X] = L \cdot \Pr(\tau + 1 \le Z_\ell \le \tau + 3)$. Post-forward error correction (FEC) bit error rate (BER) $P_{\text{post}} \approx [(\tau + 1)/n_{B,S}] \cdot \Pr(\tau + 1 \le Z_\ell \le \tau + 3)$. Suitable interleavers and codes are the combinations of $n_{B,S}$, τ, and L that meet a target post-FEC BER.

As an example, a 28 Gbaud system optimized for linewidth < 100 kHz uses a 41-tap moving average filter for Viterbi-Viterbi [4]. We assume the worst-case "poor phase estimate (PE)" curve has linewidth 25.2 MHz. Simulations use VPI [5]. Our interleaver-code combinations achieve 2 × BER target (Fig. 1).



(a) (b)

Figure 1: (a) BER vs. signal-to-noise ratio (SNR). We design interleaver-code combinations for "poor phase estimate (PE) pre-FEC" triangle (◁). In post-FEC simulations, B2 is BCH(8190,7943) with $L = 2$, and B6 is BCH(8190,7969) with $L = 6$. Pre-FEC BER is calculated on 10^6 bits, and post-FEC BER on 10^7 post-FEC bits. (b) Trade-off for ◁ in (a). Interleaver delay is proportional to L. Interleaver-code combinations for target post-FEC BER 10^{-5} are marked with a star (∗). B2 and B6 are simulated in (a).

Polarization Sensitivity Mitigation for AM-CO-OFDMA PON Uplink Transmission

S. M. Jung, **K. H. Mun**, **and S. K. Han**
Department of Electrical and Electronic Engineering, Yonsei University
50 Yonsei-ro, Seodaemun-Gu, Seoul, Korea

Abstract— In the optical coherent detection, the basic detection process is optical beating between the optical field of uplink signal and optical field of the local oscillator (LO) laser at the receiver. This detection provides the phase diversity and polarization diversity which lead to high spectral efficiency with higher order modulation. During this optical beating process, the polarization states between the signal optical fields and optical field of LO has very important relationship. Because the LO optical field and signal fields are divided as X-polarization components and Y-polarization components relative to the fiducial polarization axis, each polarization components beats each other during the photo detection process and generate the electrical signal for each polarization. But, in the multiple access system, the polarization diversity could cause serious issue. In the adatively modulated coherent optical orthogonal freuqency division multiple access (AM-CO-OFDMA) passive optical network (PON) system, the multiple access function is easly achieved just by dividing subcarrier subbands of its signal frame. However, the received uplink optical fields of ONUs could not have same polarization states each other because of its different transmission path and responses of the devices in the link. These variously polarized optical fields lead to reduce SNR after photo-detection and crosstalk between the multiple access user signals. In this work, we proposed a mitigating technique for the polarization mismatch of the uplink optical fields in the coherent AMO-OFDMA-PON. By using the trigonometric features of polarization states, we experimentally demonstrated stable transmission performance of uplink multiple access.

Optically Controlled Triple Notched UWB Antenna

Heba Zakaria[1], **Moataza Hindy**[2], **and Adel El-Henawi**[1]

[1]Faculty of Engineering, Ain Shams University, Cairo, Egypt
[2]Electronics Research Institute, Cairo, Egypt

Abstract— A new printed reconfigurable ultra-wideband (UWB) antenna was designed on a 35×28 mm FR4 substrate with relative dielectric constant of 4.6 and thickness of 1.5 mm. This design proposes triple narrow notched bands at center frequencies 3.5 GHz "WIMAX", 5.5 GHz "WLAN" and 8.4 GHz (7.4 GHz WPAN and 7.15–9 GHz) [1, 2]. The coplanar fed microstrip UWB antenna is shown in Fig. 1(a) while Fig. 1(b) illustrates the optically controlled design. The proposed UWB can work at eight modes using controlling switches ON and OFF. The optical switches are made by placing $0.5\,\text{mm} \times 0.5\,\text{mm}$ silicon wafers over the slots of the resonator. When laser is applied the switches are in the ON state (as shown in Table 1) the notches disappear and the antenna operates in full ultra wideband frequency range. In case, all diodes are OFF all the notches are activated. Moreover, the average gain of this antenna is 5.5 dBi and UWB ranges from 3 to 11 GHz. The antenna was simulated, fabricated, and measured results well agree with the simulation.

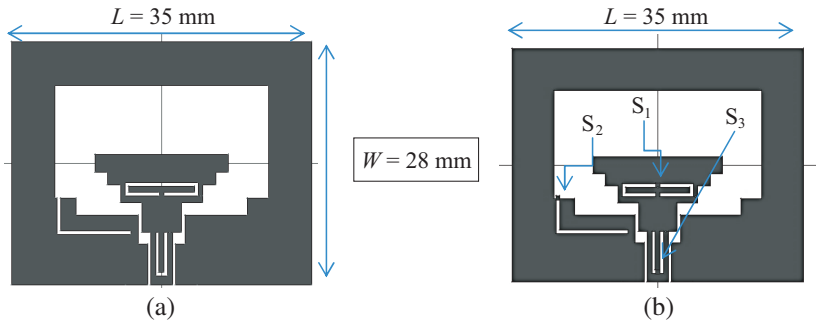

Figure 1. The geometry of the proposed ultra wideband antenna. (a) The origin design, (b) UWB antenna without 3 switches.

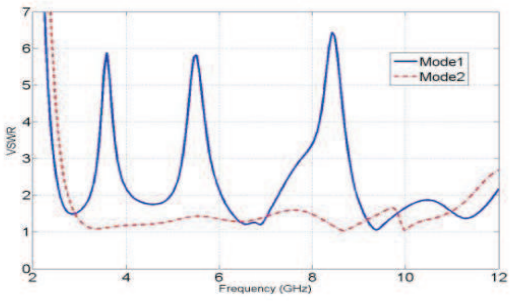

Figure 2. VSWR of UWB antenna made1 UWB "case1" mode2 "case2" UWB from 2.8 to 11.8 GHz.

case	Notched Band	S_1	S_2	S_3
1	3.5 & 5.5 & 8.5 GHz	OFF	OFF	OFF
2	None	ON	ON	ON
3	3.5 GHz	ON	OFF	ON
4	5.5 GHz	OFF	ON	ON
5	8.5 GHz	ON	ON	OFF
6	3.5 & 5.5 GHz	OFF	OFF	ON
7	3.5 & 8.5 GHz	ON	OFF	OFF
8	5.5 & 8.5 GHz	OFF	ON	OFF

Abstract— Over the past decade silicon photonics has gone through a period of rapid technological advancement coinciding with significant research effort worldwide from both academia and industry. Motivations for silicon photonics are the potential for low cost manufacture of photonic integrated circuits (PICs) and the prospects for photonic-electronic convergence. Several of the building blocks required to produce high PICs in silicon have been demonstrated from high speed optical modulators and detectors to filters, multiplexers and hybrid laser sources. The Silicon Photonics Group at Southampton University has been active across a breadth of activities within the field. In this talk an overview will be given of recent research efforts and results of the group.

Previously we have demonstrated optical modulators based on carrier depletion operating up to speeds of 50 Gbit/s. Devices such also need high speed electronic amplifiers in order to drive them with the required voltage levels. We have recently been working on the heterogeneous integration of CMOS electronic drivers with silicon optical modulators based on wire bonding. A fully integrated silicon photonics data link operating up to 10 Gbit/s has been demonstrated

We have shown that coarse wavelength division multiplexers (CWDM) based upon angled multimode interference (AMMI) structures can be advantageous in terms of fabrication simplicity and tolerance to fabrication variations. Recently we have demonstrated a bi-directional AMMI structure which results in two CWDM devices that share the same multimode region. Almost identical spectral responses are obtained from the two devices. This can be highly advantageous in applications where two (DE)MUX structures are required with matching spectral responses for example in polarisation diversity based receivers. We have also recently demonstrated a 50 Gbit/s four channel receiver based on the integration of an AMMI and germanium based photodetectors.

Wafer scale testing of PICs is essential in mass-production to ensure high yield is achieved and fabrication costs are minimised. To date few solutions have offered an efficient scheme which allows testing of individual components within an optical circuit. In our work we demonstrate a solution to this based on grating couplers formed by selective ion implantation induced amorphisation of silicon. Respectable coupling efficiencies have been achieved and it has also been shown that the amorphous silicon can be recrystallized through localised laser annealing and as a result the coupling gratings are erased.

Another area of research we have been highly active in is the use of silicon waveguides at mid-infrared wavelengths. We have demonstrated a range of waveguides and photonic components at different wavelengths beyond those traditionally used for telecommunications.

Athermal CMOS-compatible Silicon Photonics for Computing and Networking Applications

S. J. Ben Yoo
Department of Electrical and Computer Engineering, University of California, Davis, USA

Abstract— We will discuss athermal CMOS-compatible silicon photonic integrated systems designed for computer interconnects and networking applications. In particular, we will discuss CMOS-compatible athermal silicon photonic waveguides that can be building blocks for athermal modulators, lasers, and multiplexer/demultiplexers necessary for practical and scalable computing and networking systems. We will first discuss the design and fabrication processes utilizing a titanium dioxide overcladding layer on silicon photonics where full compatibility with CMOS fabrication steps have been implemented. Then, we will discuss an example of fabricated silicon photonic resonant ring modulators for athermal operations at 1550 nm and 1310 nm, respectively. We will follow up by discussing athermal silicon-photonic RFPhotonic lattice filters, arrayed grating waveguide mux and demuxes, and DBR gratings for InP/Si hybrid lasers, all designed and fabricated for large-scale integrated athermal silicon photonic systems on a die. Finally, we will discuss athermal silicon photonic optical-arbitrary waveform generation and measurement (OAWG and OAWM) system on chip for elastic optical networking applications, and prospects for future computing and networking systems.

Quantum Dot Lasers for Silicon Photonics

Yasuhiko Arakawa
Institute for Nano Quantum Information Electronics, The University of Tokyo
4-6-1 Koamaba, Meguro-ku, Tokyo 153-8505, Japan

Abstract— We discuss our recent advances in quantum dot lasers [1] for silicon photonics. High temperature stability and high feedback-noise tolerance due to small α-parameter of the quantum dot lasers are unique features for application to silicon optical interposers. High-temperature operation of silicon optical interposers showing the bandwidth-density of 15 Tbps/cm^2 up to 125 C was successfully demonstrated by integrating quantum dot lasers with flip-chip bonding method [2]. High performance operation of the quantum dot lasers on silicon by wafer-bonding technique was also examined [3, 4].

Abstract— Silicon is now considered as a material of choice for photonic applications including optical interconnects and telecommunications. These applications are mainly based on the use of optoelectronic devices (i.e., light sources/modulators/detectors) operating in the telecom wavelength range. Even if the development of silicon photonics was impressive in terms of device demonstrations, the integration of all the photonic building blocks is considered to remain as challenging due to the diversity of needed materials (Si for modulator, Ge for detector and III–V semiconductors for laser sources). The integration of all these materials on silicon is technically possible, but as different and sometimes non-compatible processes are used, the resulting scheme is not cost-effective, and consequently reduces the use of silicon photonics for a broad application domain.

The use of carbon nanotubes (CNT) as active materials for the development of all optoelectronic devices on silicon could overcome this integration issue. Indeed, carbon nanotubes exhibit the major optical properties to emit, modulate and detect light in the telecom wavelength range and can be integrated into the Si photonics platform.

In this context, we will present recent advances in CNT integration in silicon waveguides and in optical resonators. Several waveguide geometries including strip waveguides, slot waveguides, micro-disk and photonic crystal cavities have been studied and analyzed to enhance the optical interaction between the optical mode guided in the silicon structures and carbon nanotubes deposited on the top.

Subwavelength Grating Filters in Silicon Photonics

Lawrence R. Chen
Department of Electrical and Computer Engineering
McGill University, Montreal, QC H3A 0E9, Canada

Abstract— There is an increasing need for integrated solutions in optical communications interconnections, and sensing applications. In the past few years, a variety of active and passive devices as well as integrated subsystems in CMOS-compatible silicon photonics platforms have been realized. One specific structure that has attracted considerable interest is the subwavelength grating (SWG). An SWG is based on a periodic arrangement between two different materials with a period much smaller than the wavelength of the light. SWG waveguides have the potential for low loss and provide significant flexibility in tailoring the effective index. Indeed, a number of SWG-based building blocks in silicon-on-insulator (SOI) have been developed, including waveguide crossings, bends, couplers, mode transformers, polarization converters, and modulators. In this paper, we review recent progress on developing SWG filters based on ring resonators as well as Bragg structures. We compare the performance of conventional ring vs. racetrack resonator designs and discuss applications in sensing. We also describe narrowband reflection filters based on interleaving two SWG waveguides to create a periodic variation in refractive index, i.e., a Bragg grating. These filters add significantly to the SWG 'toolbox' and should enable the development of more complex wavelength selective devices with enhanced functionality, e.g., optical add/drop multiplexers.

Silicon Photonics for Data Center Networking Applications

Yung Jui Chen, **Chun Yen Chen**, **and Cheng Yu Wang**
Department of Photonics, National Sun Yat-Sen University, Kaohsiung 804, Taiwan

Abstract— Data center, a new concept of warehouse scale computing, offers economic and efficient solutions to the rapid expanding Internet applications. If Internet is a human body, data centers are the organs of the body. Currently, data center is one of the most rapid growth areas in information technology. The servers and storage devices in a data center are connected by clos switches built by high radix switch chips. As the number and speed of the servers and storage devices grow, the electronic clos switch fabric can no long keep up with the networking demand. One of the possible solutions of this data center network bottleneck is to utilize optical technology — a hybrid optoelectronic switch system. In this talk we will describe the concept of a WDM based wavelength switch solution based on silicon photonics platform. Issues and challenges of developing this novel data center networking system will be discussed.

Abstract— The recent experiments on photonic topological insulators signified a new direction. The progress on experiments and theory in this area will be reviewed, with an emphasis on universal ideas common to optics, cold atoms and quantum systems.

The discovery of topological insulators relying on spin-orbit coupling in condensed matter systems has created much interest in various fields, including in photonics. In two-dimensional electronic systems, topological insulators are insulating materials in the bulk, but conduct electric current on their edges such that the current is completely immune to scattering. However, demonstrating such effects in optics poses a major challenge because photons are bosons, which fundamentally do not exhibit fermionic spin-orbit interactions (i.e., Kramer's theorem). At microwave frequencies, topological insulators have been proposed [1, 2] and demonstrated [3] in magneto-optic materials, relying on strong magnetic response to provide topological protection against backscattering — in the spirit of the quantum Hall effect. However, at optical frequencies the magneto-optic response is extremely weak, hence a photonic topological insulator would have to rely on some other property. Indeed, numerous theoretical proposals have been made for photonic topological insulators [4–8], but their first observation [9], made by our group, relied on a different idea: Floquet topological insulators [10, 11]. Later that year, another group reported imaging of topological edge states in silicon photonics [12, 13]. These experiments have generated much follow up: predictions of nonlinear waves [14]; and of storage and release of information in such systems [15]. The purpose of this talk is to review this recent progress, discuss new conceptual ideas, and suggest applications.

Enhancing and Inhibiting Stimulated Brillouin Scattering in Photonic Integrated Circuits

Benjamin J. Eggleton
Centre for Ultrahigh Bandwidth Devices for Optical Systems (CUDOS)
Institute of Photonics and Optical Science (IPOS), School of Physics
University of Sydney, NSW 2006, Australia

Abstract— On-chip nonlinear optics is a thriving research field, which creates transformative opportunities for manipulating classical or quantum signals in small-footprint integrated devices. Since the length scales are short, nonlinear interactions need to be enhanced by exploiting materials with large nonlinearity in combination with high-Q resonators or slow-light structures. Here, we exploit the frequency dependence of the optical density-of-states near the edge of a photonic-bandgap to selectively enhance or inhibit nonlinear interactions on a chip. We demonstrate this concept for one of the strongest nonlinear effects, stimulated Brillouin scattering using a narrow-band one-dimensional photonic-bandgap structure: a Bragg grating. The stimluated-Brillouin scattering enhancement enables the generation of a 15-line Brillouin frequency comb. In the inhibition case, we achieve stimulated Brillouin scattering free operation at a power level twice the threshold.

Evolutionary Photonics: From Black-body Lasers to Ultrafast Subwavelength Rogue Waves in Photonic Seas

Andrea Fratalocchi
PRIMALIGHT, Faculty of Electrical Engineering, Applied Mathematics and Computational Science
King Abdullah University of Science and Technology (KAUST)
Thuwal 23955-6900, Saudi Arabia

Abstract— Chaos and disorder are often perceived as detrimental effects, which are typically unwanted in man-made applications due to their unpredictable character. Millions of year of evolution of natural systems, however, enabled pathways where these effects are exploited constructively and efficiently. In this invited talk, I will summarize my research activity in the field of evolutionary photonics, where I developed new types of applications that leverage on different aspects of chaos and randomness. I will begin my talk by discussing a new mechanism of energy harvesting, based on the unpredictable motion of light rays in chaotic cavities, and that is able to dramatically enhance the trapping performances of micro and nanoscaled systems [1, 2]. By using this technology, we are developing new applications in the field of solar cells [3], extreme localization of light [4], and new concepts in laser devices [5]. The traditional design of a laser exploits a cavity with single or multiple resonant modes, and their coherent amplification in a feedback structure. Following an evolutionary approach, we demonstrated a system where lasing does not result from a cavity or a resonance. In particular, we considered the possibility to achieve lasing from a black-body material. We fabricate the latter by combining a biomimetic approach with transformation optics. Measurements in the visible between 200 nm to 800 nm under isotropic illumination angles show that this material has a flat absorption $> 98\%$, behaving like an almost ideal back-body. In performing light emission experiments, we diluted a standard dye inside the black-body metamaterial, and then illuminate the system by a pulsed laser operating at 532 nm, characterized by a repetition rate 10 Hz and pulse duration 10 ns. We selected Rhodamine B (RhB) as a gain material, with fluorescence peak at 625 nm. We observed a strong emission peak that from an initial fluorescent emission 60 nm wide, creates an almost monochromatic line with 5 nm bandwidth. Further theory showed that such regime is the characteristic emission of the system, which occurs by a new mechanism of light "condensation" that coherently gathers all energy from the amplifier, confining it to a single frequency.

Soliton Explosions in Normal Dispersion Fibre Lasers

Antoine F. J. Runge, Neil G. R. Broderick, and Miro Erkintalo
Dodd-Walls Centre for Photonic and Quantum Technologies, Department of Physics
The University of Auckland, Private Bag 92019, Auckland 1142, New Zealand

Abstract— Mode-locked fiber lasers can be host to numerous exotic dissipative structures, and they have thus become ideal testbeds for the exploration of complex dissipative dynamics [1]. Among all such dynamics, soliton explosions display perhaps the most astonishing characteristics. In this regime, a *quasi*-stable dissipative soliton circulates in the laser cavity for a number of roundtrips, but then suddenly undergoes an abrupt structural collapse. Remarkably, after a few roundtrips the collapsed pulse self-recovers and returns back to its initial form [2]. However, the extreme transient nature of the explosions makes them difficult to capture in laboratory measurements. In fact, so far only one observation has been reported, in a solid-state Ti : Sapphire laser [3]. Here we report on the first observation of soliton explosions in a *mode-locked fiber laser*. We also show that explosions manifest themselves in the time-domain as abrupt, measurable temporal shifts of the pulse train.

The laser used in our experiment is an all-normal dispersion, all-PM-fiber device that is passively mode-locked using a nonlinear amplifying loop mirror. Depending on the pump power, the laser can sustain either stable or noise-like operation. By carefully adjusting the pump power to lie in between these two regimes, we observe a new mode of operation. It is in this transition regime that soliton explosions occur, as shown in Fig. 1(a). Here we plot the shot-to-shot spectra of 100 consecutive pulses emitted by the laser, recorded in real time. When an explosion occurs, the broad spectrum of the quasi-stable dissipative soliton collapses into a much narrower profile with larger amplitude, but after a few roundtrips returns back to its previous state. This is further highlighted in Fig. 1(b), where we show four consecutive spectra around a particular explosion event. Time domain measurements are shown in Fig. 1(c). We find that each explosion event gives rise to an abrupt temporal jump in the output pulse train: the pulse completes a cavity roundtrip approximately 40 ps later than in the quasistable regime.

We will present numerical simulations demonstrating how these explosions are generated by gain competition between an already existing pulse and a new one that grows parasitically on the shoulder of the first. These results demonstrate the universal nature of explosions in dissipative systems such as mode-locked lasers and should help to illuminate complicated dynamics elsewhere.

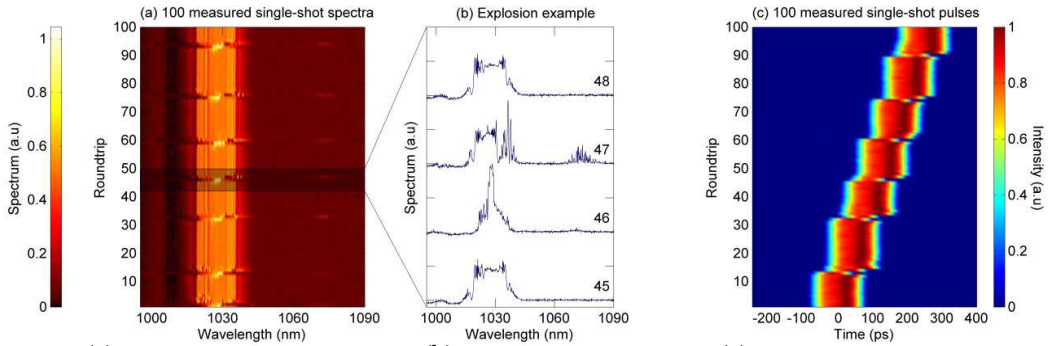

Figure 1: (a) Experimentally measured single-shot spectra of 100 consecutive pulses with the laser operating in the transition regime. (b) Example spectra at indicated roundtrip numbers around a particular explosion event. (c) Experimentally measured temporal evolution relative to the average roundtrip time over 100 roundtrips.

Abstract— Hollow-core photonic crystal fibers (HC-PCFs) with Kagome-style cladding structure have granted strong guided interactions between light and gaseous media over relatively-long propagation distances with low transmission losses and pressure-tunable dispersion in the visible region [1]. Stimulated Raman scattering processes in gases are characterized by having a very long molecular coherence relaxation time, of the order of hundreds of picoseconds or more. In this work, we analyze the propagation of two non-overlapped pulses, temporally separated by a delay smaller than the relaxation times, in HC-PCFs filled with Raman-active gases. The leading pulse is an ultrashort strong 'pump' fundamental soliton with a temporal width shorter than the Raman oscillation period of the gas, while the trailing pulse is a weak 'probe' pulse with negligible nonlinearity. The pump induces a lagging sinusoidal temporal modulation of the medium refractive index, which has been observed experimentally [2], due to Raman polarization. This soliton is uniformly accelerated with acceleration g_1 as a result of its Raman-induced spectral redshift. In the reference frame of soliton, we have found that the probe governing equation is the exact analogue of the time-dependent Schrödinger equation of an electron in a periodic crystal in the presence of an external electric field [3]. In our case, we deal with a spatially dependent Schrödinger equation of a single particle 'probe' in an induced temporal crystal by the accelerated pump.

Consider the propagation of an ultrashort soliton in a H_2-filled HC-PCF. Exciting the rotational Raman shift frequency δ in the fiber via this soliton will induce a long-lived trailing temporal periodic crystal with a lattice constant $\Lambda = 56.7\,\text{fs}$. In the absence of the applied force, the solutions are the Bloch modes, while in the presence of the applied force, the periodic potential is tilted, and the eigenstates of the system are the Wannier functions portrayed as a 2D color plot in Fig. 1(a), where the horizontal axis is the time and the vertical axis is the corresponding eigenvalue. After an eigenvalue step $g_1\Lambda$ the eigenstates are repeated, but shifted by Λ, forming the Wannier-Stark ladder. Each potential minimum allows a single localized state with weak tails. A large number of delocalized modes with long and strong tails exist in between. An

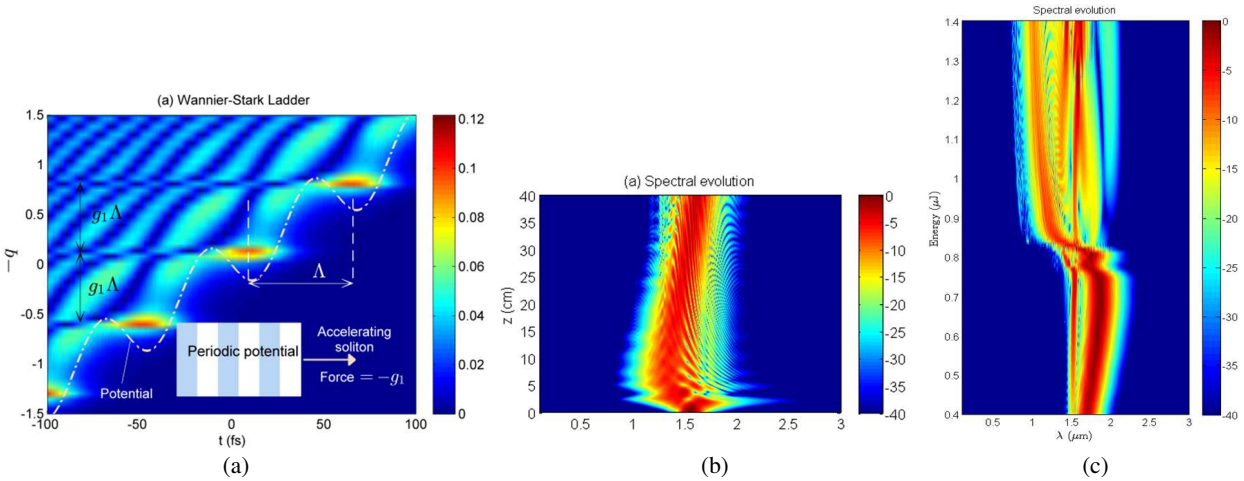

Figure 1: (a) A fundamental pump soliton with central wavelength 1064 nm, and full width at half maximum (FWHM) 15 fs is propagating in a H_2-filled HC-PCF that has a flat-to-flat core diameter 18 μm, gas pressure 7 bar, and rotational Raman frequency $\omega_R = 17.6\,\text{THz}$. (a) A portion of the absolute eigenstates of the Raman-induced temporal periodic crystal with a lattice constant $\Lambda = 56.7\,\text{fs}$ in the presence of a force with magnitude $g_1 = 0.1408$ in the positive-delay direction. The vertical axis represents the corresponding eigenvalues $-q$. The dotted-dashed line is the tilted potential. (b) Control over the Raman coherence wave in presence of Raman and plasma effects, and (c) control over the pulse spectrum due to the interplay between Raman and plasma effects as a function of pump energy.

arbitrary weak probe following the soliton will be decomposed into these Wannier modes. The evolution of a delayed probe is depicted in Fig. 2(b). Due to beating between similar eigenstates in different potential wells, Bloch oscillations arise with a period 34.7 cm. After each half of this period, an accelerated radiation to the left due to Zener tunneling is also emitted. The Zener tunneling is dominant over the Bloch oscillations, because the potential wells are relatively far from each other, hence, the overlapping between the localized modes are small.

When the intensity of light overcomes a certain threshold, the gas becomes ionized and generates an electron plasma, which in turn will influence nonlinearly the pulse. This leads to a soliton self-frequency *blueshift* and can be used to push energy into the blue part of the spectrum. We discuss the interplay between the Raman effect and the plasma effect, which leads to a very interesting control of the temporal and spectral domain of the pulse. Our novel theories on these two combined effects reveal all the main ingredient of supercontinuum generation in Raman- and plasma-active gases.

Abstract— Rogue or extreme waves have been extensively investigated in recent years in various application contexts, ranging from oceanography to nonlinear optics. A new frontier in the study of rogue waves is provided by multi-component wave systems, where the transfer of energy among the various components of a vector field may lead to novel and unexpected complex phenomena. In this presentation we discuss our recent advances in the theory and experiments on multi-component rogue waves, with a special focus on the case of vector propagation in randomly birefringent optical fibers, and in periodic Bragg gratings. Polarization coupling in telecommunication fibers is described by the vector nonlinear Schröinger equation or Manakov system. We have found a new class of coupled wave rogue wave solutions in both the anomalous and in the normal dispersion regime of the fiber. We have experimentally demonstrated the generation of black vector rogue waves by using standard telecom components. Pulse propagation in periodic fiber Bragg gratings is described by a variant of the massive Thirring model. We recently found the rational rogue wave solution of the massive Thirring model, which may open the way for the observation of rogue waves in periodic optical media, in oceans with a periodic bottom, as well as in relativistic fields.

Non-instantaneous Polarization Decay in Resonant Dielectrics

Abstract— We experimentally demonstrate and theoretically analyze the appearance of a lasting polarization response in a dielectric material. This previously unreported finding stems from a resonance condition of the third harmonic of the input light with the bandgap of the material. Polarization decay times up to 7 fs are observed for an effect that has previously always been considered to be unmeasurably fast.

Introduction: Third-order optical nonlinearities are extensively utilized in generation and characterization of ultrashort optical pulses, e.g., for frequency-resolved optical gating (FROG), which can be based on a variety of $\chi^{(3)}$ effects. FROG intrinsically relies on the instantaneity of the polarization response. Here we demonstrate that resonant third harmonic excitation in a dielectric medium may exhibit a surprisingly slow polarization decay, with a relaxation time constant that exceeds the duration of the shortest pulses generated to date.

Results: We used a collinear variant of third harmonic FROG (THFROG) [1] to characterize 7.5 fs Ti:sapphire laser pulses. Employing an identical THFROG setup, we focus either onto a TiO_2 half-wave layer or onto an uncoated SiO_2 substrate. From the recorded THG spectrum, we retrieve the intensity profiles [2] and observe that the pulse appears significantly broadened in TiO_2 relative to the measurement in SiO_2, despite of an otherwise identical setup. Deconvolution with a single-sided exponential kernel then allows determining a polarization lifetime $\tau_{\mathrm{pol}} = 6.5\,\mathrm{fs}$. For deeper understanding of this surprising effect, we solved the time-dependent Schrödinger equation (TDSE) for the parameters of the two dielectrica, which clearly identifies a resonance condition as responsible for the lasting response in TiO_2. Using the same deconvolution approach on the TDSE data, a time constant of 8 fs is reproduced in our theoretical treatment. Furthermore, extraction of the fundamental polarization reveals a similar lasting response also for self-refraction.

Conclusions: In conclusion, our results indicate a surprisingly slow few-femtosecond polarization decay of dielectrics in case of resonant excitation of the third harmonic. This previously unreported affect may impact $\chi^{(3)}$ based characterization methods, in particular at short visible or ultraviolet wavelengths [3]. Moreover, similar effects in the Kerr response may also limit the efficiency of few-cycle pulse generation schemes when they are based on self-refraction. Resolution of the measured $\approx 7\,\mathrm{fs}$ time constants is among the fastest ever reported effects at near-visible wavelengths, demonstrating the remarkable capability of FROG of resolving the temporal dynamics of nonlinear processes at the few-cycle scale.

Abstract— The upper millimeter-wave band (> 60 GHz) signals generation used for either broadband wireless or wired communications links has recently become a very attractive field having a significant interest among diverse groups comprising broadcasters, enterprise users, astronomy, security, defense issues and others; due to all the potential applications which they can be used for. However, generation of these signals is not possible by conventional techniques due to electronic limitations [1], so new devices and techniques are needed. Between the possible millimeter-wave signal generation sources are Photonic Integrated Circuits (PIC) which have a key advantage enabling the integration of multiple photonic building blocks within a single chip to develop compact systems with increased functionality and performance [2] Eliminating the need to fiber couple these photonic building blocks has a huge impact on the cost and component footprint.

Photonic integration allows us to develop compact and cost efficient transmitters, generating the wireless carrier frequency at the remote location where the antenna is to be located. There are several photonic techniques that are available for this task, and some photonic integration advances have already been reported [3]. Here, we shall present a photonic source for millimeter-waves signal generation using on-chip photonic dual-wavelength sources based on arrayed waveguide grating (AWG) using Multimode Interference reflectors (MIR). Furthermore, this paper presents our progress in F-band wireless link system technologies that contribute to extending the transmission distance of the wireless links.

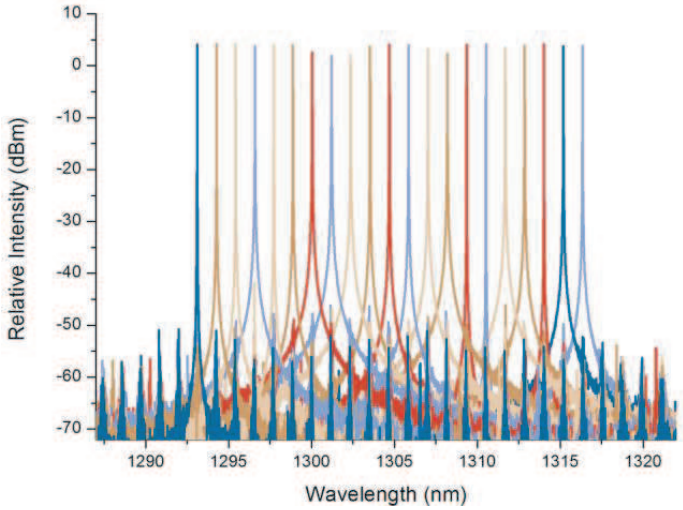
Abstract— Tunable semiconductor lasers have been intensively studied for next-generation optical networks. Besides their use for source sparing with the advantages of reduced inventory and cost, they are also the key components for wavelength-agile access and communication between data centers. However, tunable lasers based on grating or MEMS structure are expensive for the need of complex fabrication process and complicated tuning algorithm.

In this paper, we design and investigate a high-speed directly-modulated tunable V-cavity laser working at 1310-nm band, which is based on AlGaInAs multiple-quantum-wells. The V-cavity laser is ultra-compact with device size of only 300 μm × 200 μm, and it does not require grating and multiple epitaxial regrowth. This structure consists of a channel selector cavity and a reference cavity with different optical path lengths, which are coupled by a reflective 2 × 2 half-wave coupler.

By employing the time-domain traveling-wave method, the static and dynamic performances of the V-cavity laser are investigated. 21 × 200 GHz tuning with ∼ 40 dB side-mode suppression ratio is achieved by simple single-electrode-control using carrier injection effect, when the lengths of the channel selector cavity and reference cavity are 220 and 210 μm, respectively. The layer structure and ridge waveguide are optimized to obtain a mode confinement factor of 0.16 for better performance. Small signal response simulation is carried out by an impulse current injection with a fast Fourier transform algorithm, and the simulated 3-dB bandwidth is 29.9 GHz when the coupler electrode is biased at 70 mA. Moreover, 10 Gbit/s and 25 Gbit/s direct modulations are demonstrated with clear eye-opening. The corresponding extinction ratio is about 8 dB when the injection current is 100 mA and 40 mA for "1" and "0", respectively. Error-free 10-km single-mode fiber transmission is also obtained.



Self-homodyne Detection in Optical Coherent Transmission Using Extracted Carrier as the Local Oscillator by Saturated SOA

K. H. Mun, **S. M. Jung**, **and S. K. Han**
Department of Electrical and Electronic Engineering
Yonsei University, 50 Yonsei-ro, Seodaemun-Gu, Seoul, Korea

Abstract— In the homodyne coherent detection, the wavelength of local oscillator at the receiver should be same as the transmitted signal; otherwise, carrier frequency offset (CFO) noise occur and it makes system performance worse. Therefore, in the homodyne system, a technique which tunes the wavelength of LO to the signal and stabilizes the wavelength is required, such as optical frequency locked loop (OFLL), or it is required to compensate CFO using DSP. On the other hand, in case of the self-homodyne detection, the techniques are not required because LO light which originates the signal source is transmitted from transmitter. However, the conventional self-homodyne detection requires another single mode fiber or multi-core fiber for transmission of LO light, so this is inefficient in terms of cost and system realization. In this paper, we proposed a self-homodyne coherent detection technique using extracted carrier from the received optical signal as LO by saturated semiconductor optical amplifier (SOA). Saturated SOA has data erasing characteristic, so LO light can be extracted from the received optical signal by erasing modulated data of optical signal. In the proposed scheme, there is no CFO because LO light originating from the received signal has a totally same wavelength with the signal; thus, expensive OFLL or complex CFO compensation algorithm can be avoided and also colorless operation is possible. In addition, there is no additional requirement of optical fiber for LO light transmission, so it is cost efficient. The test bed has been set up and the feasibility was experimentally demonstrated.

THz Oscillations in DNA Monomers, Dimers and Trimers

Abstract— We study [1–3] charge transfer in DNA monomers, dimers and trimers (monomer is one base-pair) with a tight binding approach (I) at the base-pair level using the relevant on-site energies of the base-pairs and the hopping parameters between successive base-pairs or (II) at the single-base level using the relevant on-site energies of the bases and the hopping parameters between neighboring bases. The parameters can be found in Refs. [1, 4]. We solve numerically a system of (I) N or (II) $2N$ coupled differential equations with the eigenvalue method, determining the temporal and spatial evolution of electrons or holes along a N base-pair DNA segment [1–3]. With the approach (I), we predict electron or hole oscillations in DNA dimers [1, 2] with frequency in the range $f \approx 0.25$–$100\,\mathrm{THz}$ (period $T \approx 10$–$4000\,\mathrm{fs}$), i.e., mainly in the mid- and far-infrared with wavelengths $\lambda \approx 3$–$1200\,\mu\mathrm{m}$ [2]. The efficiency of charge transfer between the two monomers which constitute the dimer is described with the maximum transfer percentage p and the pure maximum transfer rate pf. For dimers made of identical monomers $p = 1$, but for dimers made of different monomers $p < 1$. For trimers made of identical monomers the carrier oscillates periodically with $f \approx 0.5$–$33\,\mathrm{THz}$ ($T \approx 30$–$2000\,\mathrm{fs}$) [2]; for 0 times crosswise purines $p = 1$, for 1 or 2 times crosswise purines $p < 1$. For trimers made of different monomers the carrier movement may be non-periodic [1, 2]. The method can be applied to polymers, too [1, 3] allowing us to evaluate the extent at which a DNA segment can serve as an efficient medium for charge transfer. With the approach (II) we investigate carrier oscillations in DNA monomers and dimers. This (II) approach allows us to examine the system in higher detail; the results agree in a coarse frame with the results of approach (I). Calculations based (III) on Real-Time Time-Dependent Density Functional Theory (RT-TDDFT) for the adenine-thymine and the guanine-cytosine base-pairs are under way; here we present our first results. Similar THz oscillations within smaller systems, e.g., p-nitroaniline and FTC chromophore [5], zinc porphyrin and green fluorescent protein chromophores and adenine-thymine base-pair [6] have been presented in the literature. Applying our methods (I) and (II) in the A-T monomer we get a period of oscillations in agreement with the prediction of that much more computationally complex technique [6]. Hence, the simpler approaches (I) and (II) catch the key phenomenon, while, we can easily treat dimers, trimers, tetramers [7] etc. and polymers, something exceptionally time-demanding for the approach (III). Our results show that a non conventional source or receiver of THz and above THz electromagnetic radiation can be envisaged.

Formation of Caustics by Refraction of Structured Laser Radiation in the Diffusive Layer of Liquid

A. V. Vedyashkina, I. L. Raskovskaya, and I. N. Pavlov
V. A. Fabrikant Physics Department, National Research University
"Moscow Power Engineering Institute", Moscow 111250, Russia

Abstract— Nowadays research of optically inhomogeneous media represent great scientific interest. In such media the refractive index is not the same in any point and light passes due to refraction not rectilinearly.

It is often important to know what occurs when two or more mediums with different physical characteristics contact each other, how the refractive index of liquid changes by heating or cooling objects inside it.

One method of researching optically inhomogeneous mediums is the method of the laser refractography. It is based on the phenomenon of refraction of structured laser radiation (SLR) in optically inhomogeneous media and registration of its form deviations with the digital video camera [1].

In this paper we consider case when optical inhomogeneity created by diffusion. The diffusive layer of liquid appears near interface of two liquid mediums with various refraction indexes. Refraction index of more solid liquid is n_1, less solid $-n_2(n_1 > n_2)$. The model of diffusive layer we will describe with special exponential model [2].

In this paper two types of structured laser radiation are considered: laser plane and cylindrical beam. When probing of the medium by radiation of these types caustics appear. Caustic is the envelope of light rays. In this method, it is a special line or special surface near which the intensity of light field increases sharply [3]. It is presented experimental and computer 3D-visualization of dynamics of caustics' formation when changing parameters of inhomogeneity and laser radiation. It is shown how position and shape of caustic's surface can changes by variation different parameters such as angle of SLR incidence, size of cylindrical beam, gradient of refraction index, etc.. Fig. 1 shows experimental setup for registration 3D-refractogram of cylindrical beam in diffusive layer.

It is very important to know the area of caustics' occurrence that allows optimizing experiments. At the consideration experimental refractogram, which was made in diffusive layer, it is possible to analyze how can mediums diffuse each other and estimate gradient of refraction index.

Self-organizing And Filamentary Behaviour in Broad-area Lasers

A. V. Pakhomov[1, 2], **A. A. Krents**[1, 2], **D. A. Anchikov**[1], **and N. E. Molevich**[1, 2]

Abstract— Broad-area lasers are often necessary for high-power laser applications since increasing of transverse sizes of pumping region entails increasing the output power. However, for pumping levels well above the lasing threshold broad-area lasers exhibit complicated spatio-temporal dynamics. This is caused by the development of steady lasing instabilities that turn to be especially complex in broad-area lasers as transverse space-coupling processes and corresponding nonlinearities become involved. As a result related laser operation leads to degradation of brightness of these devices and coherence reduction of emitted beam.

In presented work we report on detailed investigation of spatio-temporal instabilities emergence for steady stationary operation in broad-area lasers. Our analysis was based on Maxwell-Bloch equations for frequency detuned cavity along with transversely distributed two-level lasing media. Performed analytical investigations together with numerical modeling demonstrated several separable dynamical regimes depending on ratios between active media and cavity parameters. Principally, it allowed distinguishing filamentary instability from pattern forming instability.

Filamentary behaviour is shown to emerge for incoherent light-media interaction when medium polarization instantaneously follows the intracavity field. This dynamical regime is found to be induced by modulation-type instability and is accompanied with both temporal and spatial nonregular dynamics. Filamentation can be often explained by strong gain-index coupling or by influence of self-focusing nonlinearity in the case of strongly nonlinear regimes. Our results show possibility of such dynamics in active system for even low electromagnetic field intensity just above the threshold. Therefore we expect this instability to be one of the possible routes to filamentation and light threads formation when extending the transverse section in many active optical systems like broad-area semiconductor lasers and amplifiers.

Pattern formation is found to evolve for coherent light-media interaction according to another scenario. This type of behaviour arises when steady lasing becomes unstable in favor of self-oscillating operation and it is in turn supplemented by instability against small spatio-temporal perturbations with finite wavelength. A number of spontaneously forming regular patterns was observed in this case like standing autowaves and spiral patterns. Self-organizing can eventually lead to either stationary or oscillating inhomogeneous intensity profile. Main principles and formation concepts of these optical patterns in the transverse section of the broad-area laser emission were elaborated.

Hydrogen and Humidity Sensing Based on WGMs of Elastic Polymer Optical Microresonators

M. Eryürek[1], **Y. Karadag**[2], **S. Anand**[1], **N. Kılınç**[3], **A. Kiraz**[1]

[3]Department of Mechatronics Engineering, Niğde University, Niğde 51245, Turkey

Abstract— Hydrogen gas is an attractive energy source because of its energy conversion efficiency. However, the lower flammable limit of hydrogen gas is 4% in the air at room temperature. In addition, hydrogen storage is difficult because of its small molecular volume. Therefore selective detection of small concentrations of hydrogen gas at room temperature with a quick response is crucial for the public health and the safety of property. In this work, we propose a hydrogen gas sensor based on polymer optical microdisk resonators fabricated using standard UV photolithography. The sensing mechanism relies on the shift of optical whispering gallery modes (WGMs) due to the size change of the resonator which is induced by the volume expansion of a palladium layer coated on the resonator. These resonators and the waveguides are fabricated using SU-8 photoresist on a thick-oxide Si wafer substrate. A tunable laser (1500–1630 nm) is coupled to the waveguide using end-face coupling method. When the transmission spectrum is measured, transmission dips are observed revealing WGMs. A maximum quality factor of 2000 is measured which can be improved by either controlling the waveguide-resonator separation to obtain critical coupling or by fabricating much smoother microdisk resonators to decrease the scattering loss.

Palladium (Pd) layer is coated on these resonators for hydrogen sensing experiments. A lower detection limit of 0.3% is recorded in nitrogen environment. These sensor devices can reversibly respond hydrogen concentrations up to 1.5%. After 1.5% the sensor devices suffer from irreversible changes because of a phase transition in palladium. This phase transition can be delayed to higher hydrogen concentrations by using palladium alloys instead of Pd.

Hydrogen sensing performance of these sensor devices also tested under humid conditions. At room temperature and under 100% relative humidity the sensor did not respond to 0.5% hydrogen. However at 50% relative humidity, 0.5% hydrogen was successfully detected which is important in terms of practical applications.

Abstract— An investigation on the power energy injection in a resonator by electron stream is reported in this paper, by documenting the power transfer between the electron current to a resonant system. The beam current emitted by an electron linear accelerator (LINAC) has been monitored through a particular radiation detector. This device was developed for the dose measurements of a Medical Linear LINAC where monitoring system are required for the real time control of the dose delivered to the patient [1–4]. The power transfer has been observed employing the relation of interaction of the LINAC beam current with a passive resonant cavity [5] placed at the output interface of the accelerator. The LINAC beam current have a bunched form. The spectral content is a line at the accelerating pulsation $\omega_0 = 2\pi f$ and whole-number harmonics [4]. The beam has been used to induce TM_{010} mode oscillations in a cylindrical cavity at the frequency f [6]. The current drives the cavity in resonance and the energy exchange is heavily regulated by the transit time factor T [7] and the coupling factor k [8]. A magnetic loop antenna is inserted in the cavity in order to perceive the magnetic flux at the TM_{010} resonance. A voltage induced on the terminals of the magnetic loop is forwarded to an envelope detector through a coaxial transmission line loaded (Fig. 1). The envelope detector shows a matched impedance to the loop-cavity system where a certain amount of power is dissipated. The cavity modeling has been performed on POISSON SUPERFISH and the whole system consisting of the cavity and the magnetic loop has been optimized and finally simulated on HFSS version 15 of ANSYS

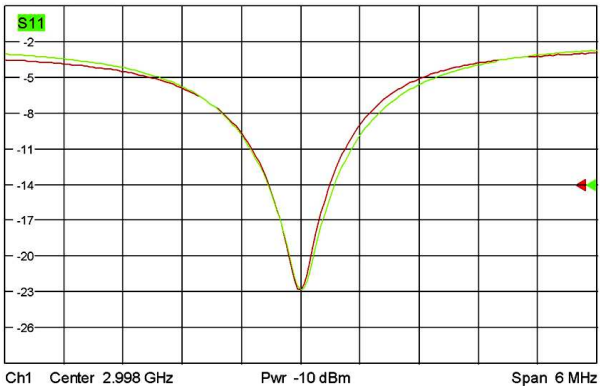

Figure 4: Measured scattering reflection parameters.

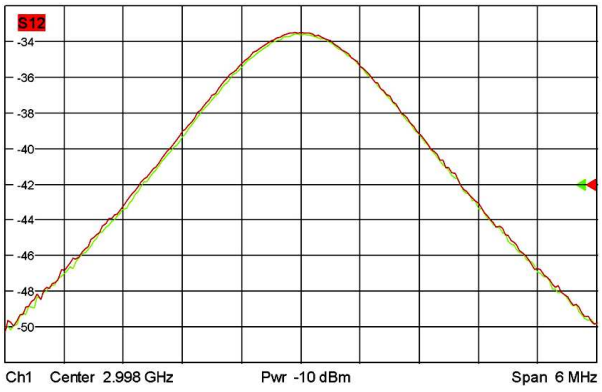

Figure 5: Measured scattering transmission parameters.

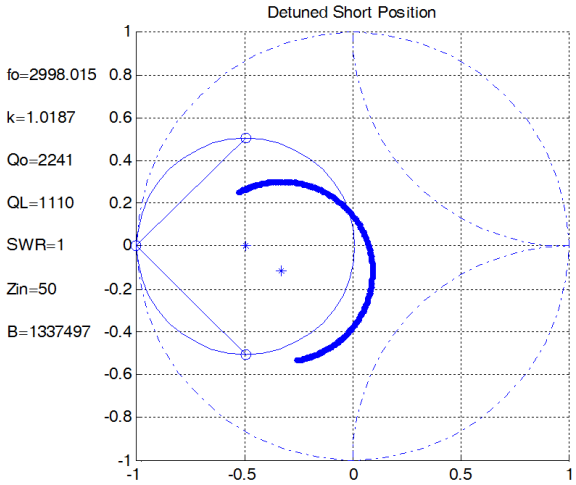

Figure 6: Detuned short position elaboration for coupling analysis.

(Fig. 2). A prototype has been fabricated (Fig. 3) and tested through VNA cold measurements and by shooting a beam current in the while cavity observing the output voltage. The input characteristic of the cavity system have been measured showing a quality factor $Q_0 = 2.24 \cdot 10^3$, a Return Loss of 23 dB a cross talk of -34 dB and a Coupling Factor $k = 1.019$, (Figs. 4–6). The output voltage has been digitalized by a microcontroller, obtaining numerical values. The system has been calibrated by relating the radiation dose, measured by a certified electrometer, to this digital output, yielding the monitor units [1]. The linearity of the monitor units for different values of accumulated dose, have allowed to employ this system for the real time measurements of ionizing radiation emitted by a medical LINAC [1–3].

Low-loss Millimeter-wave Phase Shifters Based on Mechanical Reconfiguration

Abstract— We propose the analysis, design, and implementation of mechanically reconfigurable true-time delay (TTD) phase shifters using micro-fabricated actuators at millimeter-waves (MMW). TTD phase shifters are key building blocks in many array antenna systems, including wideband beamsquint-free scanning arrays.

Reconfigurable phase shifters are critical components in modern communications and remote sensing systems at MMW. In general, advanced reconfiguration capabilities are increasingly required to dynamically update antenna characteristics, such as coverage, polarization or operating frequency. Different technologies are currently available for the implementation of tunable phase shifters, including semiconductors, RF-MEMS, Liquid Crystal, ferroelectrics. However, a common feature to all these technologies is the significant increased loss, complexity and cost with regard to non-reconfigurable devices. In this context, low-loss reconfigurability, complexity and cost are driving factors in the choice of a given technology and can constitute major limitations to future development of MMW antenna devices.

The proposed mechanical tuning allows to achieve phase shift reconfiguration with very low losses. Variable phase shift is in fact obtained modifying the physical geometry of the device in order to affect the propagation constant of a transmission line (TL) section, thus providing TTD. Using micro-actuators, this can be done by changing the geometry of the device, in order to modify the effective permittivity of the equivalent TL. Such an approach allows to completely isolate the actuation part from the electromagnetic (EM) active area, thereby achieving reconfiguration with losses comparable to the device fixed counterpart.

In particular, the preliminary design and performance of three different reconfigurable concepts operating at Ka-band is presented. The design of one concept has been further optimized to be manufactured and tested. The proposed concepts can be potentially implemented using different technologies for mechanical reconfiguration. For instance electrostatic, magnetic, piezoelectric or electroactive polymers actuators could be integrated to implement the final device. Here dielectric electroactive polymer (DEAP) actuators are used to reconfigure the phase shifter concept that has been successfully manufactured and tested. The fabricated phase shifter provides a maximum analog phase range (i.e., between maximum and minimum displacement) of around 180° at 30 GHz with extremely low losses. The insertion loss is in fact always lower than 1.6 dB with an average value of 0.83 dB over the total frequency range. The return loss is always better than 11 dB, which means good matching for all the phase shifting states in the whole 10 GHz (25–35 GHz) bandwidth. The low-loss phase shift reconfiguration demonstrated by experimental results allows state-of-the-art performance in terms of the most important figure of merit for TTD phase shifters, namely, the phase-shift/loss ratio. Indeed, a mean value of 235°/dB is achieved at 35 GHz.

Tunable Periodic Deflector Structure Based on Ferroelectric Materials

R. A. Platonov[1], **A. G. Altynnikov**[1], **I. V. Kotelnikov**[1], **A. B. Kozyrev**[1], **V. N. Osadchy**[1], **and A. G. Chernokalov**[2]

[2]Limited Liability Company Samsung Research Center, Russia Federation

Abstract— In recent years electrically tunable lenses (ETL) (so called deflectors) for microwave (MW) frequencies range becomes powerful beam-forming platform that combines the best features of MW aperture antennas and phase array antennas. This approach allows the radical decrease of MW losses and greatly simplified design due to absent of dividers and intrinsic feeder lines. There are two branches for design development of ETL: (i) array lenses (AL) based on lumped elements ($L \ll \lambda$, where L is a scale of element sizes, λ — wave length) [1–4]; (ii) lenses consist of distributed elements ($L \geq \lambda/4$), based on material with nonlinear properties in electro-magnetic field.

In a set of works the ferroelectric (FE) elements are proposed to be used as a base of tunable lenses [5–7]. Ferroelectrics of BSTO type ($Ba_xSr_{1-x}TiO_3$) in paraelectric state are promising materials for this application due to no frequency dispersion of dielectric constant (ε) up to 100 GHz and the suitable tunability of ε under electrical control field. Operating principle of such lenses is based on the variation of phase shift of signal propagated through ferroelectric material due to the change of its dielectric constant by control voltage. These tunable lenses are characterized by simplicity of construction and the absence of discrete (lumped) elements that allows to use them in a wide frequency range.

In this paper the electrically tunable lens based on periodical multilayer ferroelectric structure FE/LD/FE/LD/FE (LD — linear dielectric) with transparent for MW electrodes between layers is presented. Control voltage applied to the FE ceramic leads to the change of FE layers permittivity and, as consequence, to the change of the wave impedance and the delay time across the periodical structure for MW signal. Formation of dielectric permittivity gradient along the plane of FE layers allows to deflect phase front of the plane wave propagated through the structure. The use of periodical structure allows to decrease the control voltages value and to increase the scan angle in comparison with non periodical analogues. The main parameters of device (scan angle ~ 20 deg.; bandwidth ~ 1 GHz) were obtained by modeling and were confirmed by experimental testing of antenna prototype at frequency ~ 30 GHz.

Point-to-point Radio Link Variation at E-band and Its Effect on Antenna Design

A. N. H. Al-Rawi, **A. Dubok**, **M. H. A. J. Herben**, **and A. B. Smolders**
Electromagnetics Group, Department of Electrical Engineering
Eindhoven University of Technology, The Netherlands

Abstract— Radio propagation will strongly influence the design of the antenna and front-end components of E-band point-to-point communication systems. Based on the ITU rain model, the rain attenuation is estimated in a statistical sense and it is concluded that for backhaul links of 1–10 km, antennas with a gain of 49.5 dBi are required. Moreover, depolarization can be a limiting factor for backhaul systems that are employing orthogonal polarization in order to improve capacity. Antenna mast movement becomes a relevant problem due to the narrow beamwidth of the high gain antennas, which is around 0.7°. We propose to implement a focal plane array as feed for the parabolic reflector antenna. This is to tackle the mast movement by electronic beam steering and to increase EIRP by increasing the number of active antenna elements, and to assist the mechanical alignment during installation.

60 GHz Antenna on Metallic Nanowired Membrane Substrate

Abstract— Given the large number of wireless communication protocols functioning at microwave frequencies (0.9 GHz to 30 GHz) and the need for higher data transfer rates, interest on the millimeter wave frequency range (30 GHz to 300 GHz) has increased in both academic and industrial communities. However, integration of the millimeter-sized antenna with the micrometer-sized transceiver circuit proves to be problematic due to the high cost per square millimeter even in low-cost CMOS technologies. Several antennas have been presented in the literature at millimeter frequencies (DOI 10.1109/APS.2011.5996530, 10.1109/IEEE-IWS.2013.6616744, 10.1109/APS.2014.6904381), but only a few uses a patch topology with easy fabrication.

This work presents for the first time an antenna operating at millimeter wave frequencies, at 60 GHz using the novel low-cost Metallic nanowire Membrane substrate (MnM-substrate) (DOI 10.1109/TMTT.2014.2366108). The MnM-substrate consists of a 50-µm-thick-nanoporous-alumina-membrane filled with copper nanowires, a copper ground plane on its underside connecting all the nanowires and a silicon dioxide layer on its upper side, shown in Fig. 1.

On the top of the dielectric layer, the antenna is defined. When the membrane is filled with metal nanowires, the slow wave effect appears, confining the electrical field inside the oxide layer (Serrano, et al., 2014). Although the slow-wave effect reduces the size of the devices, it is inconvenient for the antenna, which needs to irradiate the electrical field. Thus, there are no nanowires below the antenna region, only the alumina membrane. The proposed antenna is a rectangular patch fed through a reentrant line stub transformer in order to match the 50 ohms characteristic impedance of the feed line. The feed line width at 60 GHz is close to the width of the antenna patch, degrading the antenna efficiency. Therefore, the nanowires are grown below the feed line to reduce its width. Since a patch antenna needs a thicker substrate to radiate properly it was necessary to thicken the membrane, which was done via stacking three rectangular membrane pieces on a copper-covered silicon base in order to meet the 200 µm designed thickness and guarantee ground plane continuity, as shown in Fig. 2.

The antenna was simulated in HFSS, Ansys, in order to evaluate its performance. The EM simulation of the patch antenna showed a maximum gain of 4.5 dB and return loss better than −20 dB at 60 GHz. Antenna dimensions are 750 µm × 730 µm. Although the lower gain comparing to the ones presented in the literatura, the area is highly reduced, since substrate electrical permittivity is higher (9.8 for alumina and 2.2 to 1 in onther antennas). It has been concluded that the nanowire substrate is adequate for antenna manufacturing and operation, being cheap, easy to manufacture and allowing high performance antennas to be designed. Measurements are currently in progress.

Analysis of Sampling Grids for Spherical Near-field Antenna Measurements

R. Cornelius and D. Heberling
Institute of High Frequency Technology, RWTH Aachen University, Germany

Abstract— Spherical near-field antenna measurements are commonly used to characterize an antenna under test (AUT). Therefore the electromagnetic field is measured on a closed surface around the antenna and transformed to the far-field by a near-field to far-field transformation.

The most popular transformation algorithm first calculates a spherical mode spectrum using Fourier transforms [1]. From this mode spectrum the far-field is derived. Due to the Fourier transform the transformation algorithm is very fast and efficient but requires equiangular sampling in spherical coordinates. Consequently the sampling point density is high at the poles and low at the equator. According to the number of unknown spherical modes the sphere is therefore oversampled approximately by a factor of two and this oversampling increases the measurement time. This is disadvantageous since long measurement times are a general drawback of near-field measurement systems. In order to improve the measurement speed more efficient sampling grids may be used at the expense of different and/or more complex transformation algorithms. Reformulating the transmission equation in [1] in matrix form as used for truncation error reduction in [2] is a very simple and straightforward approach. Alternatively, algorithms for general purpose presented in [3, 4] could be used. Furthermore, near-field interpolation methods could be utilized to determine the near-field on an equiangular grid [5]. Besides the larger flexibility new algorithms provide additional features like higher order probe correction, possibility of different measurement distances and position correction. Due to the technical progress in computer technology the transformation time is usually negligible compared to the measurement time and therefore a less important factor. Although new algorithms have been verified by simulations and measurements, a comprehensive investigation of different sampling grids is still missing. So far only little attention has been paid to the minimal number of required near-field samples and their distribution over the sphere. This distribution is a very important factor for the measurement time due to different capabilities of different positioning systems (e.g., roll-over-azimuth, robot arm).

In the paper we will present different sampling grids, evaluate the required hardware and the complexity of the grids. Besides the location of the sampling points the polarization will be investigated. The near-field to far-field transformation algorithm used is based on matrix inversion and calculation of the spherical modes. Therefore the condition number of the grids will be evaluated and compared. Simulations and measurements will be performed and analyzed for all grids. Finally the required relative measurement time and accuracy will be specified for the different sampling grids. It will be highlighted that the measurement speed can be increased significantly compared to equiangular sampling.

A Dual V-band Push-push VCO Using the 0.18 μm CMOS Process Technology

Yu-Hsin Chang and Yen-Chung Chiang
National Chung Hsing University, Taiwan

Abstract— In this paper, a dual-band push-push voltage-controlled oscillator implemented in the 0.18-μm CMOS process for V-band applications is presented. By using a forth order resonance network composed of symmetric inductors and varactors and a push-push topology, the oscillation frequencies of the proposed circuit can be switched with only one control signal between two bands. And the second order harmonic is extracted from the central taps of inductors to achieve the frequencies of two V-band operations. The tuning ranges of the proposed voltage-controlled oscillator are from 67.78 to 69.42 GHz and from 52.2 to 54.7 GHz, respectively. The measured phase noise at 1 MHz frequency offset are −86.4 dBc/Hz and −90.5 dBc/Hz for 69.42 GHz and 54.7 GHz output frequencies, while the corresponding phase noises at 10 MHz frequency offset are −108.4 dBc/Hz and −112 dBc/Hz, respectively. The core circuit consumes a 12.96 mW dc power from a 1.8-V supply.

Spatial Power Combiner Technology

Davide Passi[1], **Alberto Leggieri**[1], **Franco Di Paolo**[1], **Antonio Tafuto**[2], **and Marco Bartocci**[2]

[1]University of Roma "Tor Vergata", Via del Politecnico 1, Roma 00133, Italy
[2]Elettronica SpA, Via Tiburtina Valeria Km 13.7, Roma 00100, Italy

Abstract— This article describes the spatial power combining techniques dealing with the state of the art of Spatial Power Combiners (SPC) considering recent developments. A brand-new splitting scheme is proposed where different types of SPC are grouped according to the space where power combining and splitting occur. This paper should provide compendium knowledge for SPC design and selection of the opportune SPC basing on the target application.

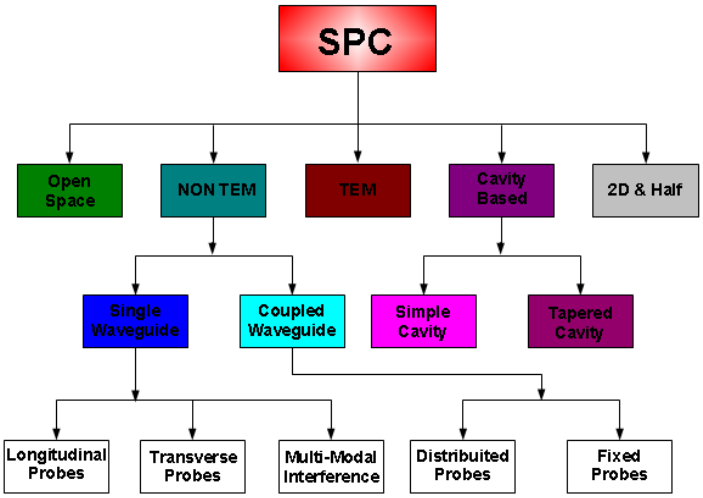

Figure 1: New splitting scheme.

The fundamental SPC Amplifier's concept is to provide a large power value with minimum losses. For this aim, SPC has several characteristics that make it unique and innovative. First one is that the electromagnetic energy coming from input is divided as much as possible in the space, without using transmission lines, and it is sent to many SSPA. After amplified energy is collected, it is sent to output port without using transmission lines. Another common feature of SPC is the presence of probes, antennas or transitions to collect the spatial RF energy and send it to a two wired transmission line. The system's quality is usually determined from its efficiency. In SPC technology efficiency can be defined basing on the portion of power sent to the active devices respect to the amount of power provided at the input port, such as it quantifies the capability of the combiner to intercept incoming energy and distribute it to N energy dividing/combining internal ports.

There are TEM and NON TEM spatial combiners, cavity based, open space and 2D&Half ones.

Non TEM SPC use waveguides to confine RF electromagnetic energy and they can be completely closed or slotted to couple energy to another slotted waveguide. This type is composed by three families: the single waveguide family, with longitudinal probes and transverse probes, the coupled waveguides and the multimodal interference families.

Then RF probes can be realized in several technologies, as monopoles, dipoles, patches or slots or combinations among them. In many other cases Fin Line transition are realized, especially when wide band applications are needed.

Two examples taken by our design experience are going to show: an X band and Ka band SPC.

Single waveguide with transverse probes and amplifiers is named Grid Amplifier. The basic concept in SPC Grid Amplifiers is to intercept the incoming signal with a defined polarization, amplify it with the active device and then send the amplified signal using the orthogonal polarization respect the incoming one.

A different type of SPC is the Multimodal Interference SPC, uses the interferences among many propagating modes in an overmoded waveguide. This multimodal interference effect is also named "Talbot's effect".

The Coupled Waveguides SPC use two waveguides connected between them through two wires transmission lines, so it is possible to insert amplifying active devices between these two waveguides.

Coupled Waveguides SPC are divided in two subgroups, the distributed probes group and fixed group of probes. In the first case, probes are located along the waveguide, while in the second case probes are located just near the shortest wall of the waveguide.

TEM SPC use TEM transmission lines to confine RF electromagnetic energy. The simplest and well known TEM structure is the coaxial transmission line, here there are going to illustrate two versions, the classic circular and the square one.

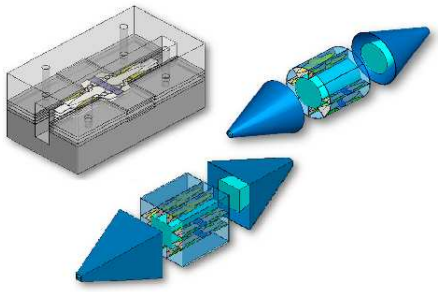

Figure 2: Non TEM and TEM SPC.

Cavity Based SPC use a closed cavity excited by an input port, and the output ports are realized inserting probes inside such cavity.

This family consists of two different groups and differing from the modality of input port coupling with the cavity: if the coupling is made through a conical transmission line the SPC is named in literature as Conical Transmission Line, otherwise it is named Simple Cavity SPC.

Their efficiency is very high due to the fact that they use closed cavities and thus energy is well confined inside it.

Open Space SPC use amplifiers connected to probes placed in an open space environment. Usually lens are used to focus the beam to and from grid amplifier.

2D&Half SPC, that are two dimensions and half SPC, remember SIW technology (Substrate Integrated Waveguide) or micro open space SPC.

Time-domain Beam Propagation Method Based on Gradient Smoothing Technique for Dispersive Materials

Khaled S. R. Atia[1], **A. M. Heikal**[2], **and S. S. A. Obayya**[1]

[1]Center for Photonics and Smart Material, Zewail City of Science and Technology, Egypt
[2]Department of Electronics and Communication Engineer, Mansoura University, Egypt

Abstract— In this paper, a novel finite element time domain beam propagation method based on gradient smoothing technique. The proposed method is described for the analysis of dispersive materials. It is more accurate and stable than the conventional finite element time domain.

Introduction: The previously introduced time domain beam propagation method [1] uses a second order triangular element. However, the first order triangular element (T3) is often preferable because of its computational efficiency. A smoothed bilinear form for Galerkin formulation has been introduced [2] to improve T3 accuracy. This paper adopts the smoothed bilinear form to analyse the dispersive materials in time domain.

Formulation: We consider a TE wave equation and a plasma model under slowly varying envelop approximation. After Applying Galerkin procedure, The Shape function derivative is then replaced by the smoothed derivative as follows,

$$\nabla N(x,y) = \frac{1}{A_s} \oint_{\Gamma_s} N(x,y) d\Gamma_s, \tag{1}$$

where $N(x,y)$ is the first order shape function, A_s is the area of smoothing domain, Γ_s is the boundary of the smoothing domain. The smoothing domain is constructed by simply connect the centroid of the element by the two end points of each edge.

Results: The proposed method is tested by computing the reflection and transmission of a 20 mm slab of dispersive material. The dispersive material has a plasma frequency and a damping frequency equal 28.7 GHz and 20 GHz, respectively. An excellent agreement between the reflection and transmission obtained by the presented method and the analytical solution can be noticed from Fig. 1.

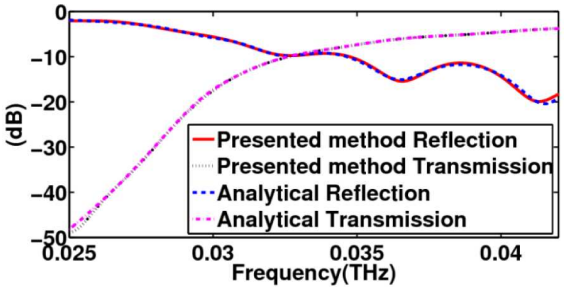

Figure 1: Reflection and transmission calculated using the proposed method and the analytical solution.

Statistical Models of Noise Distribution in Broadband PLC Networks

A. M. Nyete, **T. J. O. Afullo**, **and I. E. Davidson**
HVDC/Smart Grid Research Centre, Discipline of Electrical, Electronic and Computer Engineering
University of KwaZulu-Natal, Durban, South Africa

Abstract— The recent advancements in digital communication techniques have seen renewed interest in the possible utilization of the traditional power grid for the provision of broadband data and voice services. However, the power line communication (PLC) channel (the power network), presents a very challenging environment for communication purposes. This is due to the fact that severe noise and distortion effects are inherent in the medium. But, if these noise and distortion effects can be effectively analyzed and modeled, then the resulting models can be utilized in the optimal or sub-optimal design of a digital communication system for PLC applications. In this paper, frequency domain noise measurements done in broadband indoor PLC networks are presented. The measurement results obtained are then modeled using the alpha stable distribution, motivated by the flexibility of the distribution as a modeling tool and the fact that the measured noise distribution is heavily tailed and skewed.

Localized Surface Plasmon Enhancement of Photoluminescence Signal from Thin Silicon Nanocrystal Film

A. Marinins[1], **S. A. Dyakov**[1], **G. S. Lobov**[1], **D. M. Zhigunov**[2], **M. Yan**[1], **S. Popov**[1], **and M. Qiu**[1, 3]

Abstract— Silicon nanocrystals embedded into SiO_2 matrix possess promising luminescence properties and are a subject of interest for integrated photonics applications [1]. Compatibility with standard CMOS fabrication technologies is a significant advantage. Though, luminescence energy output does not exceed several percent from pump source energy in silicon nanocrystals thin films. One of the ideas to solve this problem is to incorporate plasmonic metal nanostructures on top of Si NC matrix. Metal nanostructures are supposed to induce localized surface plasmons (LSP) which interact with silicon nanocrystals and enhance their light emissivity. Strong near-field coupling between nanocrystals and metal nanostructures is needed in order to reach noticeable luminescence improvement. Also, periodicity and geometry of metal nanostructures play a significant role in luminescence output signal. Another thing to study are quasi-guided modes in layer with silicon nanocrystals.

The scope of this work is to study the interaction between localized surface plasmons, induced by light incident on metal nanostructures, and silicon nanocrystals in SiO_2 thin film. Mathematical simulations were run in order to estimate metal nanostructure geometry which supports resonant interaction with poossibly higher luminescence output. LSP main parameters were characterized with angle-resolved reflectance spectroscopy. The influence of metal nanostructure geometry and silicon nanocrystalline film composition on emissivity was investigated with photoluminescence measurements.

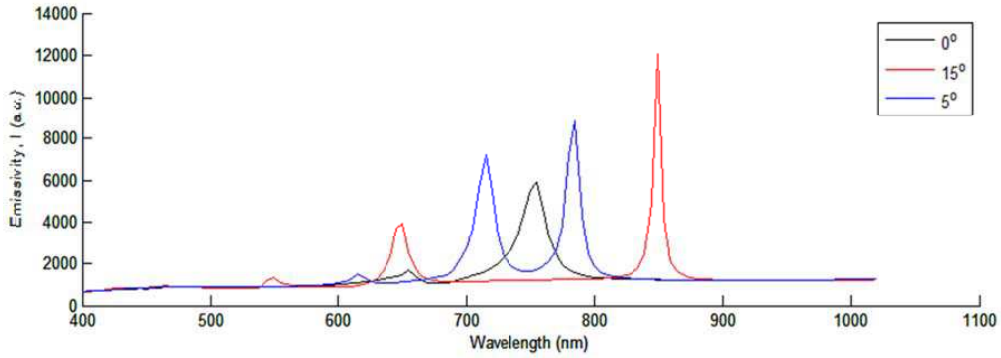

Figure 1: Emissivity spectra calculated for Si NC thin film with gold grating on top (100 nm stripe width, 450 nm period) for 0°, 5° and 15° collection angles.

Discovery of Ionospheric 'Hubble' Frequency Shifts and Impact on Gravity Wave Detection and the Age of the Universe?

Michael J. Underhill
Underhill Research Ltd, Lingfield, UK

Abstract— Measurements have been made with resolutions of a few milli-Herz of the spectra of various carrier frequencies from 100 kHz to 25 MHz propagated by the Ionosphere. Ionospheric propagation of the various world-wide Standard Frequency signal sources at 10 MHz has been found to be of particular interest. Some new physical effects have been discovered from extensive measurements. New concepts, processes and theory have been derived from analysis of these measurements and what has been observed so far [1–5].

In Figure 1 first note the persistent lower trace which is about 10 Hz below the exact (1 in 10^9) 10 MHz of the several worldwide sources all transmitting at that frequency. Also note that the bandwidth of this signal is $<\sim 20$ mHz implying a Q of $> 5 \times 10^8$. Again note there can be two overlapping components in the lower trace, on steady and the other oscillating in frequency by up to ± 500 mHz or occasionally more. These new discoveries are in need of an explanation, which will be provided in the full paper and which is based on references [1, 2, 5] expanded further. This can be said to be a 'Hubble shift' as it is to a lower frequency. But it is not a simple Hubble shift as there are other mechanisms at work [1, 2].

Secondly note the partially repeating 'diurnal' variations particularly in the upper less shifted trace. Shifts and spreading of carrier energy of up to a few Hz are visible on a daily basis. The magnitude and duration cannot be explained as Doppler shifts, since they would imply physically impossible movements of the ionosphere. The proposal is that such variations may reflect variations in gravitational potential. In effect gravity waves may be being detected? Direct EM wave detection of gravity waves may be possible?

Thirdly these observed and measureable effects imply that the astronomical Hubble shift is not a 'receding universe' Doppler frequency shift proportional to distance. But it may be a progressive reduction in photon or light-wave energy and frequency exponentially proportional to distance. This contradicts the view that the 'Big-Bang' age of the Universe is 13.8 billion years?

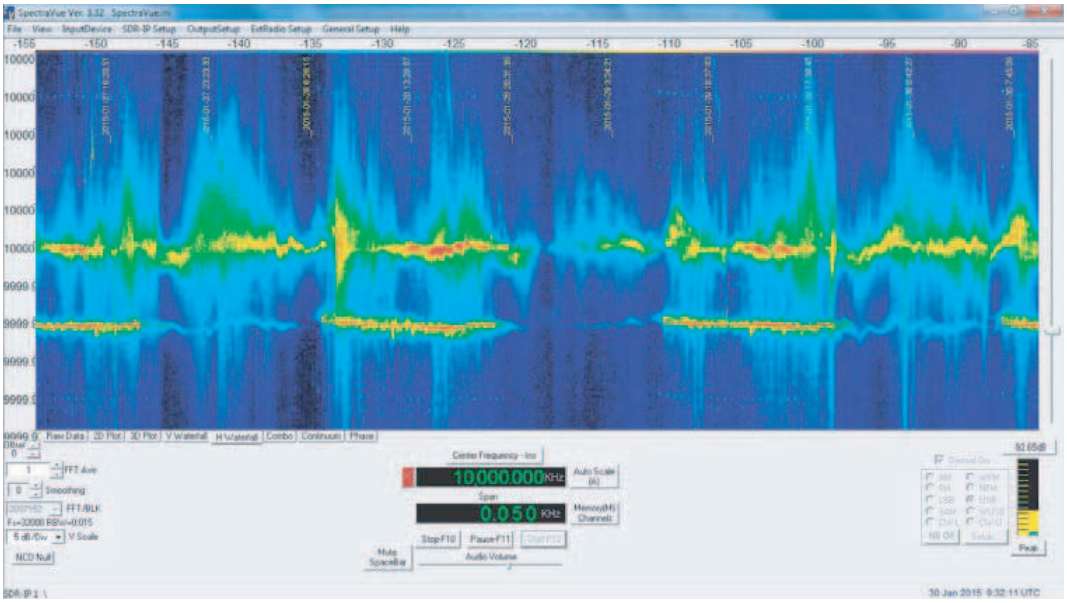

Figure 1: Three day (to Jan. 01, 2015) right to left waterfall record of 50 Hz bandwidth at 10 MHz of mixture of carriers from WWV Fort Collins USA (4700 mile NW path), BPM China (5200 miles NE path), PPE Rio de Janeiro, Brazil (5700 miles SW), WWVH Kekaha, Hawaii (7200 miles NNW). From RF Space SDR-IP receiver using SpectraVue software with 15 mHz resolution. Antenna is 83 m perimeter horizontal loop, 15 m height in Ling field (30 km south of London) UK.

Abstract— For creation of high-sensitivity high frequency (HF) photodetectors for use in telecom, spectroscopy, remote sensing and quantum informatics applications the utilization of InAlAs/InGaAs heterostructures grown on InP has been proposed. A reduced noise level and a better temperature stability of avalanche multiplication were predicted for the InAlAs-based structures. However, it was shown that a high dark count rate, being at least 2–3 orders of magnitude greater than that of InGaAs/InP diodes, is observed in such structures. Some of the reports have attributed the high dark count rates to tunneling currents in the InAlAs layer, possibly via deep levels in the material. Thus, the realization of the predicted advantages of InAlAs/InGaAs/InP structures requires optimization of the heterostructure growth technology and, first of all, of the InAlAs layer aimed at obtaining a low concentration of deep levels and therefore a better multiplying layer.

The epitaxial structures were grown using molecular beam epitaxy (MBE) technique in a Riber-32P and Compact-21 machines on (100)InP substrates. The quality of the layers was attested using in situ reflection high-energy electron diffraction (RHEED) and ex situ techniques: atomic force and electron beam microscopies, double-crystal x-ray diffraction and optical characterization by low-temperature photoluminescence.

We have studied the influence of the InP substrate temperature and V/III flux ratio on the crystalline and optical properties of $In_{0.52}Al_{0.48}As$ layers. These investigations show that we have achieved a substantial improvement in the quality of MBE $In_{0.52}Al_{0.48}As$ grown at a high substrate temperature of 520°C and a V/III flux ratio greater than 10.

Finite Element Analysis of Separation Force on Non-ferrous Metals Induced by Eddy Current Separator

Ahmet Fenercioğlu and Hamit Barutcu
Department of Mechatronics Engineering, Gaziosmanpaşa University, Tokat 60250, Turkey

Abstract— Finite element analysis (FEA) of the eddy current separator (ECS) that can separate non-ferrous metals from waste via the eddy current method have been carried out in this study. The forces induced in the non-ferrous metals to be separated by the magnetic drum determining the performance of the separator have been analyzed according to certain variables. These variables are drum speed, air gap between the material and the magnet pole, material sizes, magnet height and the type of material. The resultant force has been estimated according to these variables. The increase of drum speed, decrease of the air gap, increase of the separated metal dimensions and the high conductivity of material increase the separation force. The ECS design is determined according to the analytic equalities has been verified by these analyses.

An Easy Way to Obtain the Extinction Cross Section of Radiation Propagating in a Medium with Nonspherical Particles

Piero Bruscaglioni
University of Florence, Italy

Abstract— Radiation beams propagating in ma medium with non-spherical particles receive different attenuation according to their polarization. The effect is due to different values of the extinction cross section $\sigma\varepsilon$.

The explicit values of the latter can be obtained by considering the four f_{mn} parameters of the scattering matrix.

Then a simple method to obtain $\sigma\varepsilon$ is based on considering a distribution of equal particles along a plane normal to the direction of the propagating field.

This avoids the complexity of mixing the geometries of a planar incident wave and of a spherical scattered wave. The procedure considers a plane wave incident normally on a uniform plane distribution of equal non-spherical particles with equal orientation of their axes. By applying the principle of stationary phase one obtains a scattered plane wave which proceeds in the same direction of the incident one. Interference produces a reduction of the intensity of the incident plane wave.

The reduction of the power density of the incident wave is proportional to the planar density of the spherical scatterers. Thus one derives the extinction cross section C_{ext} of one scatterer.

By indicating as f_{11}, f_{12}, f_{21}, f_{22} the elements of the forward scattering amplitude matrix $\mathbf{J}$.

The explicit form of the derived C_{ext} then is

$$C_{ext} = (4\pi/k)\mathrm{Im}\left(f_{11}|ax|^2 + f_{12}ax\,ay + f_{21}ax\,ay^* + f_{22}|ay|^2\right)$$

with the incident electric field propagating in the z direction given as

$$E(ax\ \mathbf{i} + ay\ \mathbf{j}) \text{ with } |ax|^2 + |ay|^2 = 1,$$

Equation (2) is equivalent to Equation (31) of Ref. [1] where C_{ext} is given in terms of the extinction matrix elements K_{11}, K_{12}, K_{13}, K_{14}, on turn related to the S_{mn} elements of the forward scattering matrix given in the form presented in that reference.

The two polarization modes of radiation propagating with no polarization change in a medium with non-spherical particles can then be easily obtained, by considering the f_{mn} parameters, and by imposing that the scattered field in the forward direction maintains the ratio between the field components normal to the propagation direction.

By considering simple cases of incident radiation with different polarization, simple examples of polarization change during propagation of radiation will be showed.

Numerical Estimation of Muscle Conductivity in Terms of Human Body Internal Resistance

Hiroo Tarao[1], **Katsuaki Aga**[1], **Olenxandr Okun**[2], **and Leena Korpinen**[3]

[1]National Institute of Technology, Kagawa College, Japan
[2]National Technical University, Ukraine
[3]Tampere University of Technology, Finland

Abstract— Numerically-anatomical human models have been often used for wide band frequency electromagnetic dosimetry. For the dosimetry calculation, furthermore, typical dielectric properties such as conductivity and permittivity have been used for tissues that are assigned to each voxel of the human models. In our previous study, calculated results of human body internal resistances between hand and foot were two times larger than measured results (500–700 Ω). One possible explanation for this is that there are few voxels assigned as blood, having relatively higher conductivity, because of the limitation that blood vessels with a diameter of less than 2 mm could not be included in the model. Human body impedance is given as internal impedance combined in series with skin impedance. At low frequency, the resistive components of internal impedance are more dominant than capacitive components, and skin impedance changes greatly depending on contact area and surface wetness. Hence, we focus on internal resistances at 60 Hz in the study, ignoring skin impedance and capacitive components of internal impedance. Therefore, with consideration for the fact that conductive currents in a body flow mostly through muscle, and the assumption that conductivities of blood and extracellular fluid should be mixed into the muscle conductivity, we calculate human body internal resistances between the left hand and left foot in the present paper, with changing muscle conductivity: 0.35–2.0 S/m. Here, 0.35 S/m for muscle, 0.7 S/m for blood, and 2.0 S/m for extracellular fluid have been used as the typical conductivity values at 60 Hz. It is found for both absolute values and relative scale that the newly calculated internal resistances with muscle conductivity of 0.8–1.0 S/m are much closer to measured values. In contrast, the internal resistances did not vary when conductivity values of other tissues which distribute through the body, such as adipose tissues and bones, are changed.

Quantum Friction in Different Regimes

J. Klatt[1], **S. Y. Buhmann**[1] **D. Dalvit**[2]

[1]University of Freiburg, Germany
[2]Los Alamos National Laboratory, USA

Abstract— Quantum friction is the velocity-dependent force between two polarizable objects in relative motion, resulting from field-fluctuation mediated transfer of energy and momentum between them. Due to its short-ranged nature it has proven difficult to observe experimentally.

Theoretical attempts to determine the precise velocity-dependence of the quantum drag experienced by a polarizable atom moving parallel to a surface arrive at contradicting results. Scheel [1] and Barton [2] predict a force linear in relative velocity v the former using the quantum regression theorem (QRT) and the latter employing time-dependent perturbation theory. Intravaia [3], however, predicts a v^3 power-law starting from a non-equilibrium fluctuation-dissipation theorem (NFDT).

The main difference brought along by either relying on a quantum regression or a non-equilibrium fluctuation-dissipation theorem, is the long-time behavior of correlations of the type $\langle d(t)d(t')\rangle$, where d is the atomic dipole operator. The former approach means assuming that these correlations decay exponentially, whereas the latter approach means acknowledging a power-law behavior of that decay for very large times. We want to find a general form of $\langle d(t)d(t')\rangle$ in order to see which assumption is proper in which regimes and where exactly the transition takes place.

A Necessary Condition for Application of Topological Derivative in Limited-aperture Inverse Scattering Problem

C. Y. Ahn[1], K. Jeon[1], Y.-K. Ma[2], and W.-K. Park[3]

[1]National Institute for Mathematical Sciences, Daejeon 305-811, Korea
[2]Department of Applied Mathematics, Kongju National University, Chungcheongnam-do 314-701, Korea
[3]Department of Mathematics, Kookmin University, Seoul 136-702, Korea

Abstract— Throughout various works, topological derivative-based non-iterative imaging algorithm has demonstrated its applicability in full- and limited-aperture inverse scattering problems. However, most of researches have considered full-aperture problem. So, in the limited-aperture inverse problem, this applicability has been relied through the results of numerical simulations, and the reason behind this applicability has not been theoretically explained. Motivated from this, we consider the topological derivative for imaging of arc-like perfectly conducting crack for Transverse Magnetic (TM) polarization case in limited-aperture inverse scattering problem, and correspondingly explore a necessary condition of application. This is based on the relationship between topological derivative imaging function and infinite series of Bessel functions of integer order of the first kind. This relationship leads us explored necessary condition is highly depending on the shape of unknown crack. Numerical results are demonstrated in order to support our explore.

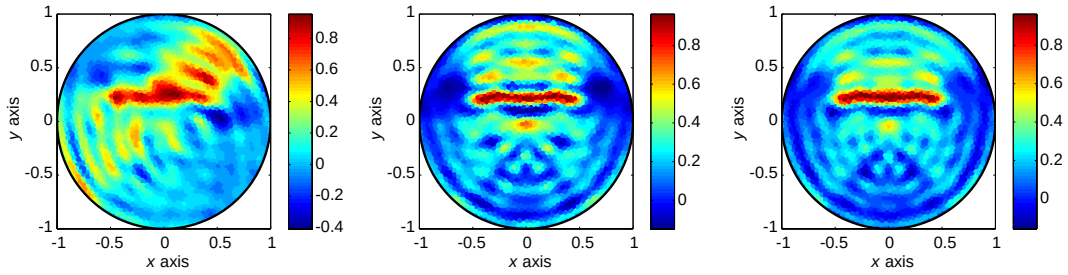

Figure 1: Imaging results via topological derivative with various settings of incident directions.

Subspace Migration for Imaging of Thin Electromagnetic Inhomogeneities without Shape Information

W.-K. Park
Department of Mathematics, Kookmin University, Seoul 136-702, Korea

Abstract— Subspace migration is a stable and effective non-iterative imaging technique in inverse scattering problem. But, for a successful application of imaging of thin electromagnetic inhomogeneities, *a priori* information of tangential and normal directions to unknown targets must be considered beforehand. Without this consideration, one cannot obtain good results via subspace migration. Due to this reason, various test vectors are applied to the subspace migration and select a vector which maximize the value of imaging functional. However, this requires large computational costs and sometimes the results are poor. Motivated this fact, we consider the structure of single- and multi-frequency subspace migration without any shape information of of unknown targets and explore its certain properties.

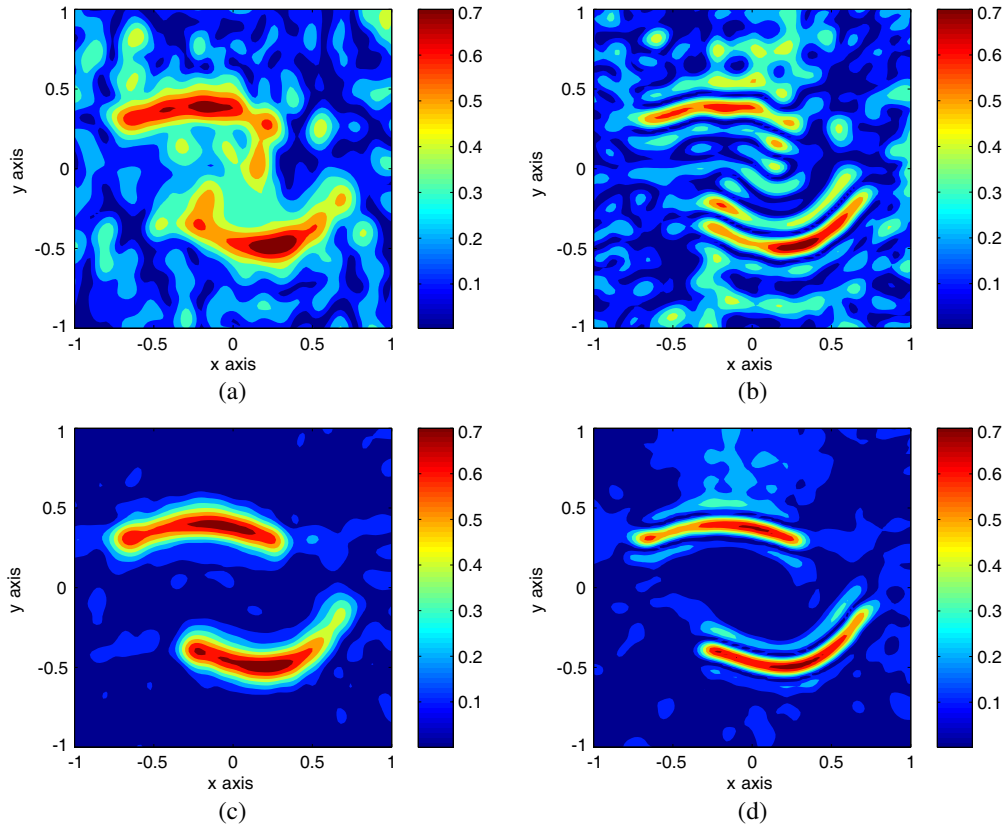

Figure 1: Imaging results via single- and multi-frequency (subspace migration with (left column) and without (right column) consideration of shape of thin inclusion. (a) Single-frequency, (b) single-frequency, (c) multi-frequency, (d) multi-frequency.

Analysis of Matching Media Effect on Microwave Brain Stroke Imaging via a Spherically Symmetrical Head Model

E. Bilgin, **A. Aygun**, **A. Yapar**, **and I. Akduman**
Electrical and Electronics Engineering Faculty, Istanbul Technical University, Istanbul, Turkey

Abstract— The objective of this study is to analyse the effectiveness of the microwave imaging in detecting stroke areas in the human brain. Microwave tomography can represent an alternative to commonly used imaging techniques such as computerized tomography or magnetic resonance imaging [1]. The researches on the subject are motivated by the need to make continuous control of the patient's state possible [2]. Since non-hazardous and portable imaging systems can be designed using microwave technology, an imaging tool operating on microwave frequency would be suitable for long term monitoring [1, 2].

Microwave imaging techniques rely on the difference in the electromagnetic properties between healthy tissues and stroke areas in the brain [1]. This difference results in a variation in the scattered field when the head region is excited by an external source operating in the microwave frequencies. Therefore, it is of crucial importance to maximize the penetration of the electromagnetic field into the inner parts of the human brain where the strokes occur. To this end, a matching medium with suitable electromagnetic parameters can be used. The effect of the matching medium is usually assessed by using 2-D head models [1, 2]. However 3-D models can provide a more realistic structure to test both the relevancy of using a matching medium, and the effectiveness of microwave imaging techniques in general.

In this work, a four layered piecewise homogeneous sphere has been used as a head model. In order to assess the feasibility of the microwave imaging techniques, the related three dimensional scattering problem must be solved. However, given the high contrast values of the brain tissues, the solution of the 3-D scattering problem by classical techniques, such as method of moments, is a computationally expensive procedure. Therefore, in this study the problem has been transformed into a one dimensional form by taking advantage of the spherical symmetry [3]. As an alternative method, the dyadic Green's function related to the layered spherical structures has been used to verify the results [4]. After solving the scattering problem, the effect of the matching medium on the field distribution in each layer has been analysed via both methods. Also, by modelling the stroke area by an internal source, the possibility of brain stroke detection through microwave imaging has been assessed.

Field Invariants, Amplitude Mapping, and Perfect Transmission in Media with Local Symmetries

C. Morfonios[1], **P. A. Kalozoumis**[2], **P. Schmelcher**[1], **and F. K. Diakonos**[2]

[1]Centre for Optical Quantum Technologies, Hamburg University, Germany
[2]Department of Physics, Athens University, Greece

Abstract— A theoretical approach for generic wave propagation in systems with local spatial symmetries is developed and applied. The concept of local symmetry refers to the presence of subsystems which obey certain symmetries while the total system is non-symmetric under the same transformations. Groups of neighboring subsystems may form additional local symmetries, emergent at a larger scale, leading to the notion of different local symmetry decompositions of a composite setup. Local mirror and translation symmetries are here shown to yield invariant quantities that characterize wave propagation in one effective dimension. The symmetry-induced spatial invariants map the wave amplitude between symmetry-related points and thereby enable a generalization of the parity and Bloch theorems to the case of broken global symmetry.

The novel theoretical framework applies generically to wave propagation in continuous or discrete media, with particular relevance for the field of micro- and nanophotonics where wave localization and transmission control are desired for devices with flexibility in setup geometry. Indeed, such designed systems are usually decomposable into locally symmetric pieces; representative examples are photonic crystal structures and dielectric multilayer systems, where pioneering applicational aspects combine with fundamental theoretical investigations. Also structurally complex photonic setups with long-range aperiodic order or even partially disordered systems feature inherent local symmetries and thereby encompass corresponding field invariants.

As an application to photonic multilayer systems with local mirror symmetries, the approach is used to classify light scattering modes according to the symmetry decomposition of the field profile. In particular, the spatial distribution of perfectly transmitting resonance (PTR) states is shown to follow the underlying local symmetries when the derived local invariants align along the medium of propagation. This connects the occurrence of PTRs to the corresponding spatial structure of the amplitude in an unambiguous manner based on symmetry principles. Further, the simultaneous presence of different local symmetry decompositions in a given device is exploited to develop a construction scheme for the design of multiple PTRs at prescribed wave frequencies.

The connection of wave transmission properties and amplitude distribution to the local symmetry structure of the medium of propagation opens the perspective for novel types of optical device designs. More generically, the proposed local symmetry approach may lead to a deeper understanding of signal response and wave localization phenomena in media with order on multiple scales.

High Resolution Ka-band Backscattering Measurement of Deciduous and Coniferous Tree

Wei-An Chuang[1], **Hsuan Ren**[1, 2], **Kuan-Liang Chen**[1], **and Jhih-Syuan Huang**[1]

[1]Institute of Space Science, National Central University, Taiwan
[2]Center for Space and Remote Sensing Research, National Central University, Taiwan

Abstract— In this paper, we present high resolution Ka-band backscattering measurement of deciduous and coniferous tree on National Central University (NCU) campus for ground-truth validation in vegetation monitoring. The coherent radar system, designed and configured based on a vector network analyzer N5245A PNA-X (10 MHz–50 GHz) is operated in a continuous-wave mode, was used to generate the transmitting signal and to detect scattered signals both in amplitude and phase for VV, HH, HV polarizations at incidence angles between 30 and 80 degrees. In measuring process, the radar system has typical trace of the frequency ranges from 28 to 38 GHz of the received power for a given footprint of tree canopy. For this ultrawide bandwidth, the wind-induced Doppler effects can be ignored. By this feature, the propagating depth through the tree can also be precisely determined so that the effective propagation constant and attenuation factor can be estimated. A reference measurement was taken at normal incidence using a conducting sphere as a calibration target, showed that the measurement capabilities of this system are satisfactory. The calibration was conducted both in anechoic chamber and in-situ measurements. Ensemble average of 2000 samples was taken to estimate the mean return power and later by inverting the radar equation to obtain the backscattering coefficient as functions of frequencies and incident angles are then estimated. To simplify the matrix inversion, a narrow beam is realized with dish antenna. Based on the measured results, backscattering characteristics and statistical properties were analyzed for the cases of deciduous (banyan) and coniferous (pine) trees.

To obtain backscattering coefficient for tree canopy, measuring system was mounted on the top of a 15 m-height roof. From this platform, the radar had an unobstructed view of the selected tree targets. The banyan and pine trees were substantially larger than the footprint of Radar with 2.6-degree antenna beamwidth. Target trees were selected where adjacent unwanted scatters (ground and tree) could be conveniently rejected by range gating in time domain. In the proposed study, frequency, polarization, incident angle, and canopy parameters are the primary factors affecting backscattering properties. The results indicated that cross-polarized returns generally presents higher dynamic ranges over the frequency and angular behavior. At Ka band, its wavelength (1.1 cm$\sim$0.7 cm) is much smaller than leaves and branches. For banyan tree, leaf stems constitute a very small proportion of the target areas, and the corresponding return signal may be reasonably ignored. However, leaf stems of the pine trees constitute a larger portion of the beam areas. The contributions from multiple backscattering are larger than those of banyan trees.

Investigation of Switched Reluctance Machine for EV Propulsion Unit with Torque Smoothening Strategy

M. Ruba and D. Fodorean
Department of Electrical Machines and Drives
Technical University of Cluj-Napoca, Cluj-Napoca, Romania

Abstract— The paper deals with the investigation of a 30 kW switched reluctance machine (SRM) designed to be used in the automotive industry, as propulsion unit for electrical vehicles (EV). The paper details the most important steps when designing such an electrical machine, and validates the structure using advanced co-simulation techniques, coupling finite element analysis software (Cedrat Flux2D) with software used to implement the controller (Matlab/Simulink). As the advantages of the SRM are known, its main drawback, the torque ripples, are reduced as much as possible using a dedicated control strategy, the direct instantaneous torque control (DITC). The solution offered by the paper highlights the possibility of using a cheap, reliable and robust electrical machine for propulsion unit.

Introduction: As already stated in the abstract, in the past years, many studies revealed the considerable advantages of the SRM against the other electrical machines, such as simplicity in design and building, low cost, simple control, robust and reliable operation, etc. [1–4]. Considering all these, implementing this machine as propulsion unit in EVs became a challenge that worth to be investigated. The increased torque ripples that are present when phase commutation occurs, makes the machine impossible to be used with its natural control strategy. However using special control strategies, this problem can be completely solved.

The SRM in Study: The design of the SRM is focused on the torque production with regards to the total volume of the machine. Hence, proper sizing of the machine will reach the optimal dimensions in order to achieve the required mechanical power. The developed torque is computed function of the machine's main dimensions, of the current and the number of turns per phase:

$$T_{SRM} = (N_f \cdot I)^2 \cdot \frac{D_g - g_x}{2} \cdot \mu_0 \cdot \frac{l_s}{2 \cdot g_x} \tag{1}$$

In Fig. 1, the preliminary validation of the SR machine in study is highlighted. As it can be seen, it develops the required torque but whit the already mentioned ripples. For the final paper, the DITC method will be implemented to prove that the machine can reach linear torque characteristic.

Conclusions: The paper will present a complex study for design, analysis and wise control of the SRM in order to place it in the field of traction motor for EV industry.

[2]Nanjing Artillery Academy, Nanjing 211132, China

Abstract— In this paper, the properties of one-dimensional (1D) photonic crystals (PCs) composed of the semiconductor (GaAs) and dielectric layers are theoretically investigated by the transfer matrix method (TMM). The absorption of semiconductor layers is investigated theoretically. Due to the magneto-optical Voigt effect, the dielectric constant of the semiconductor is modified differently in different modes and frequency ranges. If the frequency range of the incident wave is larger than the plasma frequency, TE and TM modes of the incident wave will be absorbed in a wide incident angle. TM wave will be absorbed but TE wave will be reflected while the frequency range is less than the plasma frequency. The absorption of semiconductor can also be tuned by varying the external magnetic filed. The proposed PCs have a reconfigurable application to design a tunable omnidirectional absorber and mode splitter at same time.

Tunable Electromagnetically Induced Transparency Like Transmission in Graphene Metamaterials with Indirect Coupling

[2]Nanjing Artillery Academy, Nanjing 211132, China

Abstract— Novel graphene-based metamaterials with tunable electromagnetically induced transparency (EIT)-like transmission are numerically studied in this paper. The designed structures consist of a graphene layer composed of coupled cut-wire pairs printed on a substrate. The simulation confirms that an EIT-like transparency phenomenon occurs in the metamaterial owing to indirect coupling and the proposed structure can be used in terahertz frequency range. More importantly, the transparency windows for the structures with indirect coupling can be dynamically controlled over a broad frequency range by varying the Fermi energy levels of the graphene layer (through electrostatic gating). The proposed metamaterial structures offer additional opportunities to design novel applications such as active plasmonic switching and optical sensing.

Cylindrical Metasurface Absorber Using Home Inkjet Printing System

Hyung Ki Kim and Sungjoon Lim
School of Electrical and Electronic Engineering, Chung-Ang University
221 Heukseok-dong, Dongjak-gu, Seoul 156-756, Republic of Korea

Abstract— A novel cylindrical metasurface absorber will be presented. The proposed metasurface absorber is inkjet-printed on a flexible polymer film using a commercial EPSON WF-7011 home printer as shown in the following figure. A silver nanoparticle ink is used for conductive patterns. The unit cell of the metasurface is designed with a modified Jerusalem-cross ring resonator. The absorber's flexibility and absorption performance are demonstrated by measuring the absorption ratio after coating the proposed absorber on a cylindrical object with a radius of 4.56 cm. An absorption rate exceeding 99% is achieved at 9.21 GHz for both flat and cylindrical surfaces. In addition, the cylindrical model attains an absorption rate higher than 96% for all polarization angles, and a high absorption rate of 95% is preserved until the incident angle is less than 30°.

Reversal of Microwave Propagation Nonreciprocity in Metastructures by Voltage Application under Ferromagnetic Resonance Excitation near Resonance of Dipole or Chiral Elements

G. A. Kraftmakher, V. S. Butylkin, and Yu. N. Kazantsev
Kotelnikov Institute of Radioengineering & Electronics, RAS, Russia

Abstract— In recent years, there has been increasing interest in the study of metamaterials containing resonant conductive elements, of nonreciprocal metamaterials, containing combination of ferrite and resonance elements, with tunable or switchable characteristics for development of microwave devices such as filters, nonreciprocal isolators and circulators. The emphasis is novel functionality as the fast electric control of amplitude-frequency characteristics in comparison with traditional magnetic control of ferrite by external static magnetic field. In the case of magnetic control time switching is not so fast because one depends on not fast complex processes of magnetization and remagnetization as a result of which reversal of sense of spins precession occurs.

At present there are also ideas about artificial Faraday rotation in magnetless metamaterials without gyrotropic component.

In real microwave devices and under consideration nonreciprocal effect is due to the ferromagnetic resonance (FMR). In this case circular or elliptical polarization of microwave magnetic field h is necessary. Waveguide nonreciprocal devices contain transversely magnetized ferrite plate at distance of $\pm\lambda/8$ from the side wall in a rectangular waveguide, where polarization of microwave magnetic field is circular. In the case of metastructures necessary h-field is formed by the grating of resonant elements at frequencies near their resonance. Besides metastructures show amplification and possibility of electric control of nonreciprocity [1].

In this paper electrically controlled reversing the sign of the nonreciprocity of microwave propagation is proposed and confirmed by direct experimental proofs on ferrite plate/varactor-loaded dipoles metastructures placed along rectangular waveguide axis in the presence of static magnetic field H. Dipoles of various shapes (butterfly, loop, snake, double split rings) with different type-varactors have been investigated. In Figs. 1(a), (b) we see photos of metastructure ferrite plate/varactor-loaded split Butterfly dipole (a) and ferrite plate/varactor-loaded double split rings (b). The nonreciprocity δ is defined without reversal of the propagation direction (single-channel measurements). In this case nonreciprocity δ (dB) is defined as the difference between transmission coefficients $T = |S_{21}|^2$ corresponding to the opposite direction of magnetization, when senses of h-field rotation are the same but senses of spin precession are opposite, $\delta\,(\mathrm{dB}) = T(H_-) - T(H_+)$. H_+ and H_- correspond to opposite directions of the external transverse applied field H and provide opposite senses of spins precession. Results of measurements contain dependences of δ on frequency at different bias conditions. It has been shown that inversion of the nonreciprocity sign occurs by the application of a bias voltage to a varactor in order to provide jump of resonance frequency of a dipole through the ferromagnetic resonance frequency as a result of which reversal of sense of rotating elliptically polarized h-field takes place.

Millimeter-wave Metamaterial Antenna in Standard CMOS Technology

Kazuki Hiraishi, **Takehiro Kawauchi**, **and Eiichi Sano**
Research Center for Integrated Quantum Electronics, Hokkaido University, Japan

Abstract— The crowded bands of 2.4 and 5 GHz will push the operation bands of wireless communication systems to the millimeter (MM)-wave region (e.g., 60 GHz). Reduced sizes of antennas in the MM-wave region enable them to be monolithically integrated with CMOS RF and baseband circuits. However, the low-resistivity ($\sim 10\,\Omega$cm) Si substrates commonly used in standard CMOS processes degrade the antenna gain. The antenna gain at 60 GHz remains below -10 dBi in standard CMOS technology [1]. Thus, an ingenious development is needed to increase the gains of antennas fabricated on low-resistivity Si substrates. A metamaterial-based antenna, such as a composite right-/left-handed (CRLH) antenna, has a reduced size [2], which results in reduced loss in the metal wire in the antenna. The antenna size in standard CMOS technology can be further reduced by using small-size lumped elements such as metal-insulator-metal (MIM) capacitors for the metamaterial components. In this study, a CRLH monopole antenna was designed and fabricated in 0.18 µm CMOS with six metal layers. The series capacitances for the left-handed (LH) mode were composed of the MIM structure between the 5th and 6th metal layers while the shunt inductors in the LH mode and the shunt capacitances/series inductances in the right-handed (RH) mode were composed of the 6th metal layer. The CRLH unit cell was 300×420 µm. Two unit cells were used to construct the monopole antenna. The designed CRLH monopole antenna had LH and RH radiation modes at 41 and 65 GHz, respectively. The fabricated antenna was measured on wafer by using a network analyzer, RF probe, and a horn antenna. The gain of the CRLH monopole antenna was calibrated by comparing the transmission (S_{21}) measured between the CRLH monopole and horn antennas with that measured between two horn antennas. The measured gains of the CRLH monopole antenna were -5.8 dBi in RH mode and -14.4 dBi in LH mode. A conventional slot antenna using the 6th metal layer was also designed and fabricated for comparison purposes. Its measured gain was -20 dBi at 60 GHz. These results clearly demonstrate the advantage of the CRLH monopole antenna. Further increase in the gain can be achieved by optimizing the component values in the CRLH antenna.

Technische Universität Ilmenau, Ilmenau, Germany

Abstract— Microcavity lasers made of dielectric disk-shaped resonators with sizes in the micrometer range have gained a lot of interest in recent years. A drawback of pure disk resonators for microlaser applications is their isotropic light output. To overcome this problem, deformed cavities were proposed such as limacon-shaped resonators which display directional light emission attractive for microcavity lasers.

In this work we study the coupling of a disk resonator to a limacon-shaped cavity using three dimensional FDTD wave-calculations. For this purpose a limacon resonator is placed on top of a disk resonator, a whispering gallery mode with high Q-factor is excited inside the disk resonator and its coupling into the limacon cavity is analyzed for different geometric configurations.

Furthermore we investigate the directional light emission and its tuning in such microcavity arrangements. In detail we calculate a full three dimensional emission profile with respect to the limacon cavity size and its position on the disk resonator. Thus we obtain the direction of light output in 3D and its benefit for microcavity laser applications.

Reliability Study on LED Packages Using Real-time Monitoring of Internal Quantum Efficiency

Byungjin Ma and Kwan-Hun Lee
Reliability Research Center, Korea Electronics Technology Institute, Korea

Abstract— It is very important to know the effect of the reliability of semiconductor LED chip on the LED packages. But it has been impossible to estimate the LED chip's effect on the total optical degradation of the LED packages quantitatively.

We have already proposed a new method for the internal quantum efficiency (IQE), used to investigate the mechanism of an optical degradation of the LED packages, which is based on the precise measurement of electrical, optical and thermal properties and a computational fluidic dynamic simulation [1]. IQE can be driven as a function of the junction temperatures and the optical output powers of LED packages. This IQE model is basically based on energy conservation.

We implemented our IQE testing algorithm into a real-time reliability tester for LED packages. Not only the electrical and optical properties but also the junction temperature and the internal quantum efficiency can be monitored at any time we want to measure.

Furthermore, we carried out a 2,500 hour lifetime test at 85° as shown in Fig. 1. Although there was an about 10% optical degradation after 2,500 hour aging time, there was no evidence of the IQE degradation of GaN LED chip. Thus, we could separate the effect of the LED chip on total optical degradation of the LED package for the first time. And we could conclude that a main origin of the optical degradation of the LED package affecting the lifetime of the LED packages is not from the LED chip but from other component materials in our LED packages.

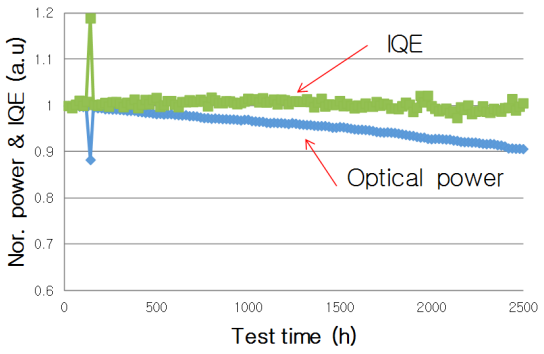

Figure 1: Relative optical output power and IQE monitored during a 2,500 hours lifetime test.

Performance Comparison of InGaN LEDs Containing V-and U-shaped Quantum Wells with and without Electron Blocking Layer and Emitting in the 400–500 nm Range

Abdelmajid Salhi, **Mohammad Alanzi**, **and Bandar Alonazi**
National Center for Nanotechnology, King Abdulaziz City for Science and Technology (KACST)
Riyadh 11442-6086, Kingdom of Saudi Arabia (KSA)

Abstract— The solid state device, such as light emitting diode (LED) is one of the best candidates to substitute the conventional incandescent and fluorescent lamps [1, 2] due to many advantages, e.g., compact size, low power consumption and long lifetime [3, 4]. However, the optical performance of III-nitride LEDs still suffers from poor light emission as a result of different mechanisms including: electron current leakage as a result of piezoelectric effect [5], non-radiative recombination in the wells due to the Auger recombination [6] and limited injection efficiency of holes [7].

In this paper, we report on the performance comparison between v-shaped quantum well (VSQW) and u-shaped quantum well (USQW) light emitting diodes with and without electron blocking layer emitting in a wide wavelength range from 400 nm to 500 nm. The physical reasons for improving the efficiency of VSQW LEDs compared to USQW LED structure are analyzed numerically using the commercial software APSYS (Advanced physical model of semiconductor devices) [8].

The simulation results showed that the devices containing VSQW have superior performance in terms of optical power and internal quantum efficiency droop compared to the devices containing USQW. The optical power of the LEDs containing USQW increases gradually and reaches a maximum at 460 nm, however the optical power of the LEDs with VSQW improves gradually and the maximum is obtained in a window from 420 to 436 nm as a result of radiative recombination enhancement. The simulation results suggest that the higher performance of the VSQW is a result of piezoelectric field reduction and an enhancement of electron and hole wavefunctions overlap.

The incorporation of the electron blocking layer in the case of VSQW structure improves the performance only for wavelength shorter than 436 nm and it's useless for $\lambda \geq 440$ nm. However in the case of USQW LEDs, the electron blocking layer is necessary to improve the efficiency as long as $\lambda \leq 470$ nm. This suggests that the VSQW design is a better choice for implementing InGaN LEDs compared to USQW design.

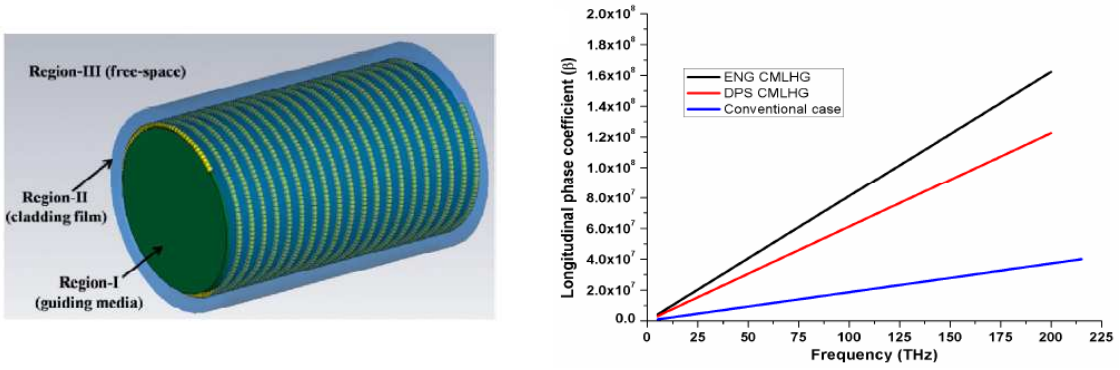
Enhanced Group Velocity Characteristics of a ENG Cladded Metamaterial Loaded Helical Guide

D. K. Sharma and S. K. Pathak
Microwave and ECE Diagnostic Division, Institute for Plasma Research, Gandhinagar, India

Abstract— In recent years much attention have been given towards slow wave structures [2, 3] for the dynamical control of EM wave velocity and power flow for numerous engineering applications in microwave to optical frequency spectrum [1].

In this paper, we propose, an ENG Cladded Metamaterial Loaded Helical (CMLHG) Waveguide, as shown in Fig. 1, to achieve enhance slow wave in THz spectrum. Both analytical as well as numerical computation has been reported to characterize the dispersion behavior. It is observed that the waveguide supports forward wave (FW) mode having parallel phase and group velocities over a wide bandwidth with an enhanced slow wave characteristics. A comparative study of slow wave behavior has been done between the ENG CMLHG waveguide and two other cases — (i) when helix is in free space and (ii) when helix is cladded with DPS material and loaded with metamaterial, as shown in Fig. 2. It is found that present structure provides almost 4 times lesser group velocity in comparison to the helix in free space. Engineering design feasibility of manufacturing these types of waveguides are also discussed and reported.



(a) (b)

Figure 1: (a) Cladded metamaterial loaded helical guide (CMLHG) structure. (b) Dispersion characteristic (β vs frequency) is plotted for different cases (i) conventional case, helical guide in free-space (ii) helix is cladded with DPS material and loaded with metamaterial and (iii) ENG CMLHG waveguide represents in blue, red and black color respectively.

Abstract— Direct analog-to-digital conversion of microwave signals with subsequent digital processing looks very attractive for microwave receivers due to clear structure and minimal number of steps for analog signal transformation. However, microwave frequencies require photonic analog-to-digital converters (ADCs) which can provide now 5–6 effective bits only. At the same time, in many practical applications, it is necessary to receive a signal with a relatively small bandwidth and carrier frequencies of tens of gigahertz. In particular, such microwave signals with a pronounced carrier frequency are widely used in radar systems. In this situation, a microwave signal can be first converted to intermediate frequency using photonic heterodyning and then digitized with a relatively slow electronic ADC. In a sense, this approach corresponds to the usual methods of microwave signals processing using electronic devices when the received signal is frequency down converted.

The key point for building a photonic receiver is the development of an optoelectronic circuit for converting the microwave signal to an intermediate or low (envelope) frequencies [1–3]. We consider a microwave photonic receiver comprising a continuous wave (cw) laser together with amplitude modulators and narrow band optical filters. An amplitude modulation of the cw optical carrier with microwave signal results in creation of the signal sidebands. Then, the optical carrier and one of the sidebands can be suppressed using optical band-pass filter based on, e.g., microresonators or fiber Bragg gratings. To create an optical reference signal necessary for heterodyning, part of the laser beam is modulated by the second amplitude modulator with a microwave signal whose frequency is close to the microwave carrier frequency. Then this part of the laser beam is also filtered to suppress the optical carrier and the same side band. After that, two optical signals containing radar signal and radar carrier can be mixed at a photodetector and digitized with a slow electronic ADC.

Performance capabilities of the microwave receiving channel with optical heterodyning are estimated analytically. Different modes of receiving channel operation are discussed and optimal parameters are derived. It is shown that homodyne as well as heterodyne methods for transformation of the spectrum of the input microwave signal to the low frequency region can be used and linearity of the transformation for these methods is studied. Also, the regime of the optical carrier suppression in modulators is considered. In this case, it is not necessary to use narrow-band optical filters in the scheme. For the photonic receiver using modern optical elements the signal-to-noise ratio at the output can reach 60–70 dB and more that corresponds to 9–11 effective bits in the digitized signal with the carrier frequency of tens of gigahertz and the frequency bandwidth of 100 MHz and more.

Influence of Optical Fiber Dispersion on Mamyshev Type Regenerator Performance

Piyush Baypajee, Jurgis Porins, and Andis Supe
Institute of Telecommunications, Riga Technical University, Azenes st. 16/20, Riga, Latvia

Abstract— Optical signal degrades considerably during propagation in the telecommunications fiber line. It is caused by many factors: fiber attenuation, dispersion (group-velocity dispersion, material dispersion, waveguide and polarization mode dispersion) that broadens the pulses, accumulated amplified spontaneous emission that is a broadband noise source induced mostly by amplifiers and, of course, different nonlinear optical effects. Distortions induced by optical fiber nonlinearity actually can be the most significant and the most difficult avoidable, especially in the high data rate multichannel transmission, used in dense wavelength division multiplexed systems. Nonlinear effects cause the undesired crosstalk between adjacent transmission channels as well as new harmonic generation in the signal frequency bandwidth. Such distortions cannot be filtered out, therefore optical signal regeneration is needed especially in a long haul transmission systems.

In this research we present results from the study on optical signal regeneration by using Mamyshev type regenerator and its dependence on fiber dispersion. Fiber dispersion is a very important parameter in the regeneration process since it influences the self-phase modulation nonlinear effect. This effect in turn provides the signal quality improvement by ensuring different transfer functions for useful signal and noise. Setup of investigated regenerator consists of a high power erbium doped fiber amplifier, highly nonlinear fiber and an optical bandpass filter that is slightly shifted away from the signal central frequency. Signal used for regeneration was an on-off keying return-to-zero code manipulated 40 Gbit/s pulse sequence covered with white noise. We have performed simulations and experimental characterization of regenerator by obtaining it's transfer function and output optical signal to noise ratio for different optical filters and fiber dispersion coefficients.

Characteristics of Femtosecond Pulse in Silicon Nanowire Embedded Photonic Crystal Fiber: Variational Approach

K. Senthilnathan[1], **E. Gunasundari**[1], **Abdosllam M. Abobaker**[2], **S. Sivabalan**[3], **K. Nakkeeran**[4], **and P. Ramesh Babu**[1]

Abstract— Waveguides with sub-wavelength dimensions known as photonic nanowires are among the most attractive optical structures for ultrafast nonlinear optics. Due to their small sizes, nanowire exhibits tight optical confinement, large effective nonlinearity and strong waveguide dispersion. Nanowires are fabricated from different materials such as silica, silicon, etc.. Silicon has excellent transmission properties compared to silica and hence, would require relatively lesser input power for the desired nonlinear applications. The silicon photonics has become the current topic of research as the silicon waveguides. Such a dielectric waveguide of sub-wavelength diameter upon being embedded into the photonic crystal fiber called photonic crystal fiber nanowire (PCF-NW) results in enhanced optical properties and the same has subsequently been demonstrated. From the literature, it is very clear that the small core silicon nanowire embedded photonic crystal fiber (SN-PCF) structures has been a good candidate for nonlinear applications such as soliton-effect pulse compression and supercontinuum generation In this paper, we investigate the propagation characteristics of femtosecond pulses using the proposed SN-PCF. The pulse propagation in SN-PCF is governed by the well known higher order nonlinear Schrödinger (HNLS) equation. Using variational analysis, we study the propagation characteristics of an hyperbolic secant pulse, namely, pulse amplitude, temporal position, width, chirp, frequency and phase.

Theoretical model: The pulse parameter equations in SN-PCF are given by:

$$
\begin{aligned}
\dot{x}_1 &= -2\Gamma x_1^3\left[\frac{1}{\pi^2}+\frac{1}{3}\right]+\frac{\beta_2}{2}x_1x_4+\frac{\beta_3}{2}x_1x_4x_5-\frac{\beta x_1^5x_3\sigma}{6h\nu_0A_{eff}^2}-\frac{\alpha}{2}x_1\\
\dot{x}_2 &= \beta_2x_5+\frac{\beta_3}{6}\left[\frac{1}{x_3^2}+\frac{x_4^2x_3^2\pi^2}{4}+3x_5^2\right]+\gamma_sx_1^2\\
\dot{x}_3 &= \frac{4\Gamma x_1^2x_3}{\pi^2}-\beta_2x_3x_4-\beta_3x_3x_4x_5\\
\dot{x}_4 &= \beta_2\left[x_4^2-\frac{4}{x_3^4\pi^2}\right]+\beta_3x_5\left[x_4^2-\frac{4}{x_3^4\pi^2}\right]-\frac{4\gamma x_1^2}{x_3^2\pi^2}-\frac{4\gamma_sx_1^2x_5}{x_3^2\pi^2}\\
\dot{x}_5 &= \frac{-2\gamma_sx_1^3x_4}{3}-\frac{8\gamma_R}{15}\frac{x_1^3}{x_3^2}\\
\dot{x}_6 &= \beta_2\left[\frac{1}{3x_3^2}-\frac{x_5^2}{2}\right]-\frac{\beta_3}{3}x_5\left[x_5^2-\frac{1}{2x_3^2}\right]-\frac{\beta_3}{24}x_3^2x_4^2x_5\pi^2+\frac{5}{6}\gamma x_1^2-\frac{1}{6}\gamma_Sx_1^2x_5
\end{aligned}
$$

A Novel Improvement Technique Using a Commercially Available Phosphorescent White LED for High Speed Visible Light Transmission Systems

Nobuhiro Fujimoto and Daiki Nakamura
Kinki University, Japan

Abstract— The white light emitting diodes (LEDs) have been dramatically developed. In specially, a low-cost phosphorescent white LED that consists of a phosphor layer and a blue LED is expected to replace incandescent or fluorescent lights in offices, homes, cars, and traffic lights. According to these backgrounds, visible light communication (VLC) system using white LEDs is one of promising infrastructure for Ubiquitous Network. In the network, they are used for both illumination and wireless data transmission.

There are many approaches to realize high-speed VLC system. A phosphorescent white LED especially is difficult to modulate at high-speed. A 230 Mbit/s on-off-keying (OOK)-NRZ-based transmission experiment [1] was demonstrated with a phosphorescent white LED. However, this experiment required filtering the low-speed phosphorescent component to increase the bandwidth of the VLC system. Then, owing to the insertion of a lossy and expense blue optical filter, its transmittable distance is decreased and its total cost is increased.

Here, we propose the two improvement techniques to realize a long distance and low-cost high-speed VLC system using a phosphorescent white LED without a blue filter. Fig. 1(a) shows a frequency response of a phosphorescent white LED (LED Engin, LZ1-10CW00). It consists of a frequency response of a phosphor layer and that of a blue LED. That response of the phosphor layer has a greater gain than that of the blue LED. Our first proposed technique focuses on a frequency response of a phosphorescent white LED to get a longer transmission distance by adding a pre-emphasis circuit for a LED driver [2] without a blue filter. Fig. 1(b) shows the improved 3 dB down frequency from 2.3 MHz to 41.9 MHz keeping a flat gain of 24 dB. On the contrary, the blue LED has a higher 3 dB down frequency than that of the phosphor layer. The second proposed technique focuses on the frequency response of a blue LED to get a higher transmission speed by adding a pre-emphasis for a LED driver and a post-equalizing circuit for a receiver circuit without a blue filter. Fig. 1(c) shows the improved 3 dB down frequency from 2.3 MHz to 82.8 MHz having a little lower flat gain of 20 dB. And the measured bit error rate characteristics are shown in Fig. 1(d). For example, it is confirmed a 100 Mbit/s error-free operation with a bit-error ratio of less than 10^{-7} at a longer distance between a LED and a Si-PIN-PD of 66 cm by the 1st proposed technique than that of the 2nd technique. And we have

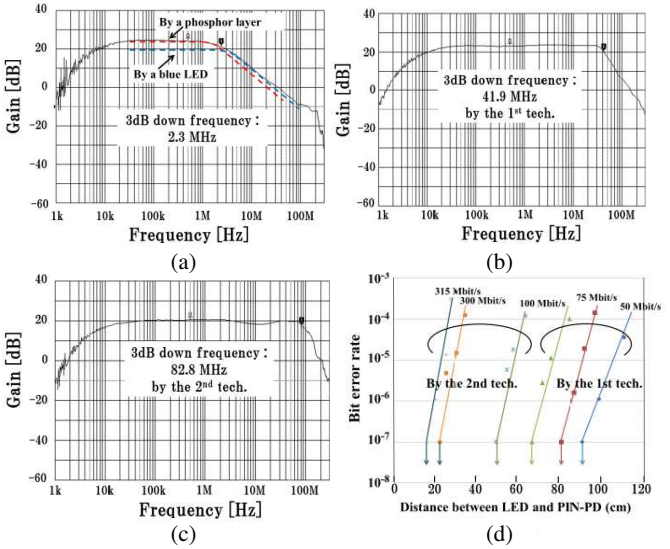

Figure 1: Measured results of a proposed high-speed visible light communication system. (a) Frequency response of a phosphorescent white LED. (b) Improved response by the first technique. (c) Improved response by the second technique. (d) Bit error rate characteristics of the system.

first confirmed the maximum transmission speed of 315 Mbit/s error-free operation by the 2nd proposed technique. This 315 Mbit/s operating speed of a simple OOK-NRZ based modulation using a single commercially available phosphorescent LED is a world record. These experimental results show that our proposed techniques are suitable for simple, low-cost, and high-speed VLC systems.

Optical WDM-PON Access System with Shared Light Source

Sandis Spolitis, **Lilita Gegere**, **Anita Alsevska**,
Ilja Trifonovs, **Jurgis Porins**, **and Vjaceslavs Bobrovs**
Institute of Telecommunications, Riga Technical University, Riga, Latvia

Abstract— We report on 16-channel wavelength division multiplexed passive optical network (WDM PON) with shared amplified spontaneous emission (ASE) light source, which is spectrum sliced by an arrayed waveguide grating (AWG), see Figure 1. In this research ASE source is generated by two cascaded erbium doped fiber amplifiers which parameters were manipulated in such a way obtaining flat spectrum in wavelength range from 1545.32 nm to 1558.98 nm (C-band). It must be mentioned, that spectrum slicing technique is one of available techniques in WDM-PON systems in order to reduce cost of components and simplify the architecture of PON network.

Investigated optical transmission system can be considered as energy efficient and cost effective in the way that single seed light source (ASE) is shared among many users instead of using individual light source for each user, for example, distributed feedback lasers or vertical-cavity surface-emitting lasers. After ASE slicing operation slices are modulated by an optical modulator (electro-absorption modulator or Mach-Zehnder modulator), multiplexed by second AWG, transmitted over standard single mode fiber transmission line, demultiplexed and received by optical receivers located in user premises. In this research, we propose 16-channel spectrum sliced optical access system based on ITU T G.694.1 DWDM frequency grid. Proposed solution shows good performance (bit error ratio BER $< 10^{-10}$) and is capable to provide data transmission at least over 20 km long fiber span with data transmission speed up to 10 Gbit/s per channel, that fit the needs of next generation passive optical networks (NG-PON).

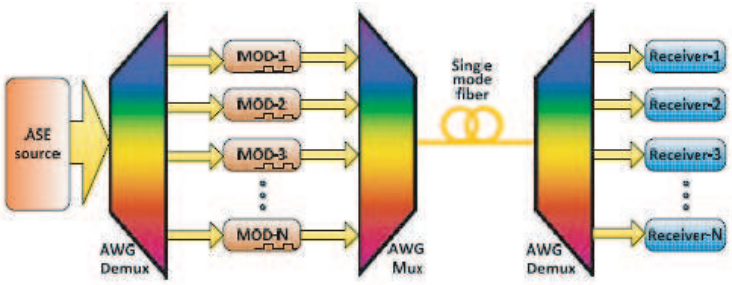

Figure 1: Operational principle of WDM PON transmission system with single light source.

Estimation of EDFA Performance in 40 Gbit/s 8 Channel DWDM Transmission System

Ingrida Lavrinovica, Jurgis Porins, and Girts Ivanovs
Institute of Telecommunications, Riga Technical University, Azenes st.16/20, Riga LV-1048, Latvia

Abstract— Erbium Doped Fiber Amplifier (EDFA) obtained a wide range of applications in research and commercial applications in optical fiber communication systems. It has been considered as an attractive solution because of several major advantages — immunity to cross talk among wavelength multiplexed channels, insensitivity to light polarization state, high energy efficiency (> 50%) and time constant enough to cover modulation noises, which is suitable solution for the simultaneous amplification of all dense wavelength division multiplexing (DWDM) channels. However, the presence of amplified spontaneous emission (ASE) limits the peak gain. EDFA gain spectrum is wavelength dependent and it applies as SNR differential between channels after passing through a cascade of EDFA. Number of cascaded amplifiers is limited by the noise accumulation [1, 2].

In this research the performance of an EDFA in a 40 Gbit/s 8 channel DWDM transmission system with NRZ-OOK modulation format and 100 GHz channel spacing was investigated. The experimental part was focused on optimization of EDFA parameters. Experimental measurement scheme is shown in the Fig. 1.

Optimal length depends on doping level and pump power, therefore different doped fiber lengths (10 m, 15 m, 20 m, 25 m, and 30 m) and excitation source power (200 mW, 300 mW, 400 mW, 500 mW) were used in order to reach the highest amplification value.

The obtained results have shown that at the pump power of 400 mW and 500 mW EDFA has already reached its saturation regime and gain is almost constant: 41–42 dB. The highest gain of 43 dB was gotif doped fiber length is chosen to 30 m. In order to reach higher gain values-longer fibers and more powerful excitation sources should be used.

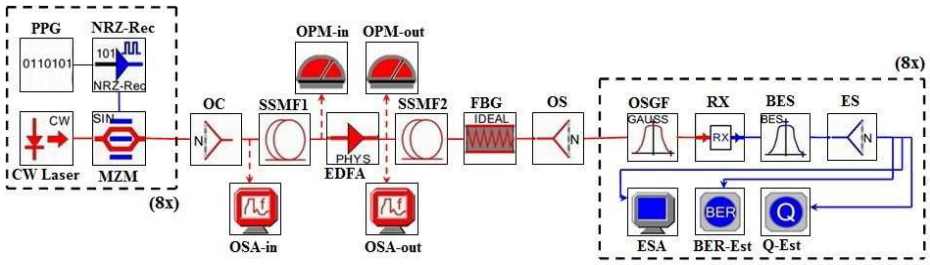

Figure 1: The experimental setup used for investigating the DWDM transmission.

Bidirectional Radio-on-Fiber Transport Systems Using Fiber Nonlinearity and Injection Locked Technique

W. S. Tsai and G. C. Lin
Department of Electrical Engineering, Ming Chi University of Technology, Taiwan

Abstract— We propose a novel bidirectional transmission system based on stimulated Brillouin scattering (SBS) effect and injection locked distributed-feedback (DFB) laser to achieve optical single sideband (OSSB) modulation for downlink transmission. For uplink transmission, we reuse transmitting light by phase modulation (PM) to avoid signal interference each other in bidirectional transport. After 25 km single mode fiber (SMF) transmission, we can observe the sideband power ratio (SBPR) $>$ 15 dB for downlink transmission and system's power penalty is $<$ 2.8 dB. Good performances for bit error rate (BER) analysis are observed in our proposed bidirectional transmission system.

Transponder and 3R Regenerator Impact on Energy per Bit and Optical Bandwidth Required for Data Transmission over 10-40-100 Gbps Mixed-line Rate WDM Links

Aleksjes Udalcovs and Vjaceslavs Bobrovs
Institute of Telecommunications, Riga Technical University, Riga, Latvia

Abstract— Although the mixed-line rate (MLR) design of wavelength division multiplexing (WDM) optical networks has proved itself as a cost-efficient solution for dealing with the heterogeneity of continuously growing traffic demands, however some MLR configurations might not be the best in term of energy consumption per bit (or power efficiency in W/bps) required accumulating the aggregated traffic. In general, power efficiency of MLR solutions depends on the number of factors, such as power consumption of transponders and 3R regenerators, number of the 10 Gbps, 40 Gbps, and 100 Gbps wavelengths, and the overall transmission distance. Depending on the configuration and the link length the MLR-based WDM system could outperform some of the 10 Gbps, 40 Gbps and 100 Gbps single-line rate (SLR) solutions or not. Therefore, it is important to use the proper criteria (e.g., transponder's or regenerator's power consumption; spectral efficiency which could be achieved with a particular modulation format; optical bandwidth required for the wavelength allocation in a transmission spectra) for choosing the number of different wavelengths. Hence, in this paper we aim at exploring the impact of transponders and 3R (re-timing, re-shaping, re-amplification) power consumption on the transmission's power efficiency for the set of link's lengths and on the optical bandwidth required for the allocation of the wavelength channels.

Diffraction Effects on a Dual External Cavity Tunable Laser ECTL Source

Ahmed Fawzy[1], **Osama Elghandour**[2], **and Hesham F. A. Hamed**[1]

Abstract— Fabrication of mirrors by using Deep Reactive Ion Etching DRIE technology allowed for production of monolithically integrated chip that contains mirrors, actuators and laser on the same die. These configurations has great importance in optoelectronics. There are many characteristics required in tunable laser also such as wide wavelength tuning, high tuning speed and minturize the device dimensions. Wide tuning range improve suitability for all practical application. New effects appear due to miniaturization of External Cavity Tunable Laser ECTL source. Diffraction effect is the important one. So in this paper presents the diffraction effects on the performance of an dual external cavity tunable laser source, whose external cavities are constructed by micro electro mechanical systems (MEMS). One of the main problems in these structures is the optical diffraction as the emitting surface of the laser diode is usually quite limited in the transverse directions. The emitted beam diffracts rapidly in the air and only a small amount of light is coupled back to the source that usually limits the tuning range of the source. We use flat mirror in our model. Device characteristics such as tuning range ($\lambda_m ax$–$\lambda_m in$), wavelength shift and sensitivity are evaluated. New expression are used and multiple reflection inside external cavities are considered. The simulation results have shown that single external cavity has limited tuning range. It is shown that multiple reflection has significant effect in our model. To get a better engineering for the dual ECTL dimensions, diffraction effects must be taken into account.

Measurement and Prediction of Non-scaling Differences between Thermal and Radiation Efficiencies of Various Antennas

Michael J. Underhill
Underhill Research Ltd., Lingfield, UK

Abstract— A previous paper put forward an explanation and theory for the significant differences found between thermal and radiation efficiencies particularly of small antennas [1]. The important discovery reported in [1] is that the 'missing' RF power is converted to a combination of broadband 'white noise' and enhanced 'spurious' sidebands. This paper reports comparative field strength measurements of the gains and associated radiation efficiencies of various types of small and large monopoles, dipoles and loop antennas, both tuned and untuned. Figure 1 shows some of the antennas measured with the MiniVNA Tiny (f) which can be used to measure and compare antenna gains and directivities at different frequencies between 1 and 1500 MHz. The coaxial cable choke balun (e) used to feed the antennas above 50 MHz is also shown. All the antennas tested have thermal efficiencies better than 95% to 98% so that gain is < 0.2 dB less than directivity.

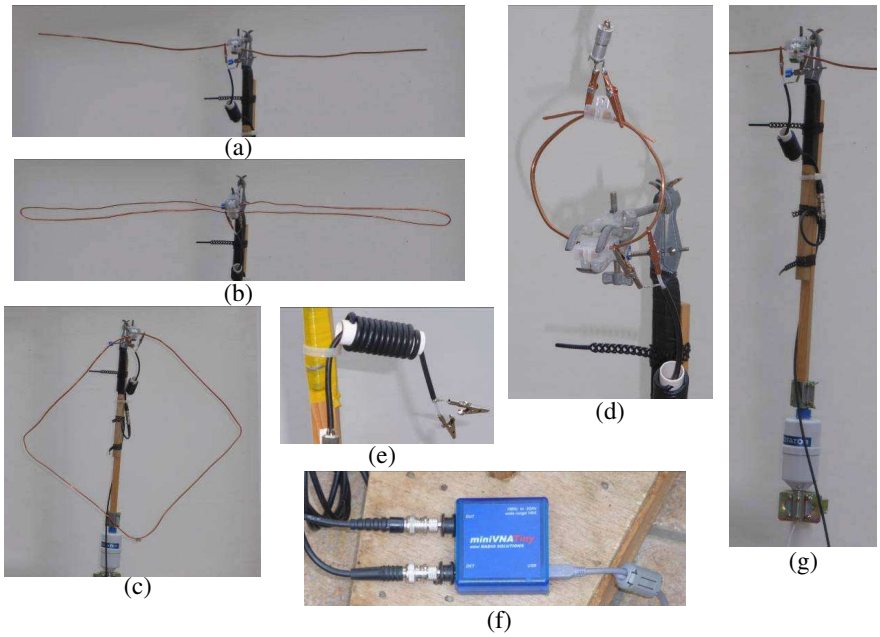

Figure 1: (a) 106 cm half-wave dipole. (b) 109 cm half-wave folded dipole. (c) 220 cm full-wave perimeter loop. (d) 10 to 20 cm adjustable diameter tuned loop with 'gamma-match' feed. (e) Choke balun feed used on all the VHF/UHF test antennas. (MRS Radio Solutions MiniVNA Tiny used for gain and antenna impedance measurements from 1 MHz to 1.5 GHz. (g) Antenna rotator for pattern measurements.

Notable results so far (with more to follow in full paper and presentation) are:

1. Full-wave perimeter loop (c) gain is ~ 4.5 dB greater than half-wave folded dipole (b) gain. Measured and computed directivities are < 1 dB different. (Measured at ~ 140 MHz.)
2. Minimum radiation efficient size of a small tuned loop (d) empirically is $\propto 1/f^{1/2}$ between 2 and 200 MHz. *Thus efficient small tuned loops do not scale conventionally, size with wavelength.*
3. The radiation efficient diameter D_e of a tuned loop is reduced as the square root of the tuned loop Q thus $D_e \propto 1/Q^{1/2}$.

Abstract— This paper develops a generalized vector magnetic potential integral formulation for the paraboloidal reflector antenna, using the elliptic paraboloid geometry as basis. First, parametric expressions informed by the problem geometry are specified for the conventional 'field' and 'source' points, and the ellipse's major and minor axes are described by a common expression, also based on the geometry. When the expressions are utilized in the integral equation for the vector magnetic potential for the problem, and following the usual 'magnitude' and 'phase' approximations, an expression for the radiation field, which may be described as a general expression for certain special cases, emerges. It is shown for example, that when the ellipse's eccentricity is set to zero to prescribe the circular paraboloid, the corresponding expression for the radiation agrees with those available in the open literature [1, 2]. A moment-method solution of the associated radiation field's integro-differential equation is also presented in the paper.

A Compact Dual-band Balanced Slot Antenna for LTE Applications

I. T. E. Elfergani[1], **Abubakar Sadiq Hussaini**[1, 3, 4], **Jonathan Rodriguez**[1, 2], **and R. A. Abd-Alhameed**[3]

Abstract— The new technology in wireless communication has brought a lot of portable devices in the future, such as a mobile phone that will possess Long Term Evolution (LTE) function for the voices and data transmissions [1]. Conventionally, the unbalanced planar inverted F antenna (PIFA) is one of the most popular candidates for compact internalized antennas for mobile handsets due to its unique characteristic that makes it suitable for use in portable wireless device especially on mobile handsets. However, PIFAs use the ground plane as a part of the radiator, enabling very small antennas to achieve adequate gain and bandwidth [2]. Therefore, radiating currents are induced on both the ground plane and the antenna element, resulting in currents flowing on the human body, which degrade the performance of the antenna's radiation characteristics and introduce losses and uncertainty in its matching [3].

To solve these problems, a balanced structure is introduced to not only to eliminate such constraints but also to avoid the degradation of antenna performance in aforementioned unbalanced antennas. In this kind of antennas, currents cancel the effect of each other, the current flows only on the antenna element and not on the ground plane. Therefore, the coupling between the antenna and the user's body will be neglected when the mobile is held by its user which leads in no effect on the performance of the antenna. Lately, several mobile antennas with the balanced technique have proved the enhanced stability of antenna performance, compared to the unbalanced type especially when the handset is positioned in a close vicinity to the human head and/or hand [4, 5]. However, these balanced antennas are not capable to meet the frequency bands of LTE. Thus, the proposed work has been investigated to offer a low profile antenna for Long Term Evolution (LTE) applications at 700 MHz and 2600 MHz bands using the balanced antenna concept.

The proposed antenna will be implemented based on built-in planar dipoles with two folded slot arms structure. Fig. 1 shows the geometry of the balanced antenna for a mobile phone. The antenna was designed first and then was mounted 4 mm on top of a finite ground plane with dimension of $100 \times 50\,\text{mm}^2$ which acts as the mobile handset chassis or what today we would identify as the ground plane of a practical mobile phone handset, as seen in Fig. 1. The dimensions of the proposed antenna geometry were found comparable to the practical handset size as illustrated in Fig. 1. The slot has a uniform width of 2 mm. The antenna was constructed from a copper sheet with thickness of 0.15 mm. The objective of the embedded slot was to tune the radiator structure to resonate at our targeted bands of LTE 700/2600 MHz. This was achieved through multiple simulated attempts, by conducting several modification of the authors' previous

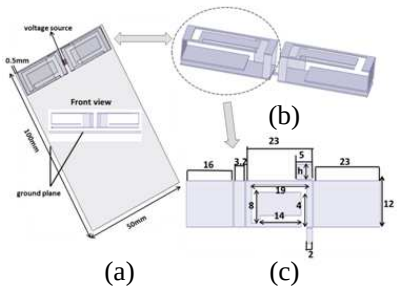

Figure 1: Basic antenna structure; (a) 3D, (b) folded slotted arms, (c) unfolded slotted arm, dimensions in mm.

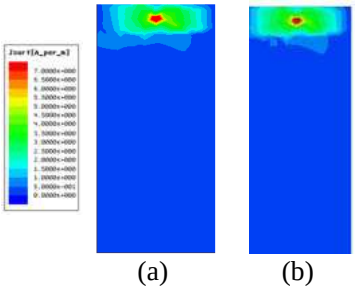

Figure 3: Surface current distributions for the proposed balanced antenna at (a) 700 MHz, (b) 2600 MHz.

work in [5] to move toward the desired outcome of developing highly compact and dual-band antenna for use in LTE applications. It is obvious that the S_{11} of proposed antenna generated by HFSS agrees well with the one obtained from the CST as shown in Fig. 2. The analysis of the current surface on the ground plane of the proposed antenna was studied using the EM simulator at the 700 MHz and 2600 MHz, i.e., the targeted frequencies within this work as shown in Fig. 3. One can clearly note that, most of the current is induced exactly underneath the two folded slotted arms at both resonant frequencies while it is more or less vanished on the rest of the ground plane in which proves the concept of balanced antenna whereby it reduces the coupling between the handset and the user's hand.

Abstract— Antennas constitute a very important part of Radio Frequency Identification (RFID) systems. Coming in various forms and types, they are usually designed and intended to ensure maximum effective and efficient communication links between tags or transponders and their associated readers or interrogators. One of the primary challenges in the design and development of antennas in RFID applications as it is in other wireless applications is having an antenna with optimised parametric features that are desirable and in consonance with laid down specifications and functional requirements. These parametric features include but are not limited to: profile, gain, directivity, bandwidth and polarisation.

Radio Frequency Identification (RFID) systems which connote the physical interaction between a tag and a reader for automatic identification operate within the global bandwidth of (860–960) MHz as specified by the International Standards Organisation (ISO). It should also be noted the RFID systems function adopting a non-contact application of radio-frequency does not require a line-of-sight channels. Thus, in order to optimise an RFID system, the orientation of the tags and associated readers must be fully established through the polarisation characteristics of their corresponding antennas. RFID tags are often designed to have linearly polarised dipoles. Consequently, their orientation in a typical RFID system is not always predictable.

The quadrifilar helical antenna (QHA) has been identified by previous works as a suitable antenna for tag reading in RFID and other wireless applications, due to its ability to give circular polarisation over a wide angular area [1, 2]. Another excellent property of QHAs in terms of the symmetry of their geometry is their ability to give a cardioid-shaped radiation pattern regardless of the axial length and diameter. It has also been established that the inherent cardioid-shaped radiation patterns of QHAs can be made conical by extending the resonant fractional turns of the QHA to an integral number for improved characteristics [2]. Consequent to the aforementioned, a novel compact QHA was designed and optimised over a perfect ground to function optimally within the RFID global bandwidth of (860–960) MHz. The novel QHA antenna is named linearly-shifted quadrifilar helical antenna (LSQHA) because its elements are linearly-shifted and made compact as revealed in Fig. 1(b). With reference to its helical elements and as can be observed, the proposed LSQHA design does not take the form of the conventional QHA. Specifying a finite ground and feeding of the LSQHA via an integrated feed network is proposed, to avoid the intricacy and losses associated with multiple feed points of a centre feed. At the risk of repetition, the

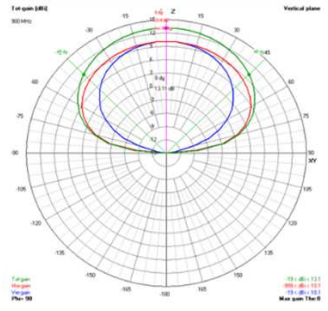

Figure 3: Computed gain radiation patterns of the proposed antenna for one vertical cut plane.

novel antenna structure is achieved by linearly-shifting the helical elements of the conventional QHA by 90° using a defined phase quadrature distance. This design is expected to reduce the axial length and overall volumetric equivalent of the LSQHA, while retaining good axial ratio, high power gain and wide beamwidth coverage.

Circularly Polarized Crossed Bowtie Dipole Radiator with a Half-wavelength-thick Partially Reflecting Surface

Huy Hung Tran[1], **Ikmo Park**[1], **and Hanjo Lim**[2]

[1]Department of Electrical and Computer Engineering
Ajou University, Suwon, Republic of Korea
[2]CINAP, Institute for Basic Science (IBS), Department of Energy Science
Sungkyunkwan University, Suwon, Republic of Korea

Abstract— The gain of a radiator can be improved by placing a partially reflecting surface (PRS) at an appropriate distance from the ground plane. The maximum radiation in the broadside direction occurs when the reflectivity of a PRS is maximized, and a cavity structure achieves in-phase electromagnetic wave transmission. The main characteristics of the antenna, such as the impedance and gain bandwidths, and radiation patterns are determined by the properties of the radiator and PRS. It is well-known that the PRS should be placed at a half-wavelength distance from the ground plane for optimum performance, and the maximum gain increase is accompanied by a decrease in the operation bandwidth. Therefore, it is very difficult to achieve both gain and bandwidth enhancement at the same time.

Recently, a method for using multiple dielectric slabs to form multiple PRSs has been proposed. This method uses several superstrates to create multiple resonances with multiple cavities, and achieved a broad 3-dB gain bandwidth. However, the design of the PRSs with multiple dielectric slabs requires a complicated optimization process. Even though a wide gain bandwidth can be achieved with multiple dielectric slabs, the size of the antennas is large, and there may have fabrication difficulties.

In this paper, a high-gain circularized polarized bowtie crossed dipole with wideband characteristics is proposed. A planar conducting screen acting as the ground plane is placed behind a crossed bowtie dipole radiator and a reflecting screen acting as a superstrate is placed in front of the radiator. The antenna employing a half-wavelength-thick PRS achieves wide reflection coefficient, axial ratio (AR), as well as gain bandwidths. The final design with an overall size of $80 \times 80 \times 28.35\,\text{mm}^3$ yielded a -10-dB impedance bandwidth of 40% (5.6–8.4 GHz), a 3-dB AR bandwidth of 25.6% (6.3–8.15 GHz), a 3-dB gain bandwidth of 42.7% (5.7–8.8 GHz).

A Bandwidth Enhanced Compact Circularly Polarized Crossed Dipole Antenna Loaded with a Parasitic Element

Son Xuat Ta and Ikmo Park
Department of Electrical and Computer Engineering
Ajou University, Suwon, Republic of Korea

Abstract— In this paper, a compact circularly polarized (CP) crossed dipole antenna loaded with a parasitic element is proposed for use in GPS L1 (1.575 GHz) and GLONASS L1 (1.605 GHz) bands. The dual-band operation is obtained by combing two CP bands; one from the crossed dipole driver and other from the parasitic element. A meander line and an arrowhead shaped ending were utilized to achieve a compact size in both driver and parasitic elements. The antenna was demonstrated to be well matched to a 50-Ω coaxial line without any matching network and to have reasonably high radiation efficiency. The antenna was characterized using a finite-element method-based full-wave electromagnetic solver, Ansoft HFSS. Both crossed dipole and parasitic elements were designed on a Rogers RT/Duroid 5880 substrate with a permittivity of 2.2, a thickness of 0.508 mm, and a loss tangent of 0.0009.

The final design with an overall size of 38 mm×38 mm×1.016 mm yields a −10-dB $|S_{11}|$ bandwidth of 1.505–1.695 GHz and a 3-dB axial ratio bandwidth of 1.555–1.635 GHz with two CP center frequencies at 1.575 GHz (AR = 1.0 dB) and 1.605 GHz (AR = 0.9 dB). The antenna radiated a bi-directional electromagnetic wave at both bands; it radiated a right-hand circular polarization wave at the broadside direction whereas it radiated left-hand circular polarization wave at the back direction. Additionally, the antenna yielded gains of 1.45 and 1.78 dBic, and radiation efficiencies of 88.3% and 93.5% for the lower and upper bands, respectively. With compact size, good impedance matching, and good CP radiation, the proposed antenna can be widely used in GPS and GLONASS applications.

A Compact Tri-band Monopole Antenna with Multiple Meander Lines for WLAN and WiMAX Communication Applications

Xinbo Liu, Yingsong Li, and Wenhua Yu
College of Information and Communications Engineering
Harbin Engineering University, Harbin, China

Abstract— In this paper, a compact tri-band monopole antenna with three meander lines is proposed and investigated for wireless local area networks (WLANs) and worldwide interoperability for microwave access (WiMAX) system applications. The designed tri-band antenna is realized by using three meander line structures that are connected to the 50-Ohm microstrip feed signal strip line to generate the desired triple resonance frequencies. By adjusting the dimensions of the proposed three meander lines, the expected resonant frequencies can be tuned for WLAN and WiMAX communication applications. The experimental results demonstrate that the optimized tri-band monopole antenna can give three impedance bandwidth for $S_{11} \leqslant -10\,\mathrm{dB}$ of 160 MHz (2.39–2.55 GHz), 450 MHz (3.30–3.75 GHz) and 730 MHz (5.14–5.87 GHz), which can be applied to cover both 2.4/5.2/5.8-GHz WLAN bands and 3.5/5.5-GHz WiMAX bands. Furthermore, omnidirectional radiation patterns and stable gains can be achieved, which make the designed tri-band monopole antenna promising for integrating into modern portable devices.

Efficient 2D Simulation Model for the Analysis and Optimal Design of DNP-NMR Solenoid Coils

Abstract— Nuclear magnetic resonance (NMR) spectroscopy is a broadly used research technique that exploits the magnetic properties of atomic nuclei with non-zero spin in order to determine the physical and/or chemical properties of the molecules in which they are contained. Specifically, it can provide detailed information regarding the structure, dynamics, reaction state, and chemical environment of the molecules, while its spectra are (at least for small molecules) well-resolved, analytically tractable and highly predictable. However, NMR has fundamental sensitivity limitations, as a consequence of the small energy difference between nuclear spin states. This drawback has always restricted its application to complex structures, like large biomolecules (proteins, nucleic acids etc.).

Dynamic nuclear polarization (DNP) has emerged as a widely applicable technique to improve the sensitivity of NMR experiments (involving RF currents in the region of few hundreds of MHz) by transferring the relatively large polarization of electron spins to bulk nuclei, a process which requires the excitation of electron paramagnetic resonance (EPR) transitions with high-power millimeter-wave (MMW) radiation. The result is a significant enhancement of the original NMR signal, thus leading to an important reduction of the corresponding spectrum acquisition times. Such experiments have been made possible in the past few years due to the development of stable, high-power gyrotrons as MMW sources and low-loss waveguides which transfer the power to the sample. DNP enhancement values depend on a number of factors, but most importantly on the intensity of the MMW magnetic field, which is oscillating in resonance with the electron spins, throughout the sample.

In this paper, we develop a 2D simulation model in order to analyze the MMW performance of a typical NMR solenoid coil operating at cryogenic temperatures. The structure is approximated by a single unit cell — corresponding to one turn of the coil — together with appropriate periodic boundary conditions, while a plane wave with the proper electric field polarization is considered for the MMW excitation. Then, this model is succesfully utilized to examine the reflection/transmission characteristics of the coil, visualize the field distributions, estimate and maximize the average magnetic field in the sample region and, hence, optimize the geometry of the device in a very fast and convenient way. The results of our analysis show very good agreement with those of a more realistic — yet computentionally intensive — 3D model of the same setup, while our conclusions can serve as the basis for the development of more advanced NMR coils, which can deal efficiently with the crucial issue of sample heating. All simulations are performed with the RF module of COMSOL Multiphysics, a simulation package based on the Finite Element Method (FEM).

Low-cost Implementation of a Waveguide-based Microwave Filter in Substrate Integrated Waveguide (SIW) Technology

Abstract— The increasingly known transmission line called SIW (Substrate Integrated Waveguide) [1, 2] is a low-cost realization of the traditional rectangular waveguide, taking the advantages of planar lines for easy integration with other circuits, and low radiation losses of waveguides. Furthermore, this new technology has been used for making a large number of microwave devices such as filters, antennas, multiplexers, etc. [3–5].

This paper presents the design and practical implementation of a waveguide-based microwave filter in Substrate Integrated Waveguide technology. The use of SIW technology for implementing waveguide filters makes the presented design specially aimed for being used in undergraduate courses related to microwave engineering and filter designing. Their low cost and easiness from the filter fabrication point of view allows their use in microwave laboratory courses where students can implement their own theoretical filter designs and measure their frequency response.

The requiring mechanics in the manufacturing of microwave filters in waveguide technology (both rectangular and circular) makes its use practically unfeasible in academic laboratories for various reasons (cost, high frequency operation ...), despite the abundant literature dealing on waveguide filters implementation [6]. For this reason, a practical design example of a waveguide iris filter using the impedance inverter model is proposed in this paper for academic laboratories, using SIW technology. This is a low cost and easy to manufacture technology. The overall process includes the design of the ideal band-pass prototype filter using the impedance inverter and its implementation in an inductive iris-coupled waveguide filter, by using a developed electromagnetic simulator based on the mode-matching technique [7]. Finally, the equivalent filter in SIW technology is obtained and optimized by using HFSS simulator [8]. Since the response of the designed filter is going to be measured using a vector network analyzer, a SIW to microstrip transition is designed at both ends of the filter, at which ends are connected SMA connectors.

Abstract— In this paper, we propose an RLC matched GaN HEMT broadband power amplifier using silicon-based integrated passive device (IPD) technology. For broadband operation, the RLC type bridged-T all-pass network is used at the input matching network [1]. The initial values are calculated by a formula from the reference [1] with an input capacitance (C_{gs}) of the GaN HEMT. Based on the calculated values, the proposed power amplifier is designed and optimized to obtain broadband characteristics. Also, the LC ladder-typed topology is employed at the output matching network, as shown in Figure 1.

The X-band power amplifier was implemented using thin-film IPD technology, as shown in Figure 2. The passive elements at the input and output matching networks were implemented using metal-insulator-metal (MIM) capacitors, spiral inductors, and thin-film resistors. The GaN HEMT and two matching networks were attached using high-K conductive epoxy and interconnect between them was done by wire bonding. This approach provides several key properties such as high integration, which is very close to MMIC dimension, high design flexibility, low cost by standard silicon technology, and so on. The measured impedance contours of the fabricated matching networks are shown in Figure 2. The dimension of the input and output matching networks is 1.4 mm × 1.2 mm and 2.2 mm × 1.6 mm, respectively. The thickness of the matching networks is only 0.15 mm. A more than 1.5-GHz bandwidth with an output power of 37 dBm at X-band can be obtained by this input RLC matched network and output LC ladder-type topology.

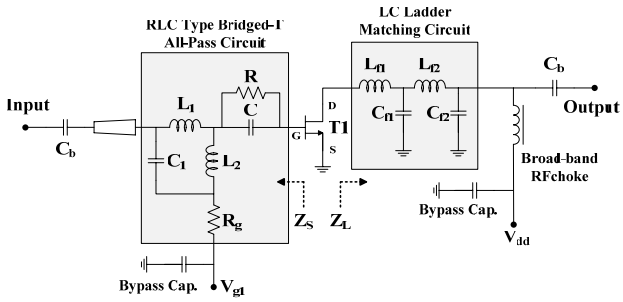

Figure 1: Schematic of the broadband power amplifier.

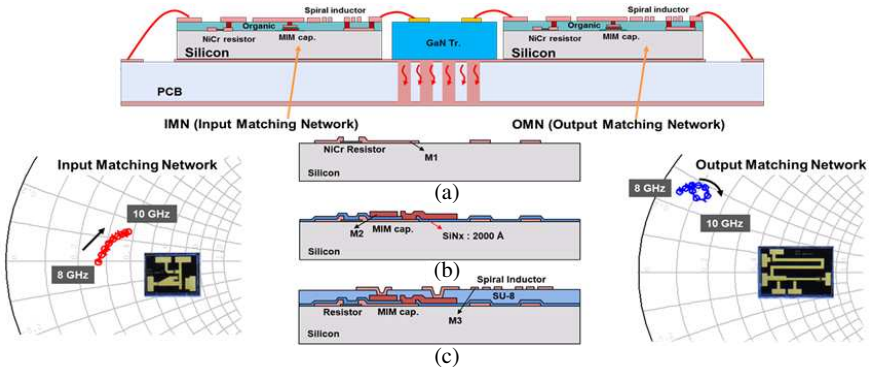

Figure 2: Proposed power amplifier structure, process and measured impedances.

Band-pass Filter Based on Magnetoelectric Composite at Electromechanical Resonance

A. S. Tatarenko, **R. V. Petrov**, **V. M. Petrov**, **and M. I. Bichurin**
Novgorod State University, Russian Federation

Abstract— Ferrite-piezoelectric layered structures are known to be magnetoelectric (ME) due to interaction of ferrite magnetization and piezoelectric polarization via elastic deformations [1]. The applicability of ME composites for signal processing devices, such as phase shifters and filterswas reported recently [2]. The present paper focuses on the ferrite-piezoelectric bilayer based LF-band filter performance. This structure enables one to control the filter characteristics in a wide range of input signal amplitude by means of bias magnetic field.

The filter considered consisted of a ferrite-piezoelectric bilayer placed into a solenoid. Bias magnetic field up to 2000 Oe was generated by an electromagnet. DC magnetic field H is necessary to provide non-zero piezomagnetic coefficient for magnetic layer and obtain the resonant characteristics. The ferrite-piezoelectric bilayer was formed by single-crystal $Zn_{0.2}Ni_{0.8}Fe_2O_4$ (NZFO) and piezoelectric lead zirconate-titanate (PZT). PZT and NZFO had dimensions of $24 \times 24 \times 2\,\mathrm{mm}^3$ and $30 \times 20 \times 2.25\,\mathrm{mm}^3$, correspondingly. Electrodes were placed on lateral surfaces of piezoelectric layer to measure the output voltage across the piezoelectric layer. Bilayer geometry corresponded to electromechanical resonance (EMR) frequency of 86 kHz. The measurements were carried out with Agilent DSO-X 2002A oscilloscope.

The resonance pick at frequency of 86.8 kHz corresponds to the longitudinal mode of EMR and has the bandwidth of 2 kHz. The output voltage was equal to 2.53 V at zero bias magnetic field and input ac voltage of 10 V. The output voltage increased to 12.62 V at dc magnetic field of 170 Oe and input ac voltage of 0.714 V. The resonance value of ME voltage coefficient equaled 0.47 V/(cm·Oe). Thus, the proposed filter design enables one to achieve the peak transmission coefficientregulation of 10 dB. The obtained results can be further used in practical applications.

Silicon Carbide MEMS Based Tunable Resonator Filters

B. Sviličić[1, 2], E. Mastropaolo[1], and R. Cheung[1]

[1]Scottish Microelectronics Centre, University of Edinburgh, Edinburgh, United Kingdom
[2]Faculty of Maritime Studies, University of Rijeka, Rijeka, Croatia

Abstract— Micro-electro-mechanical system (MEMS) resonators have emerged as a potential candidate technology for implementation of high-Q tunable filters that are able to solve power consumption and miniaturization issues [1]. Electrically tunable filters with a wide operational range are crucial elements in both multiband communication systems and wideband tracking receivers because they have the ability to replace filter banks [2]. Silicon carbide (SiC), due to its excellent electrical, mechanical and chemical properties, is one of the most promising materials for high efficiency MEMS resonators [3].

Recently, we have demonstrated a silicon carbide MEMS based resonator filter that is actuated electrothermally and sensed piezoelectrically [4]. Electrothermal technique for induction of mechanical vibrations has been attracting increasing attention as a means of allowing simple fabrication process, low actuation voltages, impedance matching and effective frequency tuning. Piezoelectric transduction allows active generation of electrical potential in response to an applied mechanical stress (no bias voltage source is needed), and it enables stronger electromechanical coupling and simpler fabrication process compared to the electrostatic transduction.

In this work, we present a two-port SiC MEMS resonator device electrothermally actuated with u-shaped designed electrode in order to provide tunable filter function with wide operation range (Figure 1). Two-port transmission frequency response measurements have shown that, by increasing the DC bias of the actuating voltage from 3 to 7 V, the operating frequency of a 1.4 MHz device can be adjusted up to 31%. Details of the design, fabrication processes and measurement setup will be presented. Moreover, the origin of resonant frequency change induced by tuning DC voltage will be studied.

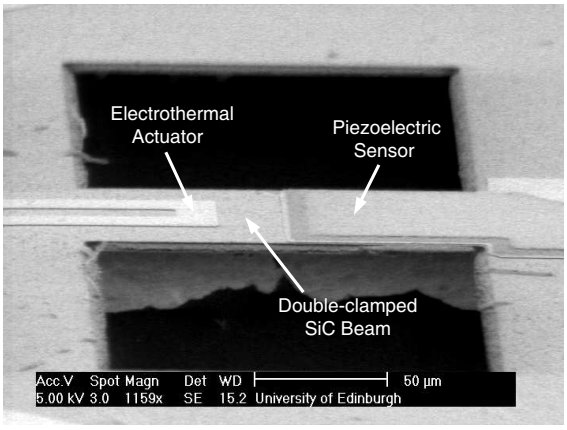

Figure 1: SEM of the fabricated resonator with the electrothermal actuator (input port) and piezoelectric sensor (output port) placed on the top of SiC double-clamped beam.

Yagi Rectenna Application to Increase the Battery Lifetime of Sensor Nodes

R. Fernández-García and I. Gil
Departmentof Electronic Engineering, Universitat Politècnica de Catalunya
08222 Colom 1, Terrassa, Spain

Abstract— In the last years a massive increase of the use of wireless communications has been produced in industrial and domestic applications. Specifically, one of the latest applications of the wireless communication is the Wireless Sensor Networks (WSNs) [1]. The WSNs consist of small communication nodes. These nodes contain a sensing part, a microcontroller, communication components and power supply (typically a battery). Moreover, these nodes should fulfil restrictions of low-cost and low-power consumption to guarantee its usefulness. In this sense, the RF energy-harvesting technology [2] can help to increase the battery lifetime of sensor nodes and, in some cases, even to avoid using the battery. The main RF energy harvesting element is the rectenna, which consists of an antenna plus a rectifier to convert the RF signal to DC voltage.

In this work, a Yagi rectenna to harvest the RF energy of the GSM system at 1.8 GHz is proposed. The rectenna has been designed by means of the commercial *Keysight Advance Design System* (ADS) software. Fig. 1 shows the proposed Yagi antenna implemented of commercial FR4 substrate (dielectric constant $\varepsilon_r = 4.6$, thickness $h = 1.53\,\text{mm}$). Fig. 2 plots the simulated return loss, bandwidth of 250 MHz (1700 MHz to 1950 MHz) it is observed at $S_{11} = -10\,\text{dB}$ with antenna gain from 4.5 dBi to 7 dBi (5.78 dBi at 1.8 GHz). At 1800 MHz the antenna input impedance corresponds to 62.74+j6.31 Ω. Fig. 3 shows a voltage double RF-DC converted base on HSMS-286c Schottkydiodes. Note that in order to design correctly the matching network between antenna and RF-DC converter the parasitic impedance of diode packed SOT-323 has

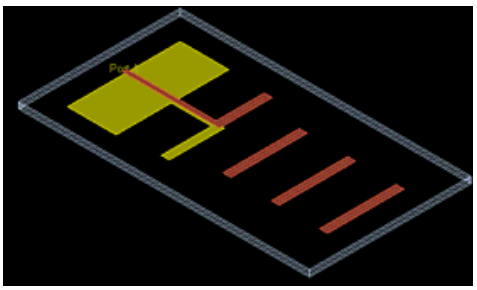

Figure 1: Antenna return loss.

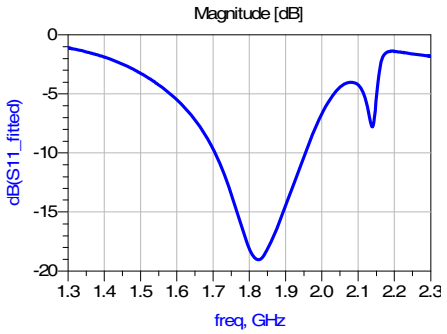

Figure 2: Antenna return loss.

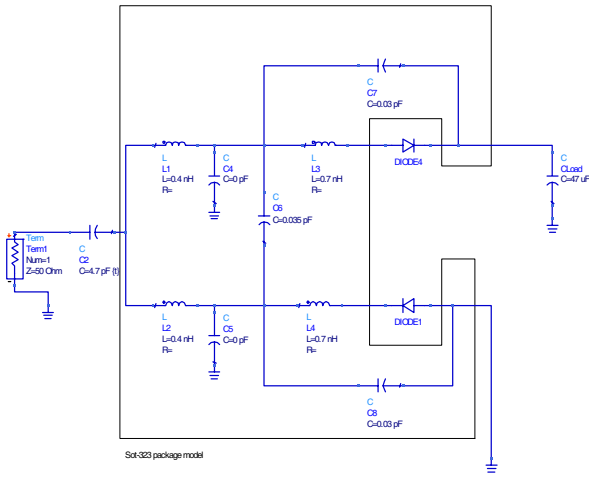

Figure 3: RF-DC converter.

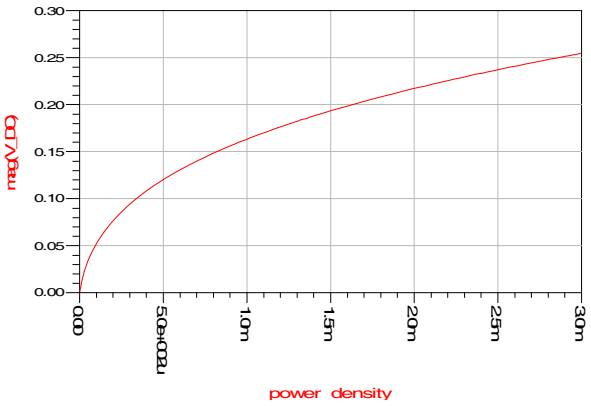

Figure 4: Output voltage versus power density (mW/m^2).

been included. The RF-DC converter input impedance at 1.8 GHz is $2.01-\mathrm{j}\,224.16\,\Omega$. Therefore,a LC matching network with 20 nH and 8.2 pF is used. In Fig. 4 the dependence of DC voltage with the RF power density of the designed antenna at 1.8 GHz is drawn, 200 $\mathrm{mV_{DC}}$ are obtained for a power density of 1.5 $\mathrm{mW/m^2}$.

A Model-free Method for Real-time High Precision Carrier Phase Observation

Tianyi Zhang, Qiao Meng, Quantao Yu, Jifei Tang, and Wei Liu
Institution of RF-&OE-ICs, Southeast University, Sipailou 2, Nanjing 210096, China

Abstract— Carrier phase observation is a ranging method with high accuracy that used in various applications including radar ranging, satellite orbits determination, high precise relative GPS positioning and mobile communication location system. It achieves the radial distance between target and receiver by measuring and tracking the changes to the carrier phase. Relative velocity could be obtained from instantaneous frequency (IF).

Carrier signal of target in motion is a typical nonstationary signal and its model is difficult to determine. This paper describes a model-free method of obtaining total phase and IF of carrier signal in real-time with high resolution. The estimation of signal model is unnecessary, which reduces the computation and complexity. Frequency rate, initial frequency and fractional phase are estimated using de-chirp algorithm in fixed short-time interval called integral time. The de-chirp algorithm is based on ambiguity function (AF) and high resolution frequency estimator is used. Total phase are calculated and filtered by Savitzky-Golay smoothing filter to reducing measure noise. Meanwhile, instantaneous frequency with better accuracy could be obtained by deriving the smoothed total phase which can also be implemented by a FIR filter like Savitzky-Golay filter. The degree of polynomial used to design smoothing filter should be chosen cautiously and the integral time should be designed wisely. This method is adapted to be implemented using hardware.

Monte-Carlo simulation using polynomial phase signal (PPS) model with additive white Gauss noise (AWGN) shows the validity of the method. The simulation results also indicate that the proposed approach could obtain accuracy total phase and IF at low signal-to-noise ratio (SNR).

Real-time Processing Technique for Panoramic Infrared Imaging System

G. Sun, G. Li, W. H. Wang, X. L. Fan, and Z. P. Chen
Science and Technology on Automatic Target Recognition Laboratory
National University of Defense Technology, Changsha 410073, China

Abstract— High-resolution, multi-pixels and large view field infrared detector is an important research direction that would improve the detection capability of infrared imaging alarm system. However, along with the aggrandizement of view field, especially for the omnidirectional search system of surrounding-view infrared imaging, the background composition of the infrared image is very complicated, and the difficulty of target detection increases correspondingly, at the same time, the data quantity of infrared image in large view field also increases rapidly. This makes the traditional spatial filtering methods those based on pixel operation or transform process methods meaningless when processing the infrared image under large view field, besides that the real-time performance and engineering realization also face more rigorous challenge.

Panoramic infrared imaging system (PIIS) based on the 1152×6 long linear array long-wave detector is introduced. Due to the real-time processing and high-speed data transfer demanding, we propose a high-performance processing platform based on field programmable gate array (FPGA) + multicore digital signal processor (DSP) architecture. To reduce the platform's power consumption, dynamic power monitoring technology is used to provide variable core voltage management for DSP. Then mapping an application to the platform is illustrated, which is guided by parallel-task segmentation mechanism of multi cores system. We show that, the designed platform with the optimization strategies achieves powerful capabilities of data throughput and processing performance.

Monitoring for Resonant Mode of High-way System at Impulsive Impact

Shigehisa Nakamura
Kyoto University, Japan

Abstract— This note concerns on monitoring for a resonant mode of a high-way system at an impulsive impact. This work might be helpful for elementary finding of a key to show an advanced techniques at design, constructing, and maintaining of the life line systems which should be in a resonant mode for safety of public use even under any severe seismic condition on the surface of the earth.

Examples of Electromagnetic Field Sources in an Indoor Distribution Substation

Rauno Pääkkönen[1], **Marko Lundström**[2], **Jari Mustaparta**[3], **and Leena Korpinen**[1]

[1]Tampere University of Technology, Tampere, Finland

[3]Turku Energia Sähköverkot Oy, Turku, Finland

Abstract— In indoor distribution substations, there are typically extremely low frequency (ELF) electric and magnetic field sources, e.g., transformers and cables. However, nowadays there can also be smart meters or collector meters. These smart meters most often send information or communicate using either a radio frequency (800–3000 MHz) aerial signal to masts or a 50–100 kHz electromagnetic field signal via cables. The aim of this paper was to present example measurements of electromagnetic field exposure to sources in an indoor distribution substation. We used the magnetic field meter MFM 3000 by Combinova, with a separate probe version, video recording with RMS values, and spectrum (Samsung smart phone type Samsung Galaxy S III), the Narda EMR-300 with probe T-33C, and a Holaday 3603 VLF Survey meter. We performed measurements at three places. Place A was near the fuse panel, where we made measurements with (1) frequency bandwidth 40 kHz–100 kHz (57 measurements) and (2) 5 Hz–100 kHz (62 measurements). Place B was on the surface of the collector meter (15 measurements), Place C was near the antenna of the collector meter (7 measurements) and Place D on the surface of the antenna (24 measurements). In Place A, using the bandwidth (1) we got eleven values, which varied from 0.011–0.039 μT, other values were 0.0038–0.0052 μT. The source of those values can be the collector meter, which signals via cables. Using the bandwidth (2), the magnetic fields were 67–74 μT. In Place B, the magnetic fields varied from 0.022 to 0.083 μT, and the frequency bandwidth was 40 kHz–100 kHz. In Place C, the radio frequency maximum field was 1.0 W/m^2, and in Place D, it was 1.8 W/m^2. To evaluate the possible effects of electromagnetic fields, it is possible to use guidelines of the International Commission on Non-ionizing Radiation Protection (ICNIRP), and measured values were below guidelines. In the final paper, we will present more details of the measurement results.

Emission of Smart Meter Electric Fields (50–100 kHz) in Finland

Rauno Pääkkönen[1], **Marko Lundström**[2], **Jari Mustaparta**[3], **and Leena Korpinen**[1]

[1]Tampere University of Technology, Tampere, Finland
[2]Tampereen Sähköverkko Oy, Tampere, Finland
[3]Turku Energia Sähköverkot Oy, Turku, Finland

Abstract— Discussion of the possible health effects of electromagnetic field (EMF) exposure caused by smart meters has become livelier as the use of smart meters has increased, for example, in Finland. The International Commission on Non-ionizing Radiation Protection (ICNIRP) has published guidelines, which are possible to use to evaluate EMF exposure. The aim of this paper was to present example measurements of electric field exposure to smart meters for cable-transmitted (50–100 kHz) signal emissions. We used the directional electric field meter Holaday 3603. The measurement distance was at the surface of the meter because the values were so small, it was not possible to get values from other distances. The operator of a utility company remotely read the smart meters when we measured electric fields. Altogether, we measured 27 smart meters, which used Power Line Communication (PLC). Meters used plan and lon protocols. The highest electric field was 5.2 V/m, which is only 6% of the recommended public exposure limit according to the ICNIRP guidelines. However, the smart meter readings were very short (about 20 s); therefore, the possible exposure time is also very short. This is important to take into account when we analyze the measurement results and compare to guidelines. Based on our measurements, it is possible to conclude that there is no specific need to improve the sheltering of the meters from the public or to measure electromagnetic field emissions from smart meters. In the final paper, we will present more examples and details of the measurement results.

Smart Receiver for Multi-antenna Transmitters with Constellation Shaping

Paulo Montezuma[1, 2, 3], **Sara Ribeiro**[1], **Mario Marques da Silva**[2, 4], **and Rui Dinis**[1, 2]

[1]DEE, FCT Universidade Nova de Lisboa, Portugal

[4]Universidade Autonoma de Lisboa, Portugal

Abstract— Power and bandwidth constrains in wireless communications systems can be mitigated by MIMO (Multiple-input multiple-output) systems. Still, high spectral efficiency is only attainable by multilevel constellations that may impose restrictions on power amplification, since efficiency in power amplification usually implies that amplifiers must operate in non-linear zone or near saturation. Thus, constant or quasi constant envelope signals are needed. This problem can be overpassed by a transmitter structure with a power efficient amplification stage where multilevel constellations are decomposed on M BPSK (Bi-Phase Shift Keying) sub constellations, which are amplified and transmitted independently by an antenna. Being uncorrelated the BPSK components, instead changes on radiation pattern there is a constellation shaping which optimizes the transmitted constellation only on the desired direction. This means, that we have directivity at information level, i.e., at the transmitted constellation. This directivity depends on the coefficient values associated to the set of M BPSK components and the constellation's shaping changes dynamically with changes on these coefficients or errors due to phase imbalances. Consequently, this transmitter has inherent security since the transmitted constellation is only optimized in the desired direction. Under these conditions, the receiver must know the set of constellation's coefficients g_i, $i = 1, \ldots, M$, associated to each BPSK component and the array phase configuration used by the transmitter, otherwise the received constellation suffers a uncompensated nonlinear distortion due to phase rotations of components associated to each amplification branch (it should be noted that these phase imbalances also change the distances between constellation's symbols which has impact on system performance).

Therefore, for successful data reception it becomes crucial a smart receiver based on an algorithm that estimates the set of coefficients used at the transmitter. We propose a "smart receiver" using an algorithm that can estimate the set of coefficients applied in constellation shaping introduced at the transmitter. Simulation results show that the good performance is attainable by the proposed receiver and corresponding algorithm, even when the directivity increases with the number of BPSK components used in the decomposition of the multilevel constellation.

Impact of Aeronautical Mobile Telemetry System on MFCN SDL Operating Co-channel in Frequency Band 1452–1492 MHz

M. Zilinskas[1], **E. Stankevicius**[2], **and S. Oberauskas**[3]

[1]Vilnius University, Sauletekio al. 9, Vilnius LT-10222, Lithuania
[2]Vilnius Gediminas Technical University, Sauletekio al. 11, Vilnius LT-10223, Lithuania
[3]Communications Regulatory Authority of the Republic of Lithuania
Algirdo str. 27A, Vilnius LT-03219, Lithuania

Abstract— This paper presents the co-channel compatibility analysis between International Mobile Telecommunications (IMT) system and Aeronautical Mobile Telemetry (AMT) system in the frequency band 1452–1492 MHz.

There is a growing mobile technology development and increasing demand for radio frequencies to mobile services. Broadband mobile communications systems (e.g., LTE) are developing at staggering rates. Companies have the resources to expand their mobile networks, but it becomes increasingly difficult to avoid interference between adjacent stations due to ever growing density of all other applications. Mobile operators always search for new possible frequency bands to expand their networks.

World Radiocommunication Conference in 2012 (WRC-12) approved Resolution COM6/6 which contains the agenda for next conference in 2015 (WRC-15). Under agenda item 1.1 additional frequency bands for IMT systems could be identified. For this purpose it is proposed to considered frequency bands 1429–1452 MHz, 1452–1492 MHz, 1492–1518 MHz and 1518–1525 MHz as possible candidate bands.

Frequency band 1452–1492 MHz is attractive for communications due to the qualified radio propagation conditions. The usage of this frequency band for IMT system enables Mobile/Fixed Communications Networks (MFCN) to provide additional Supplemental Downlink (SDL) which will increase downlink throughput to carry more data. However this band is already used by other technologies such as radio relay links, broadcasting networks and aeronautical networks. Nevertheless this frequency band is also allocated to mobile (except aeronautical mobile) service on a primary basis in Radio Regulations, however co-channel and adjacent channel electromagnetic compatibility have to be evaluated in order to identify possible harmful interference from currently existing services Electromagnetic compatibility between AMT and IMT is one of the most sensitive issues regarding the decision to designate this band to Mobile Services.

Frequency band in consideration for IMT identification is proposed only for downlink communication component hence in order to protect IMT system the study scenario will be limited to the case where only IMT user equipment (UE) receivers experiences the interference from telemetry system.

This paper compares two possible ways to evaluate the electromagnetic compatibility in co-channel operation between UE receivers of IMT system and airborne transmitters of AMT system based on Minimum Coupling Loss method and statistical Monte-Carlo method. The results show that the compatibility is feasible in particular configuration of mobile networks.

The Influence of Atmospheric Radio Refractivity on the WiMAX Signal Level in the Areas of Weak Coverage

M. Zilinskas[1, 2], **M. Tamosiunaite**[3], **S. Tamosiunas**[2], **M. Tamosiuniene**[3], **and E. Stankevicius**[4]

[1]Department of Radio Communication

[3]Center for Physical Sciences and Technology, Vilnius, Lithuania
[4]Vilnius Gediminas Technical University, Vilnius, Lithuania

Abstract— Radio refractivity of the atmosphere, N, is an important parameter in design of telecommunication systems. Gradient of N determines the curvature radius of the propagation path. Variations of N-value might influence propagation path and quality of the signal. The method for determination of N-value has been proposed by International Telecommunication Union (ITU). In the ITU method, the data of air temperature, pressure, and relative humidity are used.

As it was already emphasized in some papers, various phenomena in the radio wave propagation such as ducting, scintillation, radar acquisition, refraction and fading of electromagnetic waves are due to refractivity variations in the troposphere. Atmospheric refractivity consists of two parts — a dry term and a wet term. Therefore, the influence of weather conditions is significant.

Lithuania is situated in the intermediate zone between maritime Western Europe, continental Eastern Europe and Asia climates. Lithuania, being in the transitional geography zone from the Baltic Sea climate to Atlantic and continentals East Europe climate, distinguishes by variable humid climate. Therefore, it is very important to examine the meteorological impact on variation of the N-value, and reliability of the wireless networks, as well.

The data of measurements are presented. Reliability of the fourth generation wireless network (WiMAX technology) has been investigated. The power level of the received signal was continuously measured and compared to the calculated values of atmospheric radio refractivity. It was examined if changes of signal level and variations of the N-value occur at the same time. N-values were calculated using measured values of air temperature, pressure, and relative humidity. The long-term measurements were carried out at the same time and place. The experiment was carried out in an area of weak coverage.

It was concluded that in the areas of weak coverage WiMAX signals are strongly influenced by variations of the atmospheric radio refractivity.

Evaluation of LTE 700 and DVB-T Electromagnetic Compatibility in Adjacent Frequency Bands

G. Ancans[1], **E. Stankevicius**[2], **V. Bobrovs**[1], **and S. Paulikas**[2]

[1]Institute of Telecommunications, Riga Technical University, Azenes St. 12-201, Riga LV-1048, Latvia
[2]Vilnius Gediminas Technical University, Sauletekio al. 11, Vilnius LT-10223, Lithuania

Abstract— The 2012 World Radiocommunication Conference allocated the 694–790 MHz (700 MHz) band for the mobile service on a co-primary basis with other services in Region 1 (Europe, Africa, the Middle East). However, countries of Region 1 will also be able to continue the use of these frequencies for their digital terrestrial television services, if necessary. This allocation will be effective immediately after the WRC-15. The objective of this paper is to assess the electromagnetic compatibility of Digital Video Broadcasting-Terrestrial (DVB-T) operating below 694 MHz and mobile broadband (LTE) operating in 700 MHz band. The study contains an assumption of a preferred frequency division duplex (FDD) channelling arrangement which contains confined 2×30 MHz block: 703–733 MHz (uplink) and 758–788 MHz (downlink). The model consists of two elements, a LTE network and a DVB-T system. An adjacent channel scenario was analyzed in this paper: possible impact of LTE user equipment (uplink) to DVB-T receiver. The Minimum Coupling Loss method and Monte Carlo simulation within SEAMCAT software was used for interference analysis. The Minimum Coupling Loss method was chosen to calculate worst case (most conservative scenario) in order to understand most critical points of these two systems. The Monte Carlo simulations show more relaxed electromagnetic compatibility scenario. During simulations more appropriate propagation model was used (Recommendation ITU-R P.1546), which allows to analyse also non line of sight radio propagation conditions. The results obtained provide the minimum coupling distance required between LTE and DVB-T in the 700 MHz band to maintain the necessary performance level of the DVB-T system.

Möbius Strip with Back-to-back CPW Transmission Line: Simulation and Microwave Characterization

M. Sabrera and L. C. Kretly
Department of Communication, DECOM, University of Campinas, UNICAMP
Campinas, State of Sao Paulo, Brazil

Abstract— The objective of this work is to investigate special EM behavior of the Möbius Strip devices using simulation and measurements. This kind of device exhibit a series of interesting phenomenon not totally determined but, with practical applications. This work presents some insight into these behaviors by EM simulations using the method FIT, Finite Integration Technique adopted by some commercial software packages. The Möbius strip used in microwave band can exhibit a series of phenomenon, depending on the layout and engraved lines on it. The Möbius strip can emulate an infinite transmission line characteristics capable of retaining a large bandwidth frequencies, special resonators, and in a stritu sensu antenna or radiators. The Möbius strip is a one-sided non-orientable surface with Euler characteristic $\chi = 0$. Topologically, the Möbius strip can be defined as the square $[0, 1] \times [0, 1]$ with its top and bottom sides identified by the relation $(x, 0) \sim (1 - x, 1)$ for $0 \leq x \leq 1$. See Figure 1(a).

One of the most critical challenge related to the Möbius strip is how excite the device by means a connection to the generator. This problem was investigated by simulation and measurements with a VNA — Vector Network Analyser. Several Möbius strip devices were made with different length. A more sophisticated device based on Möbius strip topology is the CPW Back-to-Back Möbius Strip shown in Figure 1(a). Due to this special topology, antenna with Möbius strip configuration, if properly bisected could presents approximately the double of electrical length when compared with conventional ring radiators. This could improve, for example, miniaturization of RFID antennas. Several devices were simulated, fabricated and measured showing EM behavior as depicted in Figure 1(b).

Abstract— Optical fiber-based endoscopic laser technologies have been widely used for operation of the several minimally invasive medical surgeries such as prostatectomy, lithotripsy, varicose vein surgery, herniated disk surgery in modern medicine [1–4]. Recently, in addition to a frontal-firing optical fiber, a laterally light-emitting fiber probe has been required for more accurate medical operation. However, the several established methods to fabricate the lateral-firing configuration cannot be easily implemented due to complication of the fabrication process [3, 5].

In this study, we demonstrated a novel radial-firing optical fiber probe having capability of the side angle upto 87° to the direction of the fiber. The present radial-firing optical fiber probe was quite simply fabricated by electric arc-discharge process using a commercially available fusion splicer. A conventional optical fiber was spliced with a hollow optical fiber and then an intagliated conical shaped fiber region was formed by the gradual collapse of the cavity of the hollow fiber by discharging electric arcs of the fusion splicer. Then the end-face of the hollow optical fiber tip was arc-discharged again to form an air pocket, resulting in the uniform radial-firing of a laser beam ($\lambda = 632.8\,\text{nm}$) with the side angle upto 87°.

Abstract—

Background: The epidermal growth factor receptor (EGFR) is implicated in cytoskeleton kinetics and cell migration. EGFR oligomerization initiates its activationclosely relative to the actin cytoskeleton assembly (ACA). Our previous work has shown that a weak 50 Hz magnetic field (MF) induced EGFR clustering *in vivo* and *in vitro* and activated its downstream motility pathways, resulting in a weak actin-cytoskeleton and provoking the cell migration in several cell lines, suggests that the 50 Hz MF may enhance interactions among EGFRs and depressed the ACA.

Methods: Immunofluorescence and fluorescence resonance energy transfer (FRET) were used to inspect the MF effects on the ACA through exerting EGFR clustering under 0.4 mT, 50 Hz MF, and the field frequency dependent effect on the ACA under 0.4 mT MF of 35, 50, 70, 110, and 140 Hz at the protein/cell levels.

Results: Similar to EGF stimulation, the 50 Hz MF obviously enhanced the FRET signals among the EGFRs and declined the donor dye fluorescent intensity *in/ex vivo*, and induced the cellular EGFR clustering in FL, PC12, and CHL cell lines; however, significantly depressed both the ACA in cells and the FRET signal among actins. Furthermore, the ACA in FL cells were mostly depressed under both 50 Hz and 110 Hz MF exposures, not the other frequencies. These MF-induced EGFR-clustering/actin-cytoskeleton-depolymerization were obviously inhibited by a EGFR tyrosine inhibitor PD151015 (PD); Hill Plot of EGFR vs. [PD] found that the MF partially ease the PD inhibition, with increased K_d and IC_{50} values.

Conclusion: These results strongly suggest that the MF enhances the EGFR monomer clustering and eases the PD inhibition, but interrupts the actin assembly mechanism similar to EGF stimulation, possibly in a MF frequency dependent way.

Microwave Magnetoelectric Isolator-attenuator Based on Coplanar Line

A. S. Tatarenko, D. V. Lavrentieva, M. I. Bichurin, and D. V. Kovalenko
Novgorod State University, Veliky Novgorod 173003, Russia

Abstract— An electrically controlled magnetoelectric (ME) microwave isolator-attenuator based on layered ferrite-piezoelectric structure formed on a coplanar waveguide is considered. The simulations of different structures of coplanar devices are made for selecting of optimal waveguide and resonator characteristics.

The task of matching the microwave power source to the load is achieved by using nonreciprocal properties of ferrites. However, the non-reciprocal ferrite devices control the parameters realized by magnetic system, so these devices have low speed of operation, high power consumption and cannot be manufactured by integrated technology. ME non-reciprocal device can obviate the existing disadvantage of ferrite devices [1].

The difference between the ferrite devices and proposed ME nonreciprocal devices is to replace the ferrite resonator with magnetic control system by ME resonator and system of electrodes connected to the source of the control voltage.

Here we discuss the microwave isolator-attenuator. The basic design of ME isolator-attenuator is coplanar waveguide and ME resonators which have rectangular (or disks) composite samples based on lead zirconate titanate (PZT) — ittrium iron garnet (YIG). The permanent magnet creates a required magnetizing field in the area of ME resonator. The control voltage is applied to the electrodes.

The principle of operation of the isolator-attenuator based on microwave ME effect, is to shift the ferromagnetic resonance line under the influence of an electric field. ME layered structure in this case plays the role of a resonator. Shift of magnetic resonance line at applied an electric field is defined as $\delta H_E = AE$, where A is magnetoelectric coefficient; E is applied DC electric field.

The simulation of coplanar isolator-attenuator was made. That allows to get the selection of waveguide substrate parameters and the shape of ferrite and piezoelectric. For experimental verification of the simulations the coplanar device model was made. The ME resonator are based on layered structure of YIG with dimensions $13 \times 4 \times 0.9$ mm and PZT with dimensions $15 \times 4 \times 0.5$ mm. The coplanar waveguide has next parameters: the width of the gap $S = 3$ mm; distance between slits $W = 2$ mm; substrate thickness $h = 2$ mm; dielectric permittivity of substrate $\varepsilon = 10$. Isolation ratio was 20 dB. At applied an electric field $E = 10$ kV/cm, the shift of the resonance line corresponded 30 MHz.

To decrease the control voltage and the increase the valve ratio is necessary to reduce the thickness of the piezoelectric, and hence the thickness of the ferrite.

The use of ME structures in the resonant microwave devices allows electrical control of their parameters and opens promising opportunities of the new devices for functional electronics.

Modeling of Microwave Magnetoelectric Devices

A. S. Tatarenko and M. I. Bichurin
Novgorod State University, Veliky Novgorod 173003, Russia

Abstract— Computation, design and manufacturing technology of nonreciprocal microwave devices intended for application in receiving-transmitting modules of antenna array have a great interest in current time. Problems, which appear in design of integrated devices, and combine properties of several microwave signal-processing devices, are analyzed. The possibility for the development of a complex approach to designing and manufacturing of nonreciprocal microwave devices with improved radio-engineering characteristics is shown. The main directions for further research based on the use of modern computer design programs.

Currently, a large development have program High Frequency System Simulator (HFSS) of company AnSoft, which is designed for the analysis of three-dimensional microwave structures, including antennas and non-reciprocal devices containing ferrites and ferroelectrics. Electromagnetic simulation in HFSS is based on the use of the finite element method (Finite Element Method, FEM).

Passive microwave devices are units made of segments of transmission lines. In the microwave range used microstrip line, coplanar line and slot line. The microstrip lines most widely used [1]. However, at creating a non-reciprocal devices using ferrites it requires the microwave field of circular polarization. In microstrip line this region is absent and need additional elements, for example in the form of stubs to create area of circular polarization. From this point of view, the slot and coplanar line are of interest, because they contain the area of circular polarization. Also, all conductors at these types of lines are disposed on one substrate surface. The design of these lines is convenient for parallel connection of various lumped elements, including active semiconductor devices. The structure of the microwave field in the slot line and coplanar waveguide is significantly different from the structure of the wave field in microstrip line. If the area of the circular polarization of the magnetic field contains transversely magnetized ferrite, it is possible to create a non-reciprocal device.

The use of modern simulation software allows the fast design of various types of non-reciprocal microwave devices. We conducted a simulation of various types of non-reciprocal magnetoelectric devices based on slot and coplanar lines by using HFSS. A comparison with similar devices based on the microstrip line is made.

For example, the simulation of ME coplanar isolator-attenuator was made. That simulation allow to get the selection of waveguide substrate parameters and the shape of ferrite and piezoelectric. The ME resonator based on layered structure of YIG and PZT was used.

To decrease the control voltage and the increase the valve ratio it is necessary to reduce the thickness of the piezoelectric, and hence the thickness of the ferrite.

The use of computer simulation for ME structures in the non-reciprocal microwave devices opens promising opportunities for the creation of the new devices.

Equalization of EDFA Gain Spectrum and Increase of OSNR through Introducing a Hybrid Raman-EDFA Solution

S. Olonkins, **I. Lyashuk**, **V. Bobrovs**, **and G. Ivanovs**
Institute of Telecommunications, Riga Technical University, Azenes st. 16, Riga LV-1048, Latvia

Abstract— The main goal of this paper is to demonstrate the advantages of a hybrid Raman-EDFA optical signal amplification solution over the use of conventional EDFA amplifiers. To achieve this goal a simulation model of a 16 channel 10 Gbps DWDM transmission system with transmission distance of 180 km and an EDFA in-line amplifier, placed 30 km away from the receiver end, was introduced. The most promising solution of hybrid amplification is supplementing the existing discrete amplifier with a distributed Raman amplifier, as it not only can broaden and equalize the gain spectrum, but it also can increase the optical signal-to-noise ratio of the signal at the output of the amplifier and can provide higher level of amplification. The EDFA in-line amplifier was re-configured and supplemented with a distributed Raman amplifier with counter-propagating pumping. While configuring the hybrid amplifier the authors focus their attention on equalizing the gain spectrum in the wavelength region used for transmission of the 16 channels, and on obtaining higher values of optical signal-to-noise ratio for all channels. Simultaneously it was required to provide the level of amplification, which was required to ensure bit error rate below the 10^{-12} threshold in all channels. For the solution based on the single EDFA amplifier the gain for all channels has varied from 38 dB to 39.5 dB, but the hybrid amplifier has provided 38.4 ± 0.05 dB, therefore, the gain difference between the 16 channels was reduced from 1.5 dB to 0.1 dB. The obtained results have shown, that the implementation of the hybrid solution has allowed to increase the optical single-to-noise ratio by at least 1.7 dB in all of the channels.

Beam-footprint Detection for Non-cooperative Spaceborne/Airborne Bistatic SAR

Feifei Yan, **Wenge Chang**, **and Xiangyang Li**
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— In this paper, we consider non-cooperative bistatic SAR using aircraft as receiver and spaceborne radar as illuminating of opportunity. As there is no synchronization link between the transmitter and receiver, the transmitter beam-footprint should be detected in real time to realize beam synchronization. Theoretical analysis shows that the signal-to-noise ratio (SNR) of the reflected echoes from the observational area is too low to use the conventional detect method of linear frequency modulation (LFM) signal. According to the cross-correlation between the echoes of adjacent pulse repetition frequency (PRF) and M-out-of-N (M/N) detection, a beam footprint detection method is proposed in this paper. This method can realizethe accumulation of the signal energy and enormously improve the SNR of scene raw data. Therefore, it can be used for transmitter beam-footprint detection in real time.

The proposed method consists of the following two main steps:

1. Cross-correlation and CFAR detection. Since the observational area between the adjacent PRF is almost the same, so the adjacent backscattering echoes have high correlation. As noises between the adjacent PRF are irrelevant, there will be a peak value in cross-correlation result. So CFAR detection can be realized to determine whether signal exists. When transmitter and receiver achieve swath overlap of beam-footprint, the number of backscattering target is very large. Then peak value of cross-correlation result will be highly increased. So the performance of signal detection will be highly improved.

2. M/N detection. The cross-correlation result between the adjacent echoes cannot determine whether the received signal is LFM echo arisen from the spaceborne radar. As the signal bandwidth of the spaceborne radar can be get from the direct path signal, then M/N detection is performed after noncoherent integration to distinguish received signal between LFM signal and other signal in frequency domain. The proposed detection method can realize the accumulation of signal energy and enormously improve the performance of backscattering echo detection method.

Monte-Carlo simulation is carried out to test the performance of the proposed detection method. Simulation results show that the proposed method is superiority over the conventional detection method; meanwhile, the detection performance is gradually improved with the increase number of noncoherent integration. **Simulation results show that when the overlap between the beam footprints of the transmitter and receiver exceeds 10%, and the noncoherent integration numbers exceed 30**, the backscattering echo can be stably detected by the proposed method.

We also use raw data of one monostatic SAR to test the propose detection method equivalently. Monostatic SAR can be equivalently seen as the beam footprint overlap is 100% in bistatic SAR. Three kinds of scene echo are chosen to test the proposed method. The number of noncoherent integration is 30. Cross-correlation results show that there is an obvious peak value in cross-correation result, which is suitable for CFAR detection. At the same time, the bandwidth of noncoherent integration result is coincide with the bandwidth of the transmitter. The detection probability of homogeneous scene is slightly higher than heterogeneous scene; meanwhile, as the beam footprint overlap of monostatic SAR is 100%, so the detection probability is very high.

Studies of the RF Energy Delivery Mechanism and Its Reformation in the Low Pressure ICP Discharge

A. F. Piskunkov and V. A. Riaby
Research Institute of Applied Mechanics and Electrodynamics of the Moscow Aviation Institute (National Research University), Moscow, Russia

Abstract— The model of a cylindrical inductively coupled plasma (ICP) discharge based on movable current layers travelling towards the axis of discharge space from the steady-state skin sheath at the external plasma boundary has been proposed. Current layers act like magnetic electrostatic traps catching electrons with small pinch-angles that are responsible for gas atom ionization. Movement of the layers induces electric field excites currents. At the optimal driving frequency magnetic field of a definite sign fills all discharge space during current half-period in the process of convective diffusion and eventually it is replaced by the field of opposite sign. Ohmic losses in the current layers are compensated by annihilation of magnetic field. The layers are formed by the Hall Effect while their boundary areas are shaped in a forceless magnetic field. They have form of one-turn spirals and their pairs are short-circuited in the edge plasma areas.

Concentration of trapped layer particles is determined from the equation for trapped electrons entering and leaving the layer by way of single-shot Coulomb collisions at the pinch-angle.

Discharge power loss, ion energy price and electron temperature are calculated at different argon pressures for the discharge chamber of 35 cm external radius. Comparison with published experimental data showed that the proposed model satisfactorily describes the main ICP discharge characteristics.

Single Feed Dualband Miniaturized E-shaped/U-slot Patch Antenna

Abstract— This letter presents the design of dual band microstrip patch antenna. This antenna is with single layer E-shaped patch loaded by two U slots. The −10 dB return loss impedance bandwidths of 2.26% and 1.91% are realized at center frequencies of 10.94 GHz and 13.06 GHz, with gains of 9.12 dBi and 8.54 dBi respectively. The radiation patterns are also presented. Compared with the published results of the similar scenario, in this design the size is reduced. The design guidelines are provided.

Abstract— Wireless technology is an indispensable part of modern lifestyle. The exponential increase in the use of wireless transmission in varied forms of gadgetry has posed a grave interest in RF functionality producing circuits and systems. The most prominent and promising solution the wireless transmission and microwaves technology have been through RF MEMS, they produce radio-frequency through resonating cantilevers.

RF MEMS are Microelectromechanical devices that produce radio waves for wireless transmission and other applications, these are quintessential in modern circuitry for providing RF functionality. The MEMS devices are fabricated using SiO_2 and Si_3N_4 along with other insulators. The electrostatic charging in these materials poses a challenge to reliability and performance of MEMS devices. Also, the irradiation due to Electromagnetic waves contributes significantly to this phenomenon.

The semiconductor when subjected to irradiations produces electrostatic charge that may get absorbed and hence produce a charging in the device that can alter the dynamic behavior of the device. This effect is profound when the devices are exposed to ionizing radiations.

This paper is a study of the behavior of the cantilever beams under the influence of Electromagnetic Radiation/ionizing radiation and its effect on the working and efficiency of RF MEMS especially for medical devices where RF MEMS components are used. Also, the sensitivity of RF MEMS devices towards electromagnetic irradiation is studied. Varied irradiations were studied

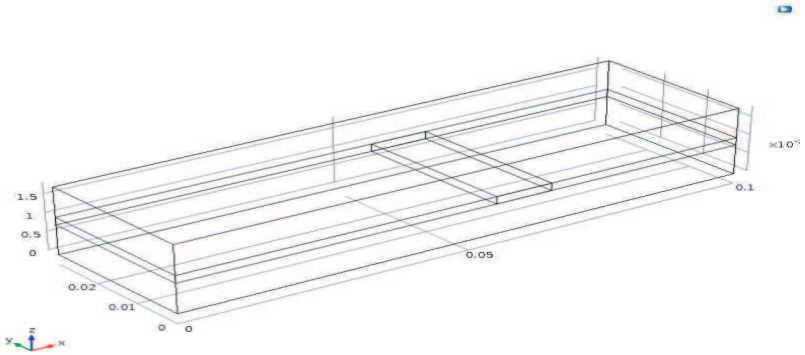

Figure 1: Test structure.

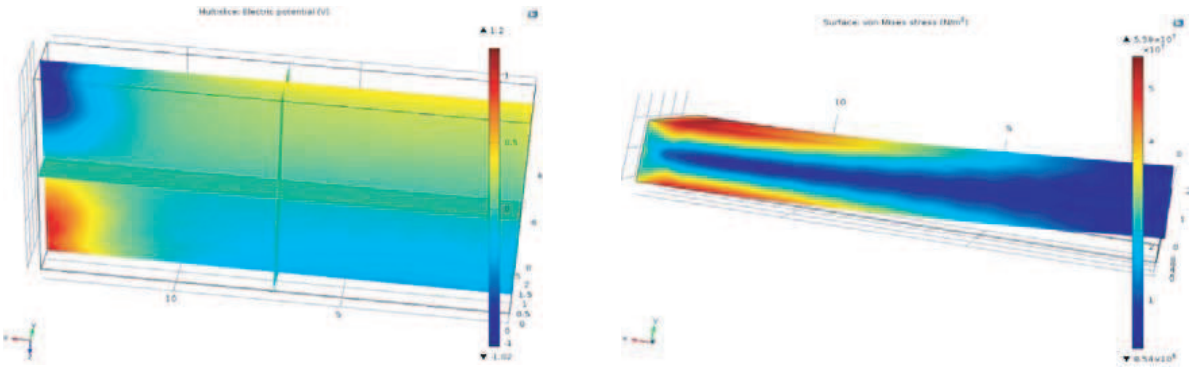

(a) (b)

Figure 2: (a) Voltage distribution across the whole structure. (b) Displacement.

and their effects on the materials were recorded through simulations using multiphysics simulation software.

Figure 1 shows the part of resonator which is in the shape of cantilever and was tested for the material properties. Different Piezoelectric materials were used for testing the structure. Figures 2(a) and (b) show voltage distribution and displacement produced across the whole test structure.

It was observed that the behavior of the RF MEMS devices changes drastically with the change in type of different piezoelectric materials used. In the present case Zinc Oxide, Lead Zirconate Titanate (PZT-2) and Quartz were used. The effect of EM radiations were also evlauted.

Performances Evaluation of a Magnetic Gear with High Transmission Ratio Used for High Speed Applications

D. Fodorean[1], **C. Irimia**[2], **and P. Minciunescu**[3]

[1]Technical University of Cluj-Napoca, Romania
[2]Siemens Industry Software, Romania
[3]ICPE SA, Romania

Abstract— The paper presents a study of a magnetic gear used for high speed applications, and its performances are analytically and numerically evaluated.

The advantages of the magnetic gear (MG) are clear: There is no need for lubrication, no local heat (and losses) due to teeth contact and no risk for teeth breaking. Moreover, a MG offers a higher range of use since for high transmission ratio there is no need to link 2, 3 or more gears together; thus, globally, the efficiency and power density are improved. Besides, with a specific configuration of the MG is possible to obtain smooth mechanical characteristics — i.e., torque and speed.

The attention of the designer, when dealing with a MG, is focused on the used materials, especially the permanent magnets and the active steel. Here, several rear-earth and non-rear-earth materials will be evaluated for the excitation of the MG, as well as different steel materials and sheets thickness. Different magnetization variants will be evaluated too. It is clear that the main loss component is in the active iron, but for high speed applications the mechanical loss component cannot be neglected. All these elements will be investigated by looking also at the torque wave characteristic, which should be as smooth as possible. Thus, we will have a complete picture of the efficiency and performances of the proposed high transmission ratio MG, used for high speed applications.

The main data of the application under study are: 22 kW for the output power, input speed is 26'000 r/min and the output speed is 1625 r/min, meaning that the transmission ratio is 1/16.

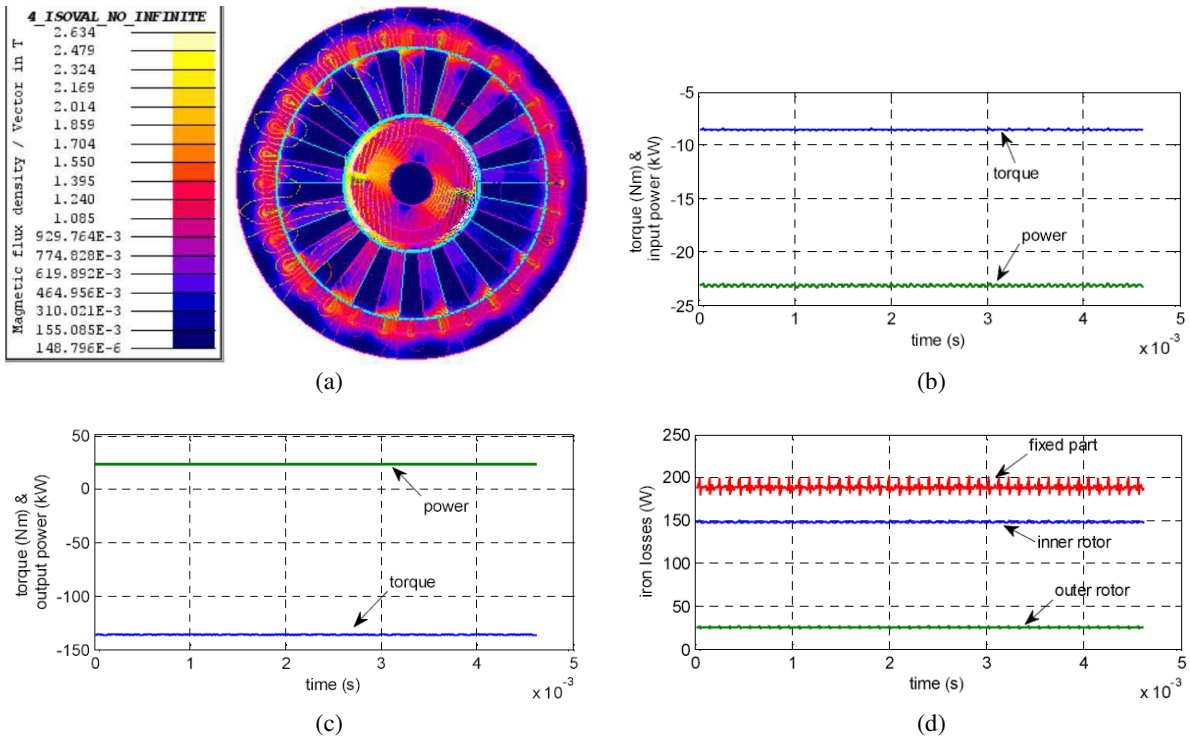

Figure 1: (a) The field and flux density distribution in the active parts of the MG; (b) input torque and power; (c) output torque and power; (d) iron losses in the MGs active parts.

Preliminary results of the numerically analyzed MG are presented in Fig. 1. Here, the flux density distribution, the input & output power and the iron losses are presented. It worth notice that

the input power is negative, since the inner rotor (high speed one) receives, externally, the input torque. On the other hand, the output power is positive since the outer rotor (low speed one) rotates in oposite direction. Very smooth mechanical characteristics are obtained with this MG configuration. Also, the iron loss level is low: the inner rotor, outer rotor and fixed part poles iron losses are plotted in Fig. 1. *More results and conclusions will be presented in the final paper.*

Visible Light Communication between Moving Objects Using a Camera Receiver

Jiri Libich[1], **Stanislav Zvanovec**[1], **and Zabih Ghassemlooy**[2]

[1]Department of Electromagnetic Field
Czech Technical University in Prague, Prague 166 27, Czech Republic
[2]OCR Group, Northumbria University, Newcastle-upon-Tyne NE1 8ST, UK

Abstract— Visible light communication (VLC) has attracted attention of many researchers in the last years. New technology enables to use light emitting diodes (LED) as light sources in many applications from illumination of rooms, street lighting to car lights and many more. These light sources are characterized mostly by their lower power consumption, relatively higher energy efficiency, switching capability and much wider bandwidth compared to incandescent bulbs. Hence LEDs are suitable not only for illumination but also for data transmission as well as localization [1–3].

Typical communications scenario involves a data source, driver, transmitter, detector, transimpedance amplifier and decision circuit. This arrangement is not suitable for communication where both objects can move and the setting of the system needs rapid adaptability in time. Camera based receiver can capture the entire scene present in its field of view and acquire the information data by means of image sequence processing. This dual purpose detection technique also offers a unique feature, the multiple input and multiple output (MIMO) capability supporting multitude of sources simultaneously. Nowadays, almost every smartphone and many new cars come with a camera which can be also used for data communication. However, camera based communication offers a low data rate because of the low frame rate of standard low cost cameras. Thus, it makes them attractive for car-to-car communications, financial transaction, low data rate navigation, and low content advertisement etc..

This paper aims to experimentally demonstrate the concept of VLC communications with the camera as a receiver (see in Fig. 1). The transmitter is composed of white LEDs that are intensity modulated. At the receiver the output of the camera is processed using Matlab to extract the data information from the captured image. The system performance is validated in terms of the bit error rate performance under the degraded channel conditions and for a number of LED configurations.

An Efficient Progressive Phase Distribution Consideration of Reflectarray Antennas

M. Y. Ismail and M. Inam
Wireless and Radio Science Center (WARAS)
Universiti Tun Hussein Onn Malaysia, Batu Pahat, Johor, Malaysia

Abstract— Reflectarray is a high gain antenna which combines the unique features of a flat reflector and an array of microstrip patch elements printed on a thin dielectric substrate. It is illuminated using a primary feed horn placed at a particular distance from the array. The reflectarray exhibits a number of significant advantages over conventional parabolic reflector and phased array antennas such as easy deployability, lower manufacturing cost, scannable beam, and surface mountability with lower mass and volume. Due to these growing numbers of advantages, reflectarray has been considered as a potential alternative to the parabolic reflector and phased array antennas.

The most important aspect of reflectarray antenna design is the design of printed microstrip elements which can be used for the performance appraisal of the antenna. The individual elements of the periodic array have to be designed with progressive phase distribution so that the spherical beam from the horn antenna can be converted into a planar wavefront. The required reflection phase values from individual elements of an array also depend on the location of the feed horn. For proper phase requirements, different techniques such as, identical patches of variable-length stubs, square patches of variable sizes, identical planar elements of variable rotation and identical rectangular patches with different types of slot configurations have been used. All these phasing techniques increase the possibility of reflectarrays to become an alternative option to the parabolic reflectors. However one of the main concerns of a reflectarray antenna is its limited bandwidth performance as compared to the parabolic reflector antennas. Different configurations have been proposed by researchers in the past few years for the bandwidth improvement of reflectarray antennas but considerable efforts are still required to improve the bandwidth performance of reflectarrays.

This paper provides a novel and efficient procedure for the X-band reflectarray antenna design emphasizing on the progressive phase distribution which is required to achieve the planar wave in front of antenna aperture. Detailed theoretical procedure has been provided with mathematical modeling of the required reflection phase from each of the individual reflectarray elements. The importance of material properties in reflectarray antenna design has been highlighted and different novel design configurations has been proposed for the unit cell reflectarray elements. Scattering parameter measurements and simulated results provide a very close agreement for different slot embedded designs proposed in this work. Two different configurations of mixed rectangular and circular slots embedded patch elements have been investigated. The variation in width of slot in the case of three rectangular slot patch configuration, the measured reflection loss varied from 2.89 dB to 5.60 dB while in the case of mixed rectangular and circular slot configurations, measured reflection loss is varied from 7.90 dB to 5.60 dB by varying the radius of circular slot. Moreover a maximum frequency variation of 2.58 GHz and a dynamic phase range of 345° with the variation in slot dimensions have also been demonstrated.

Problems of Statistical Decisions for Remote Monitoring of the Environment

F. A. Mkrtchyan
Institute of Radioengineering and Electronics, RAS
Vvedensky sq. 1, Fryazino, Moscow Region, Russia

Abstract— In connection with technical progress and growth of the population of a planet the anthropogenic stress on biosphere sharply amplifies. Therefore the role of remote monitoring allowing sharply raises to receive an estimation and the forecast of anthropogenic changes, to reveal sources of influence and the reasons of these changes. Modern scientific and technical level gives sufficient means for remote monitoring.

The basic sense of the concept of remote monitoring consists in connection in system of means of data gathering, methods of their processing, mathematical models of natural objects, computer implementers of algorithms and models with a wide spectrum of service maintenance at visualization of results of monitoring. Now wide development in the world is received by multichannel monitoring systems of remote basing. These systems occupy an important place for the study of sea surface.

The technique of detection offered in given work and identification of the abnormal phenomena in the water environment (microwave and optical) combines presence with application of possibilities of remote measurements algorithmic and the software, allowing to solve measurement and detection problems in real time. The effective decision of these problems is impossible without wide introduction in practice of researches of the automated systems of gathering, storage and data processing on the basis of modern computer systems with application of technology of open systems. Already created methods and algorithms possess ability to overcome such difficulties, as scantiness and not stationarity information, presence small statistically non-uniform samples.

It is obvious that complex research of the given land and remote measurements can raise reliability of estimations of parameters of natural systems and solve a problem of planning of these measurements. Application of means of remote monitoring in many cases is connected with acceptance of the statistical decision on presence on a surveyed part of studied space of this or that phenomenon. One of features of conditions of gathering of the information for such decision is the impossibility of reception statistical samples great volumes. Therefore working out and research of optimum algorithms of distinction of the casual signals characterized by samples of the limited volume, in the conditions of parametrical aprioristic indefinite are necessary.

One of the important features for the detection and classification of phenomena on the sea surface of the sea is a "spottiness" of the sea surface. Therefore the study of the statistical characteristics of "spottiness" is important. In this paper the analysis of the statistical characteristics of "spottiness" for certain areas of the Atlantic, Pacific and Arctic oceans. These statistical characteristics were determined for the most informative thresholds.

Simulation Evaluation of the IEEE 802.11ac ad-hoc Network for Voice Communication in Emergency Scenario

J. Jarmakiewicz, K. Maślanka, and K. Parobczak
Military University of Technology in Warsaw, Poland

Abstract— The paper presents simulation study of a voice communication system consisting of mobile nodes during crisis situation scenario. Nodes' network interfaces work in compliance with the IEEE 802.11ac standard in ad-hoc mode, while smartphone devices operate under control of the Google Inc. Android operating system.

Overview of current Wi-Fi techniques was described, with respect to current mobile market shares and an indication of further standard evolution. Limitations of the current Wi-Fi ad-hoc mode implementation in the Android operating system were addressed, with emphasis on ongoing research projects oriented toward overcoming specific wireless communication protocols restrictions: the Wi-Fi Peer-to-Peer extension and a multi-hop transmission. Studies of power management issues were conducted, with particular attention to sustain reliable conditions in case of multiple "exposed" and "hidden" terminals phenomenon.

An evaluation of network efficiency with Voice over IP service activity during an emergency scenario was performed in a simulation environment. Lack of cellular connectivity, no external power access and no special communication equipment availability during rescue operation were assumed. About 50 smartphone mobile nodes, randomly placed across a 150-meters radius area, participate in voice-data exchange, with possibility to relay frames through one intermediate node (two-hop transmission mode) or through two or more intermediate nodes (multi-hop transmission mode).

Obtained results show insignificant impact of service realization on network resources utilization, low maximum end-to-end packet delivery delay and jitter values during continuous telephone conversations. Thus, described assessment shows high degree of IEEE 802.11ac ad-hoc network applicability in scope of basic voice communication service realization, in case of absence of usually ubiquitous cellular infrastructure, when only typical communication equipment is available. Future works are focused on implementation of developed custom software solutions in order to confirm obtained results in laboratory conditions.

Improvement of the Radiated Immunity Test Using a Broadband Signal

[3]Department of Electronic Engineering, Chungbuk National University, South Korea

Abstract— In this paper, we have investigated improvement of the radiated immunity test using a broadband signals. We have analyzed the recent standardization activity related with radiated immunity test based on IEC 61000-4-3 and have proposed a new test method using digitally modulated broadband signals to improve the testing time and frequency step. The possibility of this new test method has been practically verified through a radiated immunity test on GTEM cell. The results show that the devices were influenced same or much more by digital modulation signal than by AM or PM signal. It shows that we can use the broadband signal for a radiated immunity test and it is possible to improve the RS test using new method.

Study of a Wide-band Strip Line Couplers' Susceptibility Based on the Number of Transmission Lines with Non-uniform Impedances

Javad Soleiman Meiguni and Ehsan Faalpour
Faculty of Electrical and Computer Engineering, Semnan University, Semnan, Iran

Abstract— Hybrids and couplers are commonly used in the microwave applications as very important elements. These elements are made of various forms and used at the specific applications. The strip line structure is one of the cheap structures for couplers and hybrid's design due to their less radiation loss and interference on the micro strip. Presented is a wideband stripline directional coupler which is of interest in any measurement application. The susceptibility parameter of this coupler at 2–6 GHz band, have been reported based on the number of transmission line with non-uniform impedances.

Fluctuations of GPS-derived Atmospheric Integral Water Vapor versus Ground Meteoparameters Variability

O. G. Khutorova, **G. M. Teptin**, **V. E. Khutorov**, **V. V. Kalinnikov**, **and A. A. Jouravlev**
Kazan federal University, Russia

Abstract— Water vapor is one of the most important constituents of the troposphere which effects the weather in various ways. Water vapor is a greenhouse gas. Over the past decades, considerable progress has been made in satellite navigation systems monitoring technology, which is significantly increasing the atmospheric information. The integral water vapour (IWV) is an important parameter of the atmosphere and directly or indirectly reflects the weather processes and variations.

This paper presents a hardware and software complex for continuous measurements and prediction of atmospheric thermodynamics. The main part is a network of ground-based spatially separated GPS-GLONASS receivers, which allows the remote sensing zenith tropospheric delay one per second. The network of weather stations measure meteorological parameters at the same points synchronously and allows determining the integrated humidity. Comparing the results with remote sensing data of weather stations, radiosonde and reanalysis showed good agreement. GPS-Derived integral water vapor shows the mesoscale spatial and temporal fluctuations and its seasonal variability. Variations of atmospheric integral water vapor were found. Greatest intensity as mesoscale and diurnal IWV variations observed in summer and the minimum — in the winter. Intensity IWV fluctuations in the summer is 21% higher, and in winter 13% less than in other seasons. A relationship with the fields of humidity and pressure fields of wind speed is found.

Steady-state Analysis of Permanent Magnet Synchronous Machine for Integrated Starter-alternator Applications

Florin Jurca and Daniel Fodorean
Department of Electrical Machines and Drives, Technical University of Cluj-Napoca, Romania

Abstract— Due to their high efficiency and reliability, permanent magnet synchronous machine became more and more used in the automotive applications in the last decade. There are two main reasons for this trend: the reduction of the fuel consumption and the increase of the travel comfort. In this study we consider the approach of the electromagnetic design of a special topology of permanent synchronous machine (radial flux machine with outer rotor) suited for automotive applications.

A preliminary design procedure will be presented and its results will be used in order to perform a numerical analysis using finite element method in order to analyze the performances of the machine: magnetic field density, saturation level, torque, distribution of magnetic flux density in the air-gap. Starter-alternator applications require operation at high speed in the generator regime. This is a sensitive issue for any type of electrical machine, since by increasing the frequency the iron losses increase considerably with a negative effect on efficiency value. In order to reduce these effects we consider the possibility to use various materials capable of operating at high frequencies. The main drawback of the permanent magnet synchronous machine (PMSM) is the price of rare earth permanent magnet. In this context it is necessary to investigate for this type of machine the use of new types of advanced materials in the construction of magnetic core in order to maintain a low cost for PMSM construction at high energy efficiency and the use of considerably weaker permanent magnets than those of rare earth type.

The thermal behavior is another problem in the automotive application. For this machine we have developed a thermal model in order to study the thermal stresses as a consequence of the level of losses (iron, copper), in conditions of high temperatures of ambience for the vehicles with internal combustion engine.

Prediction of Temperature and Stress in a Multi-stage Depressed Collector under Different Enviornmental Conditions

Vishant Gahlaut[1] and Sanjay Kumar Ghosh[2]

[1]Department of Physics, Banasthali University, Banasthali, Rajasthan, India
[2]CSIR-Central Electronics Engineering Research Institute (CEERI), Pilani, Rajasthan, India

Abstract— Increasing requirement of traveling-wave tubes (TWTs) with miniature size, less weight, high efficiency, high power, high gain, etc., increases complexity of packaging for thermal modeling. Specially, high power TWTs has to have very good heat dissipation from its sub-assemblies, specially, from the collector where the spent beam is collected (Figure 1) [1]. Moreover, collector, may be, conduction and or radiation cooled, should have metallic jacket or packaging such that weight should be less with efficient cooling which is very much important for TWTs is to be used for space applications. In this paper authors have temperature distribution and stress developed, during operation, in a multi-stage depressed collector for typical space applications.

In this paper, temperature distribution in different electrodes has also been studied under different environmental conditions. However, under the extreme condition, say, at 80°C, the temperature in all the collector electrodes in much more compare to other two conditions and which needs to be proper packaging of the TWT. Moreover, expansion of electrodes and stress developed at different braze joints have also been studied. Heat dissipation, expansion and stresses developed among the collector electrodes in a typical MDC, under different environmental conditions, under development for space applications. Present study has been made using COSMOS which provides one screen solution for thermal, stress, frequency and harmonic analysis. It has post processing options to give the results as per convenience. 3-D model of the complex geometry with symmetric is constructed in Solid Works [2] and imported in COSMOS finite element analysis (FEA) [3].

Study on Thermal-mechanical Issues of Co-axial Interaction Cavity for High Power Gyrotron

Vishant Gahlaut[1], **A. R. Choudhary**[2], **and S. K. Ghosh**[2]

[1]Department of Physics, Banasthali University, Banasthali, Rajasthan, India
[2]CSIR-Central Electronics Engineering Research Institute (CEERI), Pilani, Rajasthan, India

Abstract— The fast wave microwave tube, gyrotron, as a source of high-power microwave radiation, plays an important role in controlled thermonuclear fusion energy research and is found to be an efficient tool for heating of magnetically confined fusion plasmas (electron cyclotron resonance heating), to drive a noninductive plasma current Electron Cyclotron Current Drive (ECCD) and to suppress instabilities in the plasma [1]. As this device deals with very high thermal loading hence, efficient thermal management of gyrotron and its constituent parts is very important.

In this manuscript thermal-mechanical analysis of co-axial interaction cavity operating in $TE_{22,8}$ mode has been presented using the ANSYS code. The analysis of temperature built in the cavity and the study of its structural deformation has been carried out in order to address the thermal and mechanical issue which arises due to the heat dissipation at the cavity wall. In the interaction cavity, some amount of RF power is lost due to the finite electrical conductivity of material (called as ohmic wall loss). The ohmic wall loss for the above mentioned operating mode has been calculated. A 3-D interaction cavity with and without grooves has been modelled in ANSYS Workbench 10.0. In the simulation, the conduction mechanism is applied to transfer the heat from inner wall to outer wall of the interaction cavity whereas from outer wall to the coolant, convection mechanism is applied. The DI water (288K) has been used as a coolant. Iterating repeatedly, the heat film coefficient, the hydraulic diameter and the water flow rate have been optimized. Figure 1 shows the 3D cross sectional view of the co-axial cavity with radial grooved for the above mentioned optimized values of the thermal parameters.

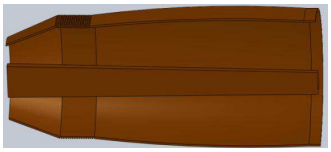

Figure 1: Cross-sectional view of co-axial cavity.

[3]Institute of Optoelectronic Technology, China Jiliang University, Hangzhou, China
[4]School of Electrical & Electronic Engineering, Nanyang Technological University, Singapore

Abstract— An erbium-doped fiber laser with low coherence, low threshold, high efficiency and narrow linewidth is demonstrated for the first time based on distributed feedback from a fiber Bragg grating (FBG) array. The FBG array contains tens of FBGs with identical Bragg wavelength but very weak reflectivity of ∼1‰, inscribed along a normal single-mode fiber with random separations. Low pump threshold power of 3 mW and high slope efficiency of 24% are achieved, which are comparable with that of normal erbium-doped fiber lasers but much better than that of conventional random fiber lasers based on distributed Rayleigh scattering.

Antenna Factor Measurements for Electrically Small Antennas Immersed in a Lossy Medium

R. Mouthaan and B. Loader
National Physical Laboratory, UK

Abstract— Wireless body area networks are increasingly being leveraged to try to provide telemedicine solutions to contemporary healthcare problems. Applications include heart rate monitors, accelerometers and temperature sensors, whereas implanted technologies include pacemakers, glucose sensors and insulin pumps. Both body-mounted nodes and the implanted nodes present measurement challenges when the antenna and communication link are considered. It is important to simulate the presence of the body by or around the antenna when trying to characterise its resonant frequency, bandwidth, channel performance or radiation pattern. This is done using a phantom with similar permittivity ϵ and conductivity σ to the human body. Measuring the antenna factor of an implanted antenna presents further challenges, and these shall be discussed and addressed.

The antenna factor of an antenna is defined as the electric field required to induce a unit voltage across the terminals of the antenna. The antenna factor is a function of the design of the antenna and also of the properties of the surrounding medium. In the case of a lossy medium such as a phantom it can be difficult to correct the free-space properties to obtain an accurate description of how the antenna would behave once immersed. Instead, an antenna intended for use inside a lossy medium must be directly calibrated inside the medium.

A standard field method using a matched waveguide system (Fig. 1) is proposed here. Exciting the input port of the waveguide with a known voltage allows the electric field induced inside the liquid to be calculated. The antenna under test can then be introduced into the known field and the antenna factor calculated from the voltage induced across the terminals of the antenna. Using a network analyser allows the antenna factor of the antenna under test to be measured across the entire waveguide band. The described system operates in the 490 MHz to 750 MHz range, but the relevant theory can be applied to different waveguide sizes.

An electrically small dipole antenna is used as a test antenna for which the antenna factor is measured at a number of heights inside the liquid section of the waveguide. The antenna factor is calculated by taking a weighted average of the individually measured antenna factors. The weighting factors used are based on the uncertainties associated with each individual measurement. The approaches used to calculate both the uncertainties associated with the individually measured antenna factors and the uncertainty associated with the average antenna factor shall also be presented.

Analysis of Optimized Embedded Antennas Using Radiation and Energy Storage Modes

K. R. Schab and J. T. Bernhard
University of Illinois at Urbana-Champaign, USA

Abstract— In many wireless devices, antennas occupy small volumes embedded within a larger device volume also containing circuit boards, screen components, batteries, and other antennas. These are frequently referred to as embedded antennas and often analyzed as electrically small antennas mounted on or near other conducting scatterers. Several approaches have been taken to incorporate contemporary electromagnetic theory (such as source-based Q calculations and characteristic modes) into the optimized design of such antennas. Many of these techniques are based heavily on the use of method of moments solvers. As such, a common step in many analyses is subdomain reduction, by which a fixed component of the system (e.g., a circuit board acting as a finite ground plane) is modeled as a distributed load on the antenna being optimized. In this way the order of computation can be greatly reduced by removing the need to reanalyze the ground plane during each iteration. However, this reduction also removes the intuition and potential design improvements to be gained by leveraging the innate properties of the chassis or finite ground plane.

In this presentation, we present the analysis of electrically small antennas and finite ground planes using radiation and energy storage modes derived from method of moments based radiation and energy storage operators. We discuss and give examples of using these modes in the analysis of single embedded antennas and multiband, collocated multi-antenna systems produced by various optimization methods. In particular, we use these modes to understand the role of finite ground planes and other internal scatterers in designing for parameters such as reactive current localization, pattern diversity, and pattern reconfigurability. We then propose methods to efficiently specify such properties as additional costs in optimization routines for antenna design.

A Universal Method for the Design of Antenna Arrays

Geyi Wen
Research Center of Applied Electromagnetics
Nanjing University of Information Science and Technolgy, Nanjing 210044, China

Abstract— The major target of antenna designs for telecommunication systems is to achieve maximum possible power transfer between the transmitting antenna and receiving antenna in the systems. For this reason, the power transmission coefficient between two antennas, which is defined as the ratio of the recived power to the transmitting power, can be used as a performance index or a target function for antenna designs. In this presentation, we demonste how the power transmission coefficient may be used to design antenna arrays in complicated envirionments for various purposes, such as beam steering, energy focusing, patten systhesis etc.. The design process is based on the optimization of the power transmission coefficient betwee the antenna arrays to be desgined and a testing antenna introduced in the desired direction in which radiation must be enhanced. The power transmission coefficient may be expressed as a Rayleigh quotient, by extremizing which an eigenvalue equation can be obtained. The solution of the eigenvalue equation gives the optimized distribution of excitations for the antenna arrays in the specified direcition. The optimized distribution may be realized by various feeding techniques. A number of design examples for various applications are expouned to illustrate the design procedure.

Optimal Array Antennas for Mask-constrained Shaped Beams: A Review

T. Isernia and A. F. Morabito
DIIES, University 'Mediterranea' of Reggio Calabria, Italy

Abstract— A huge amount of synthesis problems could be defined for arrays according to the degrees of freedom one has at his/her disposal (excitations, locations, excitations and locations, and so forth) and to the kind of pattern one wants to realize (pencil, difference, shaped, reconfigurable) [1]. In all cases, one is interested in a kind of 'optimal' synthesis, which means to optimize some performance parameters for given resources (and constraints) or, vice versa, to minimize the resources, e.g., the number of elements, for given radiation performances and constraints.

In order to enlarge the degrees of freedom available to the designer, specifications in terms of a 'mask' for the power pattern have to be preferred to the pursuit of a fixed (field or power) nominal pattern.

In [2, 3] it has been shown that the optimal synthesis of a mask-constrained shaped beam by means of a uniformly-spaced array can be conveniently tackled in terms of a linear programming problem (establishing the feasibility of the given problem) followed by a factorization allowing to determine all the possible solutions to the given problem.

Recent extensions of the basic theory include a class of planar arrays [4] as well as the synthesis of circularly symmetric planar apertures radiating shaped beams [5]. Interestingly, the capability to get all the different solutions has allowed establishing a new framework for the optimal synthesis of reconfigurable arrays [6], as well as to choose particularly convenient reference solutions for the case where locations and excitation phases (rather than the complex excitations) are the degrees of freedom of the synthesis problem [7].

Contribution will briefly discuss basics, relevance (per se as well as for creating reference solutions for more cumbersome synthesis problems), and possible extensions of the results above.

Antenna Q and D/Q Bounds for Small Antennas with Electric and Magnetic Sources

B. L. G. Jonsson[1] and M. Gustafsson[2]

[1]Electromagnetic Engineering Lab, School of Electrical Engineering
KTH Royal Institute of Technology, Stockholm, Sweden
[2]Department of Electrical and Information Technology, Lund University, Lund, Sweden

Abstract— Small antennas are today an essential part of data and voice communication and they appear in, e.g., cellular phones, computers, watches, clothes and shoes. Often there are constraints on the physical size of these antennas, and worse they are also often electrically small. The smallness is known to limit the available matching bandwidth of the antennas. It is therefore interesting to examine the essential elements in this type of bandwidth limitations.

The physical bounds on bandwidth of small antennas have had some recent development. It was shown in [1], that passivity as a system property yields on set of bandwidth limitations on the absorption cross-section. For small antennas with separate resonances this bound can be expressed in terms of the partial directivity over the antenna quality factor, D/Q.

The classical Chu-bound for antennas bounded by a sphere use both electric and magnetic sources. An alternative approach to passivity based bandwidth bounds is to dene a stored energy for small antennas [2]. Using such an approach it is possible to obtain bandwidth limitations on the antenna Q and on D/Q. In our recent paper [3], we proposed a method of how to include both electric and magnetic sources in the bounds on antenna Q. In the present paper we compare optimal D/Q with optimal antenna Q in the presence of both electric and magnetic sources. Each of these problems results in explicit optimization problems, which strongly depend on the enclosing geometry of the antenna and the choice of sources in the domain of the antenna. The D/Q optimization is a convex problem, and the optimal Q-problem is an eigenvalue problem. Analytical and numerical solutions are shown.

Topology Optimization of Wideband Directive Antennas

Emadeldeen Hassan[1], **Daniel Noreland**[1], **Robin Augustine**[2], **Eddie Wadbro**[1], **and Martin Berggren**[1]

[1]Department of Computing Science, Umeå University, Umeå SE-901 87, Sweden
[2]Ångström Laboratory, Department of Engineering Sciences, Uppsala University, Sweden

Abstract— There is a growing interest in using microwave detection and imaging systems, especially for medical applications. Wideband directive antennas are key elements for such systems to function efficiently. There are only few antenna types that are characterized as being wideband and directive. One example is the famous Vivaldi antenna introduced by Gibson [1]. These antennas can be described with a small number of parameters, which limits the possibility to find satisfactory designs by optimizing only these parameters.

On the other hand, topology optimization techniques allow parameter-free optimization to the whole layout of a device hosted in a given design domain. In other words, to optimize a specific objective function, topology optimization techniques decide on each point in a given design domain whether to hold void or a predefined material. Topology optimization was first introduced for structural optimization [2]. Recently, the approach has been extended to design various antenna types [3–5].

Here, we present a topology optimization approach to design, from scratch, wideband directive antennas for the purpose of near-field sensing. The antenna design is formulated as an optimization problem with the objective to maximize the coupling coefficient between two neighbouring antennas separated by a specific distance, and also to minimize the reflection coefficient of each antenna. We use the FDTD method to numerically solve the 3D Maxwell's equations and the design variables are the local conductivity at each Yee edge in a given design domain. Design problems with more than 100,000 design variables are solved, in less than 200 iterations, by using a gradient-based optimization method. The objective function gradient is computed based on solutions to an adjoint-field problem, which is also a FDTD discretization of Maxwell's equations but with a different excitation. For any number of design variables, the objective function gradient can be computed with only two FDTD simulations. The optimization problem is solved iteratively through solutions to a series of subproblems, in which the design variables are updated by using the globally convergent version of Svanberg's Method of Moving Asymptotes [6].

By using this approach to design planar antennas, we obtain novel antenna topologies that show wideband directivity and matching over more than two octaves. When used to detect a nearby phantom, experimental and simulation results show that the optimized antennas give more than 400% improvement in signal strength compared to a standard wideband antenna with comparable size.

Investigation of the Optimal Matching Impedance for Finite Array Antennas

S. Shi and B. L. G. Jonsson
Electromagnetic Engineering Lab, School of Electrical Engineering
KTH Royal Institute of Technology, Teknikringen 33, Stockholm 114 28, Sweden

Abstract— The growth of data rates for communication demands a more efficient use of the bandwidth spectra, and also of a higher lateral concentration and flexibility of the coverage. One solution to these problems is to use array antennas in base-station applications. Such arrays should be efficient preferably optimally efficient both from an environmental point of view and in their use of the available spectrum. Optimality on matching bandwidth for small antennas has recently became better understood with the Gustafsson bound [1]. However, for array antennas many optimality questions remain open. A recent result here was the array figure of merit [2].

In this paper we investigate the behavior of the matching impedance for finite array antennas. The goal is to absorb as much power as possible of the incoming waves. The absorption cross section of an array is limited over any frequency range, as is shown by the sum rule for extinction [1].

Here we use CST Microwave Studio to simulate the arrays and their extinction and absorption cross sections. The results are validated by a comparison with the result in [3, 4]. We examine several antenna elements, their array, on its influence on the absorbed power and associated optimal matching resistance. Since the absorbed power over a frequency interval is bounded, there is an optimal resistive matching. We use here the same resistance on all elements, as a simplification. We explore the properties of the best resistive matching as a function of element number, element shape and array configuration.

Antenna Current Optimization and Optimal Antennas

Mats Gustafsson
Department Electrical and Information Technology, Lund University, Box 118, SE-221 00 Lund, Sweden

Abstract— Design of small antennas is challenging because fundamental physics constrains the antenna performance [2, 11]. Physical bounds provide basic restrictions on the antenna performance solely expressed in the available antenna design space. Here, an overview of antenna current optimization for physical bounds and antenna optimization is presented [3, 7]. Physical bounds are presented for antennas in free space, antennas integrated in metallic structured, and antennas embedded in lossy dispersive media. The physical bounds are compared with numerical data for several antennas.

Several proposals for the definition and interpretation of stored energy have been presented the last years [1, 4–6, 9, 10]. Here, the stored energy is derived from a state space representation generalizing previous expressions to more general cases [8]. The stored energy expressions are also used for antenna optimization and several antenna designs are presented.

[3]Dipartimento di Ingegneria dell'Informazione, Università degli Studi di Padova, Italy

Abstract— Linear monopole arrays are extensively used in many antenna systems due to their simplicity, low cost, polarization purity, reasonable bandwidth, and power handling capability.

In this work we show a novel antenna array design in which $N+1$ parasitic monopoles, properly placed in a linear array of N active elements, allow a broadside radiation reaching a gain value close to that one of a standard $2N+1$ active element array. For each active element we place symmetrically on both sides of the monopole (at a distance of $\lambda/4$) two parasitic metallic strips which are protrusions of the ground plane. Since currents in active and parasitic radiating elements are required to oscillate in phase, meandered lines are inserted between the feeding microstrips and the active monopoles: in such a way, the correct phase lag for the currents in the elements is obtained.

The uniqueness of this design is due to its simple feeding network since a balun section is not necessary: for a $2N+1$ array only N elements will be fed reducing the problem of spurious radiation and losses. The N active elements, the meanders and the feeding network can be fabricated on the front of a standard FR4 substrate, whereas the ground plane and the parasitic elements are fabricated on the back of the same substrate (see Figure 1). We present two designs of broadside array working in the wireless local area network (WLAN) band around 2.4 GHz. The microstrip arrays composed of 5×1 and 9×1 linear monopoles with their feeding network have been simulated by using CST. In order to obtain a unidirectional pattern, a metallic plane reflector is placed at a distance of $\lambda/4$ from the array board: predicted gain (11 dB for 5×1 linear array and 15 dB for 9×1 linear array) and bandwidth (around 400 MHz) are larger than for conventional microstrip patch arrays (having similar board dimensions). The proposed antenna arrays are also compact: the size of a 9×1 array working at 2.4 GHz is $27\times9\times3.2$ cm as in Figure 1, where 3.2 cm is the distance between the array board and the reflecting plane.

Technology Advances in GNSS High Precision Positioning Antennas

D. V. Tatarnikov
Topcon Positioning Systems, Russia

Abstract— Currently, typical error of differential positioning with the Global Navigation Satellite Systems (GNSS) is of the order of 1–2 cm in real time. In open sky environments, multipath reflections from the earth surface are recognized to be the largest error source. With the GNSS signals below the ambient noise floor, antennas employed for positioning are to accommodate the signals with the smallest possible losses and to possess the decreased gain in directions below the local horizon to mitigate the reflections. Three types of antennas are currently in use: compact rover antennas, field base station antennas and reference station antennas. Novel developments in regards to these types are discussed in the paper.

To achieve 10–12% bandwidth in the Lower GNSS band and 4–6% in the Upper band for patch antenna stacks, artificial dielectric substrates are employed in the form of dense grids of metal elements. Homogenization techniques to estimate the effective dielectric constant of the structures have been discussed in the paper. Antenna design examples are also presented. One of novel antenna types is a compact end-fire helix antenna with the size of the order of a quarter-wavelength; it allows a 15 dB multipath suppression in the direction downwards.

Field base station antennas are to provide with improved precision in practical environments; besides mitigation of the reflections, antennas are to have the decreased field intensity in the near field region underneath. A novel antenna with a semi-transparent ground plane combined with an artificial magnetic conductor structure has been designed and developed. For practical applications such an antenna ensures the phase center stability in vertical coordinate on the level of 1 mm.

Convex impedance ground plane reference station antenna is to provide with multipath suppression typical for the common choke ring structures along with the improved gain for low elevated satellites; the surface impedance is provided by a grid of straight pins. The internal volume of the antenna allows accommodating high-Q cavity filters for interference protection.

Antennas with a cutoff pattern are to provide improved multipath suppression starting from low elevations. The purpose of their development is to achieve the mm-level precision of positioning in real time. Thus far, the antennas are known to be spacious in the wavelength scale. New results for large impedance ground plane antennas are presented. There is also given a discussion of potentials to achieve the cutoff pattern in the antennas of practical size.

Travelling Wave Antennas with Semitransparent Surfaces for Forming a Cutoff Pattern

D. V. Tatarnikov and I. M. Chernetsky
Topcon Positioning Systems, Moscow, Russia

Abstract— Antennas with a cutoff pattern are of special interest to various applications, in particular, to high-precision positioning with the Global Navigation Satellite Systems (GNSS). Since ground reflections are the largest error source, antennas with a cutoff pattern allow approaching millimeter-level precision of real-time positioning.

Solutions known so far involve structures of 10–15 wavelengths span. Such are a vertical array antenna of [1] or a large impedance ground plane antenna of [2]. However it has been found out that by employing semi-transparent surfaces with pure reactive grid impedance a travelling-wave antenna with the size of about 1.5 wavelengths would serve the purpose. Thus, systems with millimeter-level precision in real time would be considered as practical. The relevant discussion and results achieved is a purpose of the paper.

An electromagnetic model of a parallel-plate waveguide with semi-transparent endings has been developed. By means of optimization techniques it has been shown that if the endings are of about 1.5 wavelengths span, then grid impedance varying along the endings could be synthesized such that a cutoff pattern would be achieved along with the proper return loss levels.

Quadrifilar helix antenna has been chosen as a principle for practical implementation. The antenna has lumped impedances embedded into the strip conductors. Antenna forms a homogeneous pattern within the top semi-sphere with about 20 dB drop of the gain while crossing the local horizon. A proper functionality within the bandwidth of about 10% has been achieved.

Precision of GNSS positioning in open-field environment has been evaluated. RMS of the error in real time was found to be below 1 mm.

Parametric Analysis and Optimisation of a 8–18 GHz Quad-ridged Horn Antenna

Deniz Bolukbas[1, 2] **and Ali Ziya Ozer**[2]

[1]Department of Electrical and Electronics Engineering, Okan University, Istanbul, Turkey
[2]Electromagnetic Design and Analysis Team, Figes A.S., Pendik, Tuzla, Turkey

Abstract— In this paper, parametric analysis and optimization of a 8–18 GHz ultra wide band (UWB) quad-ridged horn (QRH) antenna is presented. As an initial configuration a horn antenna is designed with boxed dimensions of $5.4 \times 5.4 \times 8$ cm as defined in [1]. The gain of the antenna varies between 10 dBi–13 dBi over the entire bandwidth. To analyze these effects the parametric analysis simulations are performed with HFSS.

Introduction: Horn antennas can be used as a feed and provide high gain, relatively wide bandwidth. In this paper, the parametric analysis and optimization of a QRH antenna is presented. A QRH antenna is designed based on the design explained in [1]. The dimensions of the antenna are described in Figure 1. The physical sizes of the antenna are given in Table 1. The horn fed by coaxial cable.

The gain of QRH antenna is presented in Figure 2. In 8–18 GHz frequency band, the gain varies between 10 to 13 dBi.

The outer dimensions A_1 and B_1 is selected to be equal and the gain patterns for five cases are given for 8 GHz and 18 GHz at Figure 2 respectively.

This analysis is repeated while $A_1 = 5.6$ cm and constant, B_1 is varying from 2.6 cm to 8.6 cm. The numerical values of gain are presented at Table 2.

Table 1: The physical sizes of QRH antenna for initial configuration.

Parameter	*Length (mm)*	*Parameter*	*Length (mm)*
A	1.6	L_1	4
B	1.6	L_2	4
A_1	5.6	d	0.3
B_1	5.6	w	0.14

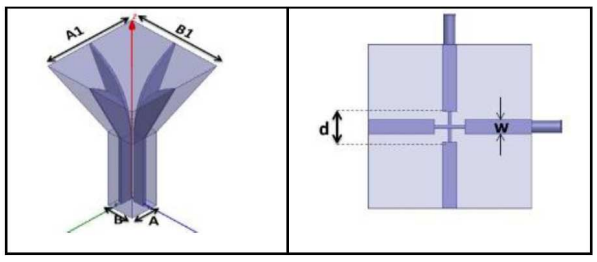

Figure 1: The description of horn antenna's dimensions.

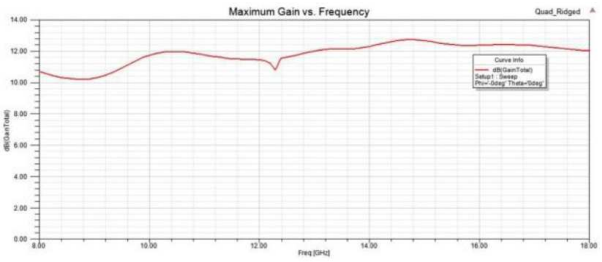

Figure 2: The gain of QRH antenna at 8–18 GHz.

Table 2: Gain vs dimensions for $A_1 = 5.6$ cm.

	Freq [GHz]	B1=2.6cm	B1=4.1cm	B1=5.6cm	B1=7.1cm	B1=8.6cm
1	8.00	9.37	10.83	10.76	9.91	9.21
2	10.00	10.22	10.87	11.84	10.63	10.80
3	12.00	10.54	11.52	11.57	11.65	10.80
4	14.00	10.52	12.46	12.34	11.40	11.01
5	16.00	11.79	13.15	12.42	11.52	12.24
6	18.00	12.62	13.06	12.08	12.33	12.01

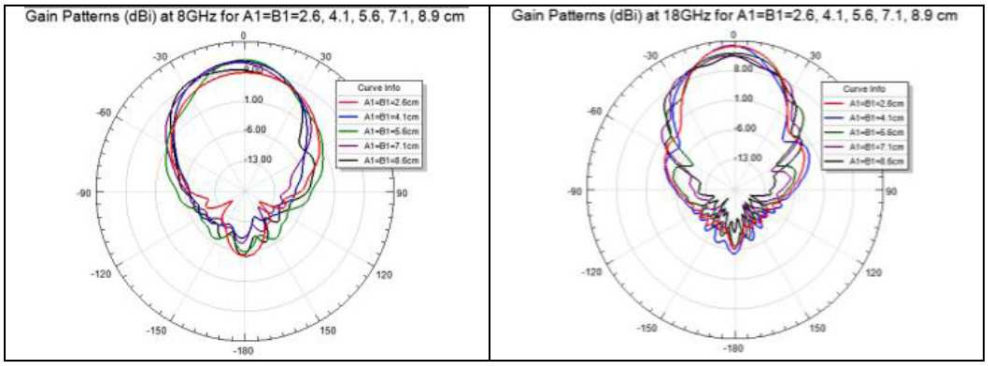

Figure 3: Gain pattern for (a) 8 GHz, (b) 18 GHz.

In this case to obtain the maximum gain, B_1 can be selected around 5.6 cm, while A_1 is constant. The parametric analysis are performed also for d and w parameters as they were described at Figure 1.

Conclusion: In this paper, the quad ridged horn antenna design is performed, parametric analysis are simulated and the results are presented. The simulation tools are very useful for this kind of parametric analysis. With the help of such tools the best performance of the antenna can be achieved.

Si Nanoparticles with Optical Resonances for Dielectric Photonics

Andrey B. Evlyukhin, Urs Zywietz, Carsten Reinhardt, and Boris N. Chichkov
Laser Zentrum Hannover e.V., Hollerithalle 8, D-30419 Hannover, Germany

Abstract— Strong resonant light scattering by Si nanoparticles is experimentally and theoretically demonstrated, revealing pronounced resonances in the visible spectral range associated with the excitation of magnetic and electric modes in these nanoparticles. In this work we discuss the origin of the magnetic dipole resonance in dielectric nanoparticles. Our consideration is based on the approach of quasi-static electromagnetic field and Mie theory.

Theoretical and experimental results concerning the resonant optical properties of differently shaped Si nanoparticles are presented. The role of magnetic and electric modes in the scattering optical spectra is clarified. A new theoretical approach allowing multipole analysis of light scattering by arbitrary-shaped nanoparticles located on flat substrate surface is demonstrated. This approach is applied to investigations of light and surface plasmon polariton (SPP) scattering by Si nanoparticle structures. It is shown how the particle resonant magnetic mode can affect spatial distribution of the scattered SPPs and light. Applications of Si nanoparticles for realization of nanoantennas and metametrials will be discussed.

Interrogating Nanoparticles with Focused Doughnuts

Abstract— The propagation of electromagnetic radiation in free-space is described by the source-free Maxwells equations. In contrast to conventional solutions such as infinite-energy plane waves and Gaussian pulses, there exists a family of exact solutions which represent localised transmission of finite electromagnetic energy [1]. One such solution is known as the Focused Doughnut (FD) pulse a peculiar single-cycle electromagnetic perturbation with a unique toroidal field topology and 3-dimensional, polynomial energy localisation [2]. Here, for the first time we present a comprehensive study of the FD pulse: we investigate the propagation dynamics and interactions of these complex electromagnetic pulses with homogeneous and structured media.

The FD pulse exhibits a number of intriguing properties. Its purely single-cycle nature results in an ultra-broadband frequency spectrum and a well defined spatial-chirp. In fact, the spatial dependence of the pulse is inseparable from its temporal dependence. In addition, the toroidal topology of the pulse gives rise to significant longitudinal field components at the pulse that hold potential for particle acceleration applications [2]. Although the FD pulse has remained a theoretical curiosity since its first prediction, successful experimental realisation could lead to its use in a variety of settings, such as microscopy, communications, directed energy transfer, spectroscopy, and particle trapping and acceleration. Further interest in the FD pulse stems from the burgeoning field of toroidal electrodynamics, owing to the topological similarities between the FD pulse and the near-field configuration of the toroidal dipole excitation [3].

The intriguing light-matter interactions of the FD pulse are examined from several perspectives. We present a full evaluation of the transformations the FD pulse undergoes due to interactions with dielectric and metallic interfaces. This has revealed the unusual behaviour of both the TE and TM pulses under reflection, with respect to the reversal of the azimuthal and radial field components. Furthermore, the interactions of FDs with small dielectric and plasmonic particles are considered, where the broadband nature and complex field topology of the pulses is expected to play a significant role in mode excitation. Recent work has demonstrated broad modal excitation within the nanostructures and distinct differences between the interaction with TE and TM pulses. Possible experimental realisations of these complex electromagnetic perturbations resulting from the theoretical/computational treatment presented here will be discussed.

Dielectric Mie Antennas

N. Bonod
Aix Marseille Université, CNRS, Centrale Marseille, Institut Fresnel UMR 7249, Marseille 13013, France

Abstract— Dielectric antennas are composed of subwavelength sized particles that feature electric and magnetic Mie resonances. These antennas can be used to enhance at subwavelength scales either the electric or the magnetic field counterparts, to accelerate the spontaneous emission or to shape the emission pattern of light emitters.

Introduction: The interplay between electric and magnetic resonances in dielectric resonators offers novel opportunities to control the light scattering. In particular, when coupling Mie resonators to a dipolar source, the excitation of both electric and magnetic dipoles (or multipoles) permits to achieve very high gain in directivity [1]. It can be also proved that by tuning the emission frequency, light can be emitted either toward the forward or the backward direction [1, 2]. Interestingly, the presence of magnetic modes can lead to strong magnetic Purcell factors [3]. In the case of lanthanide ions that feature electric and magnetic transitions, enhancing preferentially the magnetic Purcell factors could promote a magnetic transition. Reciprocally, when illuminated from far field, dielectric antennas can strongly enhance the magnetic field, without enhancing the electric field counterpart [4].

Fabrication: The development of fabrication methods of Mie antennas made of semi-conductors is very challenging. Recently, we followed a bottom-up strategy to fabricate over wafer scales monocrystaline Si-based resonators. The technique is based on the dewetting of thin silicon layers over silica at high temperature. The dewetting can be spontaneous, assisted by electron-beam lithography or by FIB to fabricate individual resonators or oligomers. This technique is well adapted to large samples since the time process does not depend on the size of the sample.

Theory: Silicon mie antennas are very promising to design light cavities. In this context, it is important to quantify the Purcell factor silicon particles doped with quantum emitters. For that purpose, we derived the effective volumes as a function of the normal modes of the Mie resonator. It is seen that when Mie resonators are doped with electric dipolar emitters, the electric modes provide stronger Purcell factors than the magnetic ones [6].

Abstract— Plasmonic structures enable control and manipulation of light at the nanoscale, allowing for strong enhancements of the electric field for interactions with molecules and materials in their vicinity [1]. Unfortunately, these large enhancements come with the cost of high optical losses due to absorption in the metal, severely limiting some real-world applications. Specifically, localized heating strongly limits the total power that can be delivered to a nanoscale field hot spot before the nanostructure melts and reshapes, affecting their suitability for applications such as lighting and photonic modulation [2]. Moreover, the emission properties of molecules placed near the nanoantennas, can also be modified by this local heating [3]. Here we present a method to overcome these heating issues via the realization of a novel nanophotonic platform based on the low absorption dielectric nanostructures (silicon, germanium or gallium phosphide) that we theoretically proposed in [4, 5] to form efficient non-plasmonic nanoantennas with ultra-low light-into-heat conversion. We show that silicon-based nanoantennas produce both high surface enhanced fluorescence (SEF) and good surface enhanced Raman scattering (SERS), while at the same time producing a negligible temperature increase in their hot spots and surrounding environments compared to gold [6].

Abstract— High refractive index dielectric nanoparticles have risen to prominence in the nanophotonics toolkit for control of light in the near-field [1–3]. Compared to metallic nanostructures employed in plasmonics, the near-fields in dielectric nanostructures immediately adjacent to the particles are less intense but can have larger far-field scattering cross sections [4]. Dielectric nanoparticles can reduce quenching and provide higher quantum efficiency of localized emitters than plasmonic structures that can be important for engineering emission at the subwavelength scale [4].

We present for the first time to our knowledge the experimental evidence of near-field enhancement of the magnetic fields with silicon resonant nanodimers at visible frequencies. The response of the system has been studied as a function of wavelength, polarization, and gap [5]. Theory and numerical simulations predict that such a structure should have a strong magnetic response [4, 5]. The near-field measurements show a very good correlation with the simulations. When the simulated near-fields are broken down into their components, it is confirmed that the resonance measured in the near-field is strongly magnetic in nature, for both polarizations.

Additionally, we have conducted a complete analysis of the modes excited inside the dielectric nanodimer system by means of the multipole decomposition. This analysis reveals the excitation of a toroidal dipole moment which interferes with the Cartesian electric dipole moment resulting in a dip in the total electric dipole radiation. This is the first reporting of toroidal dipole excitation in dielectric nanodimer antennas. The dimer system is the basic building block for many nanophotonics systems. The results demonstrated in this paper lay the groundwork for future engineering of the magnetic field response at optical frequencies with high-index dielectric nanostructures for the ultimate control on the subwavelength scale.

Dual and Chiral Dielectric Scatterers for Optical Activity in General Directions

I. Fernandez-Corbaton[1], M. Fruhnert[2], and C. Rockstuhl[2]

[1]Institute of Nanotechnology, Karlsruhe Institute of Technology, Germany
[2]Institut für Theoretische Festkörperphysik, Karlsruhe Institute of Technology, Germany

Abstract— We demonstrate a route to design structures exhibiting optical activity in general scattering directions. When the structure is illuminated from an arbitrary direction, the polarization of the field measured in another arbitrary direction is a rotated version of the incident polarization. The angle of rotation depends on both incident and scattered directions. The design guidelines are based on two necessary conditions for optical activity: Lack of spatial inversion symmetries, and helicity preservation, i.e., zero coupling between the states of opposite polarization handedness of the incident and scattered plane waves [1]. In forward scattering, helicity preservation can be achieved by geometrical means: Scatterers with discrete rotational symmetry with degree equal to or higher than 3 preserve plane wave polarization handedness. In an arbitrary scattering direction, helicity preservation is achieved by scatterers with electromagnetic duality symmetry [2]. While materials meeting the exact duality condition are usually not available, it is possible to purposefully design electromagnetically small scatterers to show approximately dual behavior [3–5]. Particles with such properties have attracted attention, particularly in the context of zero backscattering and the Kerker conditions [3, 4, 6, 7]. We show that approximately dual symmetric structures can be built using small dielectric spheres whose dipolar response is dual symmetric. We show that a chiral arrangement of such spheres exhibits optical activity in general scattering directions. In our work, the electromagnetic responses of the designed structure is calculated through rigorous techniques which allow to compute its scattering matrices to an arbitrary multipolar order [8], and renders our analysis and conclusions valid up to the approximations inherent in the macroscopic Maxwell's equations. We believe that the consideration of the electromagnetic duality symmetry is a valuable addition to the research in optical activity, to both its fundamental and practical sides.

Refractory Plasmonics for Harsh Environment

U. Guler[1], J. Liu[2], H. Eragamreddy[2], A. V. Kildishev[2], A. Boltasseva[2], and V. M. Shalaev[2]

[1]Nano-Meta Technologies Inc., 1281 Win Hentschel Boulevard, West Lafayette, IN 47906, USA
[2]School of Electrical & Computer Engineering and Birck Nanotechnology Center
Purdue University, West Lafayette, IN 47907, USA

Abstract— Plasmonic materials and their response to electromagnetic radiation has been a hot topic over the last decades mostly because of the exciting properties and useful functionalities arising from the interaction of electrons with light. The deviation from bulk material properties dramatically increases as the lengths in one or more dimensions become sub-wavelength. Moreover, once the material properties change with downsizing to the nanometer scale the structures get more vulnerable against the environmental effects such as temperature, mechanical stress and contaminants Changes in thermal, mechanical, and chemical properties of the material result in reduced durability of the elements. Increased surface to volume ratio leads to corrosion due to enhanced chemical interaction with the surrounding medium, melting point depression and deformation. The problem gets more serious due to the softness and solubility of noble metals which otherwise could've been able to provide desired plasmonic properties in the visible and near infrared regions of the spectrum.

Although the initial stages of research on plasmonics was focused on noble metals, it has been evident that a richer pool of materials would be required in order to cover the needs of a wide variety of proposed applications. Harsh environmental factors such as high temperatures, aggressive chemistry, and extreme local forces require harder plasmonic materials. Transition metal nitrides are well known for their refractory properties and they are used in a wide variety of industries where hard surface coatings are required in order to enhance material durability. Recent advances in the development of high quality thin films of transition metal nitrides resulted in improved optical properties and enabled the use of nitrides as refractory plasmonic materials. Exhibiting plasmonic properties in the visible and near infrared regions of the electromagnetic spectrum, transition metal nitrides allow the use of plasmonic components, which would otherwise suffer from extreme local thermal and chemical properties, in emerging technologies.

Plasmonic components based on refractory materials will be discussed in this talk. Spectrally selective refractory metamaterial absorbers and emitters for solar energy harvesting, spectral manipulation, and optical sensing will be introduced. Use of transition metal nitrides as near field transducer for light confinement applications such as heat assisted magnetic recording will be discussed. Photothermal properties of titanium nitride colloidal solutions with plasmonic dipolar resonance in the biological transparency window will be presented.

Measuring Chromatic Aberration in Imaging Systems Using Plasmonic Nano-particles

Sylvain D. Gennaro, **Tyler R. Roschuk**, **Stefan A. Maier**, **and Rupert F. Oulton**

Abstract— We demonstrate a method to measure chromatic aberrations of microscope objectives with metallic nano-particles using incoherent white light. Extinction spectra are recorded while scanning a single nano-particle through a lens's focal plane. We show a direct correlation between the focal wavelength and the longitudinal chromatic focal shift through analysis of the variations between scanned extinction spectra at each scan position and peak extinction over the entire scan. The method has been tested on achromat and apochromat objectives using aluminum nano-particles.

Chromatic aberration in optical systems arises from the wavelength dependence of a glass's refractive index. Polychromatic rays incident upon an optical surface are refracted at slightly different angles and in traversing an optical system follow distinct paths creating images displaced according to colour. Despite the capability to correct chromatic aberration in individual lens components, its accumulation within imaging systems is difficult to assess. While longitudinal chromatic aberration is readily measured with interferometry, less elaborate methods are attractive for their ease of use and low cost. These involve measuring transmission spectra through a pinhole or optical fibre placed at the focus. Unfortunately, the sensitivity of these techniques diminishes rapidly with aperture size limiting their usefulness, especially in high magnification imaging [1]. This limitation can be circumvented by applying Babinet's principle. In a chromatic aberration measurement, we can consider replacing the aperture with a scattering object and measuring extinction instead of transmission. Although Rayleigh scattering by small particles suggests this approach has a similar limitation to Bethe's, it has been shown that dipole scattering in a focused beam allows near perfect extinction [2, 3]. Metallic nano-particles are particularly attractive dipole scatterers as they support surface plasmon resonances that provide strong extinction cross sections in the visible spectral range. Moreover, due to the fast radiative rates and electronic damping in metallic nano-particles, extinction spectra can be octave spanning enabling assessment of chromatic focal shift across the entire visible spectrum in a single measurement. We retrieve the longitudinal chromatic focal shift of high numerical aperture (NA) achromatic (not shown here) and apochromatic (See Fig. 2) corrected microscope objectives from the extinction spectra of metallic nanoparticles placed within the focal plane. We show that the technique is accurate even for the finest measurements on high NA objectives with apochromatic correction. The method enables rapid assessment of the chromatic aberration of any microscopy system since it uses incoherent illumination and is straightforward to implement.

A Study in Asymmetry: Resonances in Arrays of Asymmetric Disc Dimers

Alastair D. Humphrey, **Nina Meinzer**, **and William L. Barnes**
School of Physics and Astronomy, University of Exeter
Stocker Road, Exeter EX4 4QL, United Kingdom

Abstract— Symmetry is one of the most fundamental concepts in nature. From elementary particles to complex protein molecules it impacts on the properties of a physical entity and on the interaction with its environment. In photonics, for example, the symmetry of a system determines if and how strongly it couples to an electro-magnetic field. In the specific case of a symmetric plasmonic antenna, which can support several multipolar eigenmodes only modes with a non-vanishing net dipole moment can couple to a normally-incident plane wave; all other modes are non-radiating, or *dark*, meaning that although the antenna can support these modes they cannot be observed under the given conditions. However, one can render such modes *grey*, i.e., weakly radiating, by symmetry breaking, either by deviating from normal incidence and thus lowering the symmetry of the excitation or by introducing an asymmetry to the antenna itself. There has recently been significant interest in *grey* modes because their small net dipole moment results in narrow spectral features with high quality factors, which are desirable for many applications.

In this paper we study the resonance behaviour of asymmetric disc dimers (ADD), both as individual dimer structures and within periodic arrays, ranging from the non-diffractive metamaterial regime to the diffractive case, where they exhibit interesting surface-lattice resonances (SLR), which are very narrow and appear as a double resonance for the right excitation conditions. We discuss the ADD resonances in all three regimes (single dimers, non-diffractive, diffractive) both experimentally and with additional data from numerical modelling but we focus specifically on the SLR of asymmetric dimers, for which we have also modified a previous analytical model to incorporate the effect of an asymmetric two-element base.

Field Enhancement in Rhodium Tripod Stars and Dimers

Abstract— During the last two decades, local field enhancements produced by metal nanoparticles have been widely investigated in the visible range for common metals like gold and silver. Interest in extending nanoplasmonics into the ultraviolet (UV) spectral region has grown in the past few years [1]. Very recently, the UV plasmonic properties of Rh tripod stars have been examined, by means of surface-enhanced Raman spectroscopy, surface-enhanced fluorescence, and photo-induced degradation [2]. These findings confirmed the exciting potential of Rh nanostructures for UV plasmonic and photocatalytic applications.

In this research, we report results of our numerical study of the plasmonic properties of isolated Rh tripod stars and dimers. We explore the role of the geometry, shape, angle of incidence and polarization of the incident radiation on the performance and generation of localized surface plasmon resonances in the UV, as well as, the possibility of generating hot spots with nanoparticle aggregates for applications in SERS experiments.

Figure 1 shows a near field intensity map of a tripod star dimer with their points confronted and separated by a given gap distance. The dimer is illuminated under normal incidence with the electric field parallel to the line connecting the dimers. The inset shows spectra of the electric field intensity averaged over the dimer's surface and the absorption efficiency.

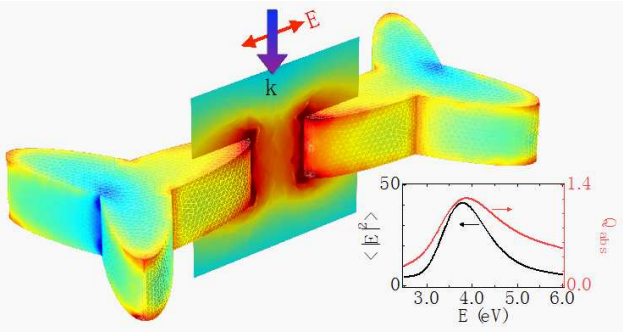

Figure 1: Near field intensity map of a tripod star dimer illuminated under normal incidence with the electric field parallel to the line connecting the dimers. The inset shows spectra of the electric field intensity averaged over the dimer's surface $\langle|\mathbf{E}|^2\rangle$ and the absorption efficiency Q_{abs}.

Abstract— We report results on the optical absorption of thin gold nanorods (NRs) produced with a seed-mediated growth method followed by a filtering process [1]. Gold NRs are obtained with different aspect ratios and lengths covering the range between tenths to a few hundred of nanometers. Because of our interest in medical applications, these nanostructures are dispersed in colloidal solutions, so that molecules are bound to their surfaces and keep them partially separated. We use well-known solvents: first a CTAB aqueous solution, where gold NRs of different sizes are grown from Au NP seeds, and then a thiolate solution. Nanorod samples of different lengths are characterized using HRTEM and UV-Vis-NIR spectroscopy.

The study focuses on the long NR samples ($L > 100\,\mathrm{nm}$) obtained after filtering. One of the main challenges concerning the characterization of their optical response is to understand the origin of the different peaks in the absorption spectra, in particular a main peak that appears about 960 nm for several solvents, and their evolution with the Au NR colloidal concentration.

A theoretical analysis is performed by using the boundary element method (BEM) to solve the full electrodynamical problem and obtain the extinction cross section and near field distributions around the NRs. In the case of the thiolate solution the main peak of the long NR sample, which is attributed to the $n = 3$ antenna mode, is split when the surface of the NRs is chemically modified due to the thiolate coverage around their surface. The use of a dielectric model which incorporates parameters based on ab-initio calculations of thiolate-gold cluster surfaces allows us to explain the trends observed in the spectra recorded for the self-assembled thiolate functionalized gold NRs.

Abstract— Second-order correlations are an essential tool in characterizing the nature of light. The second-order autocorrelation is important in distinguishing between classical and quantum light sources, and of particular importance here, the single-photon purity. The second-order cross-correlation offers insight into the indistinguishability properties of the light. As technology improves and material system change, these measurements naturally evolve. Here we discuss one or two evolutions in these techniques.

In typical second-order correlations ($g^{(2)}$) measurements, a time invariant emission process is assumed, where the optical field properties depend only on the time difference of the two photon detections, not when the detections occur. This has been robustly applied to atomic and parametric down-conversion systems for several decades, but it assumes there are no time dynamics in the system. For solid-states sources, such as quantum dots, where resonant excitation of a state is not always necessary and coupling to environmental reservoirs is likely, there are time-dependent processes, and new second-order correlation tools are needed. We demonstrate timeresolved $g^{(2)}$ measurements of the photons emitted from a single exciton in an InAs quantum dot in a GaAs/AlAs planar microcavity. These measurements shows the dynamics of a nonclassical optical field, quantifying single-photon purity and coherence as a function of when in the excitation-decay cycle of the QD a photon is detected. The results offer an optimization scheme by selecting detection regions. Time permitting, we will discuss more efficient and practical second-order measurement variations and protocols.

Quantum Dots in Photonic Wires: Highly Efficient Single Photon Sources for Free-space and On-chip Applications

Abstract— Optimizing the coupling between a localized quantum emitter and a single-mode optical channel represents a powerful route to realise bright sources of non-classical light states. Reversibly, the efficient absorption of a photon impinging on the emitter is key to realise a spin-photon interface, the node of future quantum networks

Besides optical microcavities [1], photonic wires are very attractive in this context [2, 3]. We introduce the Photonic Trumpet [4], formed by a high-index single-mode waveguide and a conical tapering. Nearly perfect single mode emission, low-divergence Gaussian radiation pattern, linear polarization control and high efficiency single photon emission (> 0.75 photon per pulse) are reported for a single quantum dot embedded in a Photonic Trumpet. We also demonstrate a broadband tuning of the emission wavelength without efficiency loss using strain-effects. More generally, this novel photonic microstructure appears as a very promising platform to explore the unique optical properties of "one-dimensional atoms" [5] and hybrid optomechanical systems where the interaction between the two-level quantum system and mechanical modes is mediated by strain [6].

Finally, we will also report experimental work on QDs embedded in ridge waveguides on a chip, showing efficient control over QD spontaneous emission, which is promising in view of the integration of efficient QD single photon sources on photonic integrated circuits [7].

Quantum Optics in One-dimensional Photonic Reservoirs

I. Söllner and P. Lodahl
Niels Bohr Institute, University of Copenhagen, Denmark

Abstract— Here we review the recent experimental progress on the use of quantum dots coupled to photonic-crystal waveguides [1]. We show that single photons can be channeled into the waveguide with an efficiency exceeding 98% [2], constituting an almost ideal 1D artificial-atom. In such a system a single quantum dot couples exclusive to a 1D photonic reservoir, enabling the experimental demonstration of dipole-induced transparency and strong quantum-dot-mediated photon-photon interaction. Furthermore, we discuss how chiral photon-emission can be achieved in specifically engineered waveguides and present experimental results showing that the directionality of single-photon emission in such waveguides exceeds 90% [3]. Finally, we discuss the prospects of scaling the platform to larger quantum architectures for applications in quantum-information processing, such as efficient photon sorting [4] and a deterministic CNOT gate for photons [3].

Design and Simulations of Highly Efficient Single-photon Sources

N. Gregersen, J. R. de Lasson, and J. Mørk
DTU Fotonik, Department of Photonics Engineering, Technical University of Denmark, Denmark

Abstract— The realization of the highly-efficient single-photon source represents not only an experimental, but also a numerical challenge. We will present the theory of the waveguide QED approach, the design challenges and the current limitations. Additionally, the important numerical challenges in the simulations of sources with in-plane emission will be discussed.

Introduction: Within optical quantum information processing, deterministic generation of single indistinguishable photons on demand is a key functionality. An optically or electrically excited quantum emitter, e.g., a semiconductor quantum dot, embedded inside a solid-state semiconductor host material represents an attractive platform for such a single-photon source. However, for an emitter in bulk material, the symmetry of the system leads to a collection efficiency of only 1–2%, and efficient light extraction thus poses a major challenge in single-photon source engineering [1].

Several approaches have been proposed to control the light emission and ensure an efficient coupling to the collection optics. Within waveguide quantum electrodynamics, the quantum dot is placed inside a waveguide. By carefully tailoring the waveguide dimensions, the relative coupling of the spontaneous emission (SE) to the fundamental waveguide mode, known as the SE β factor, can reach 0.95 in uniform GaAs waveguides. This high β is obtained thanks to a suppression of the SE contribution to radiation modes due a screening effect [2]. Furthermore, in photonic crystal waveguides the β additionally benefits from increased SE into the fundamental mode near the band edge, thus enabling an experimentally measured β above 0.98 [3].

Such near-unity coupling to a waveguide relies critically on correct engineering of the dimensions, which in turn requires accurate numerical simulation of SE in the considered waveguide. This simulation represents an extremely demanding task. Whereas determination of the SE contribution to the fundamental mode is straightforward, the contribution to the radiation modes must be evaluated for a waveguide placed in an open system. The difficulty lies in that most computational methods require that the computational domain be limited to fit in memory, leading to parasitic reflections from the surrounding wall. Here, an absorbing boundary condition can be employed to reduce the influence of the size of the computational domain, and to compute the correct SE contribution the absorbing boundary condition must perfectly mimic the open geometry system.

State-of-the-art methods to compute the SE will be discussed with emphasis on the influence of the size of the computational domain. We will show that proper convergence towards an open boundary limit is generally not obtained, representing a major numerical challenge in optical engineering of high-efficiency single-photon sources.

Design of Slow and Fast Light Photonic Crystal Waveguides for Single-photon Emission Using a Bloch Mode Expansion Technique

J. R. de Lasson[1, 2], B. Rigal[2], E. Kapon[2], J. Mørk[1], and N. Gregersen[1]

[1]DTU Fotonik, Department of Photonics Engineering, Technical University of Denmark, Denmark
[2]Laboratory of Physics of Nanostructures, École Polytechnique Fédérale de Lausanne, Switzerland

Abstract— We design slow and fast light photonic crystal waveguides for single-photon emission using a Bloch mode expansion and scattering matrix technique. We propose slow light designs that increase the group index-waveguide mode volume ratio for larger Purcell enhancement, and address efficient slow-to-fast-light waveguide coupling.

Introduction: In the quest to realize quantum information technology and quantum computers, development of efficient and deterministic single-photon sources is an important step on the way. Single-photon emission occurs from quantum emitters, like atoms or quantum dots, via spontaneous emission that inherently is a non-deterministic process. To obtain a deterministic single-photon source, the spontaneous emission must be controlled, which is typically achieved by placing the quantum emitter in a suitably designed photonic environment; both resonant systems (cavities) and broadband structures (waveguides) have been proposed [1]. In cavity systems, matching of the spectrally narrow emitter and cavity is required, while waveguides relax this requirement due to their broadband nature. For on-chip emission and detection of single-photons, planar integration is necessary, and for this purpose semiconductor photonic crystal (PhC) membranes constitute a flexible and versatile platform. Theoretical efforts [2] and experimental demonstration [3] of single-photon emission in PhC waveguides have been reported.

In this contribution, we employ the Bloch mode expansion technique [4] for engineering of PhC waveguide modes as well as of quantum dot light emission. With this technique, one spatial direction is treated analytically, which makes it highly suitable for long structures like waveguide based single-photon sources, in contrast to spatial discretization methods as FDTD and FEM. In addition, direct access to scattering matrices [5] makes the optimization of multi-section structures particularly transparent, for example when interfacing slow and fast light waveguides in a PhC waveguide based single-photon source.

Specifically, we address the designs of slow and fast light PhC waveguides that serve the purposes of enhancing light-matter interactions and photon transport, respectively. In the former, much attention has been paid to increasing the Purcell factor via large group indices, while little has been said about designs that minimize the waveguide mode volume [2]. We propose designs that simultaneously provide large group indices and small mode volumes, and furthermore propose efficient transmission from slow to fast light PhC waveguides, needed for efficient routing of singly emitted photons to collection optics.

Abstract— Single quantum emitters embedded in semiconductor nanocavities represents a key building block for the generation and manipulation of non-classical light in envisioned quantum photonic circuits. In the past decade, the monolithic integration of quantum dots (QDs) with photonic crystals has been successfully adopted to demonstrate the basic cavity quantum electrodynamics (c-QED) phenomena ranging from non-linearities arising in the strong coupling regime [1] to the static and dynamic [2, 3] control of the spontaneous emission process. Nevertheless, the integration and interconnection of multiple c-QED nodes pose the major limitation to the number of qubits that can be generated within the same chip. One of the leading experimental challenges in this context resides in the spectral matching of several cavity-emitter systems. Indeed, for scalable and indistinguishable single-photons, tuning the energy of both emitters and cavities is crucial in order to overcome the inhomogeneous broadening of self-assembled QDs and the energy spread in the cavity resonance caused by unavoidable fabrication imperfections. Here we report the energy control over a full cavity-emitter node, consisting of Stark-tunable QDs coupled to electromechanically reconfigurable double-membrane photonic crystal cavity [4]. The all-electrical wavelength-tuning of the emitter over 7.5 nm as well as an 8.5 nm mode shift are demonstrated on the same device. Furthermore, by bringing a tunable single excitonic line into resonance with a tunable cavity mode, we demonstrated a ten-fold Purcell-enhancement of its spontaneous emission rate at two distinct wavelengths [5]. Finally, we discuss the integration of this fully-tunable architecture with ridge waveguides, needed to build a low-loss photonic channel between several solid-state qubits.

Integration of Site-controlled Quantum Dots with Photonic Crystal Cavities and Waveguides

Eli Kapon
Laboratory of Physics of Nanostructures, Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Abstract— Integration of semiconductor quantum dots (QDs) with photonic cavities and waveguides is useful for studying the fundamentals of light-matter interaction as well as for applications such as quantum light sources, quantum information processing and low power consumption lasers for optical interconnects. Recent progress in the realization of QD systems with good control over dot position and optical spectra opens new possibilities for on-chip generation, detection and manipulation of single photons. Here we review such progress achieved with pyramidal QDs epitaxially grown on pre-patterned substrates. The site-controlled InGaAs/GaAs QDs are grown by metallorganic vapor phase epitaxy on (111)B GaAs "membrane" substrates pre-patterned with arrays of inverted pyramids of different configurations [1, 2]. This QD system exhibits excellent site control, inhomogeneous broadening as small as < 2 meV, reproducible QD exciton spectra [3], and high in-plane QD symmetry [4] essential for emission of entangled photons. Photonic crystal (PhC) cavities and waveguides are designed and fabricated on top of the QD arrays with the aid of alignment marks by electron beam lithography. Spatial alignment accuracy of better than 50 nm and QD-cavity energy matching of better than few-meV can be achieved with this approach. The integrated QD systems allow observation of QD-cavity coupling free of spurious multi-excitonic effects, mediated only by phonon exchange [5]. Experiments and modeling yield insight into the role of pure QD depahsing in the weak-coupling regime [6]. Coupling of several QDs to the same cavity mode is evidenced by the co-polarization of the QD emission with the related PhC cavity modes [7]. Integration of pyramidal QDs with PhC cavities for few-QD lasers and with PhC waveguides for multiplexing single photon sources will be discussed.

Abstract— Since the seminal proposal of Feynman in 1981 [1], different well-controlled quantum computing systems suitable for solving complex quantum physics problems have been proposed [2]. A promising implementation of quantum simulators would be an array of quantum dots (QDs) interacting through the optical modes of an array of coupled photonic cavities [3]. Construction of such systems requires strict position and spectral control of the QD systems involved as well as avoiding mode localization due to optical disorder. Here, we present the fabrication and optical study of a system composed of two InGaAs/GaAs pyramidal QDs [4] deterministically integrated in two coupled photonic crystal membrane cavities ("photonic molecule") (Figure 1(a)). A statistical analysis of the energy splitting between the symmetric and antisymmetric modes of the fabricated photonic molecules evidenced strong inter-cavity coupling, indicating delocalisation of the supermodes across both cavities. Scanning micro photoluminescence (PL) spectroscopy based on the high reproducibility of the QD emission spectra allowed identification of the spectral features of each QD (Figure 1(b), X_i and XX_i denote exciton and bi-exciton of dot i.) The simultaneous weak coupling of both QDs to the delocalized cavity supermode is demonstrated thanks to the Purcell effect inducing a vertical co-polarization of these otherwise unpolarized lines (Figure 1(c)). This demonstrates the versatility and scalability of pyramidal site controlled QDs for integration with nano-photonic elements.

Abstract— Progress in quantum dot integrated in photonics crystal nanocavity for single dot photonics are discussed. The presentation includes experimental and theoretical discussion on single dot lasers with a high-Q photonic crystal nanocavity. Moreover, spontaneous two photon emission controlled with the high-Q nanocavity is demonstrated. Finally, single photon emission from a nanowire quantum dot at room temperature is also discussed.

Abstract— The prospect of studying quantum optics effects in the solid state and the development of quantum light sources for applications in the field of quantum communication has triggered enormous efforts in the fabrication of micro- and nanocavity systems with embedded quantum dots (QDs). These structures exploit cavity quantum electrodynamics (cQED) effects and can act as efficient non-classical light sources and as high-β microlasers. Their further development towards applications in quantum technology focusses on the realization of triggered sources of indistinguishable photons and efficient schemes for electrical pumping. Combining these two goals has turned out to be highly challenging because a high degree of indistinguishability requires resonant excitation schemes while electrical pumping using pin-diode structures is intrinsically non-resonant. To tackle this issue we propose an on-chip quantum optics concept where an integrated microlaser resonantly excites a QD-micropillar cavity acting as non-classical light source. As such, our approach combines two very active but so far independent routes of cQED, namely high-β lasing and single QD light-matter interaction at the quantum in a novel, integrated device concept.

The on-chip device concept is illustrated in Fig. 1(a) and relies on the opportunity that micropillar cavities allow for the localization of vertically emitting modes and laterally emitting whispering gallery modes (WGMs). We take advantage of this unique opportunity provided by the micropillar geometry to utilize an electrically pumped WGM micropillar as in-plane laser source. Here, the integrated WGM microlaser resonantly excites a peripheral QD-micropillar. This specific configuration allows us to demonstrate for the first time on-chip quantum optics experiments in the cQED regime by applying an integrated coherent light source (cf. Fig. 1(b)) [1]. Moreover, we apply pulsed electrical excitation of the integrated microlaser (cf. Fig. 1(c)) to demonstrate electrically triggered emission of non-classical light from the peripheral micropillar [2].

Deterministic Coupling of Multiple Quantum Dots to Selected Modes of a Photonic Crystal Cavity

A. Lyasota, C. Jarlov, B. Dwir, A. Rudra, P. Gallo, and E. Kapon
Ecole Polytechnique Fédérale de Lausanne, Lausanne CH-1015, Switzerland

Abstract— Quantum information science relies on the possibility to transfer information between qubits or quantum memories with photons. Advances have been made recently in this direction in atomic systems [1], however the need for scalability and on-chip integration makes semiconductor systems better candidates. In this abstract, we present the integration of up to four site-controlled semiconductor quantum dots (QDs) in linear photonic crystal (PhC) cavities, and demonstrate the coupling of each QD to the same cavity mode. This is an important step towards the observation of collective effects in few quantum dot systems, such as QD-based nanolasers [2].

We rely on the site-controlled nature of InGaAs pyramidal QDs [3] to ensure a finite overlap of the QD dipoles with the cavity mode field pattern. Furthermore, the high spectral uniformity of these QDs (∼5 meV) is in the range of phonon-mediated coupling interactions [4], ensuring a finite spectral coupling between each QD and a selected cavity mode. We use the QD-cavity coupling signatures already observed in systems comprising of a single QD coupled to a PhC cavity, which include the co-polarization of the excitonic lines with the cavity and off-resonant cavity emission (Figure 1(a)), to investigate the coupling of up to four different QDs to the same cavity mode. QDs are identified by monitoring the intensities of the excitonic spectral features while changing the position of the excitation spot (Figure 1(b)). These excitonic features are indicated in the photoluminescence spectrum displayed in Figure 1(c). The cavity peak was identified by performing polarization resolved photoluminescence measurements while varying the sample temperature. The upper panel of Figure 1(c) shows the degree of linear polarization of the photoluminescence (DOLP). All the QD features, initially unpolarized, have a positive DOLP in the presence of the cavity mode, proving the simultaneous coupling of each QD to the cavity mode.

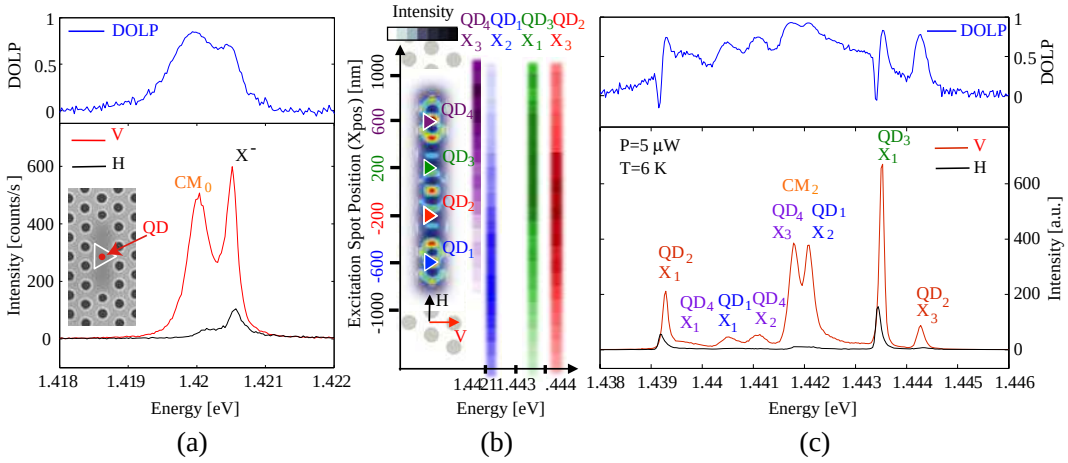

Figure 1: (a) Spectrum of a single QD coupled to the mode of a PhC cavity (see inset for design); upper panel: degree of linear polarization. (b) Design showing the nominal position of the four QDs in the L7 PhC cavity. The intensity of four QD features as a function of the excitation spot position is shown to illustrate how the lines were identified. (c) Spectrum of a four QD structure. The upper panel shows the degree of linear polarization of the luminescence.

Hybrid Approaches for Single Photon Collection: Diamond Defect Centers on Fibers, Chips, and Polymer Photonic Structures

Oliver Benson
Nano-Optics, Humboldt-University Berlin, Germany

Abstract— Single photon emitters are a key element for future integrated quantum optical technology. Until today many different realizations have been demonstrated, for example single molecules, semiconductor quantum dots or color defect centers. Requirements for scalable applications are reliable integration into other optical elements, stability and room-temperature operation.

Very promising quantum emitters fulfilling all these constraints are defect centers in diamond, and among them the most prominent ones, the nitrogen vacancy (NV) and the silicon vacancy (SiV) center. However, compared to the well-established semiconductor technology micro- or nanointegration and fabrication are still challenging. For this reason a hybrid approach seems promising, where diamond-based single photon emitters are integrated on a different material platform.

In this presentation we present two approaches. One utilizes optical fibers where single photons from color defect centers in nanodiamonds are collected with high efficiency by near-field coupling [1, 2]. Assembly and experimental challenges will be discussed.

In another approach we use direct laser writing to fabricate various light collecting microstructures, such as waveguides, modified lenses or microresonators around pre-characterized nanodiamonds containing single defect centers. We discuss the potential of this technique to realize almost arbitrary three-dimensional architectures, which can be aligned on-demand with respect to several single photon emitters.

SC2: Manipulating Light-matter Interaction by Plasmonics 2

Coupling of NV Centers in Nanodiamonds to Plasmonic Waveguides

Sergey I. Bozhevolnyi
Department of Technology and Innovation
University of Southern Denmark, Odense DK-5230, Denmark

Abstract— Surface plasmon (SP) modes supported by various dielectric-metal waveguide configurations facilitate ultra-strong (subwavelength) confinement of electromagnetic fields, enabling miniaturization of photonic circuits and also strongly enhancing interaction of emitters with these modes. The latter feature has important implications in quantum optics, sensing and lab-on-a-chip applications. Here we report experimental investigations of local SP excitation by nitrogen vacancy (NV) centers in individual nanodiamonds (NDs) incorporated into different waveguide configurations. First, we studied the excitation of SPs at a silver-air interface using ND fluorescence. In this case, NDs acted as both a source and a scatterer for propagating SPs. Fluorescence spectra measured from the illuminated ND and from the ND scatterer exhibited significant difference originating from the wavelength-dependent SP propagation loss. We have further studied the SP excitation in waveguiding structures such as dielectric-loaded SP polariton waveguides (DLSPPWs) and V-grooves. Fabricated DLSPPWs were terminated with diffraction gratings that out-coupled fluorescence excited by an illuminated ND and guided as the DLSPPW modes. V-groove geometry is one of the most promising plasmonic waveguide configurations for efficient coupling to quantum emitters. We present fluorescence images, featuring NV centers in one (or several) ND located near the center of the V-groove and coupled to channel SP modes propagating towards terminations shaped as nano-mirrors. Also, in these cases, the local SP excitation by NV fluorescence was evidenced not only by the images obtained but also by the correspondently recorded fluorescence spectra. In parallel, life-time measurements indicate that NDs containing multiple NV centers result in different life-time characteristics for different radiation channels, contrasting the free radiation channel against channels of SP excitation. While we continue further experiments with NDs containing multiple NV-centers studying their spectral and life-time characteristics, we intend in the nearest future to extend our investigations to SP excitation with single NV centers and present the corresponding results at the conference.

Exciton Emission from Plasmonic Metal/Organic Multishell Semiconductor Nanowires

Abstract— We investigate the emission of excitons in bare and coated plasmonic metal/organic wurtzite/zincblende (WZ/ZB) InP and zincblende AlGaAs/GaAs shell-core nanowires (NWs) by intensity- and temperature-dependent time-integrated (TI) and time-resolved (TR) photoluminescence (PL). The $\sim$ 100 nm diameter III-V NWs were grown using the Au catalyzed vapor-liquid-solid method. The plasmonic InP NWs were coated with a 20 nm thick Alq_3 interlayer and a $Mg_{0.9}$:$Ag_{0.1}$ metal cluster top layer with nominal metal film thicknesses ranging from 10 to 20 nm by organic molecular beam deposition (OMBD). The AlGaAs/GaAs NWs were coated with a 10 nm thick gold film and various Alq_3 spacer thicknesses by OMBD.

Figure 1 shows the PL spectra from uncoated and coated InP NWs at 20 K. The incident excitation intensity was 40 W/cm^2. The red line shows the spectrum of bare InP NWs revealing two strong emission bands at $\sim$ 1.48 and $\sim$ 1.44 eV. These bands, which are separated by the LO-phonon energy, are attributed to nonthermalized weakly and deeply localized indirect WZ/ZB excitons due to randomly distributed short WZ and ZB segments within the NW. The PL yield of both bands increases by a factor of nearly 4 when the InP NWs are covered with an Alq_3 layer (see blue line) which is attributed to surface charge passivation. When the Alq_3 coated InP NWs are subsequently covered with a nominally 15 nm thick Mg:Ag layer, the PL yield of the weakly and strongly localized indirect WZ/ZB exciton bands is reduced by a factor of $\sim$ 20 and $\sim$ 10, respectively, compared to the Alq_3 coated sample, shown by the black line in Fig. 1. Increasing the nominal thickness of the deposited metal to 40 nm further reduces the PL intensity by a factor of 2 (dashed black line). The PL intensity quenching of the indirect WZ/ZB emission is attributed to Förster energy-transfer from mobile or weakly trapped indirect excitons to plasmon oscillations in the Mg:Ag clusters. TR PL investigations on uncoated and plasmonic InP NW support this interpretation revealing the shortest lifetime of weakly localized indirect excitons in metal coated InP NWs while the dynamics of strongly localized indirect WZ/ZB excitons is less affected.

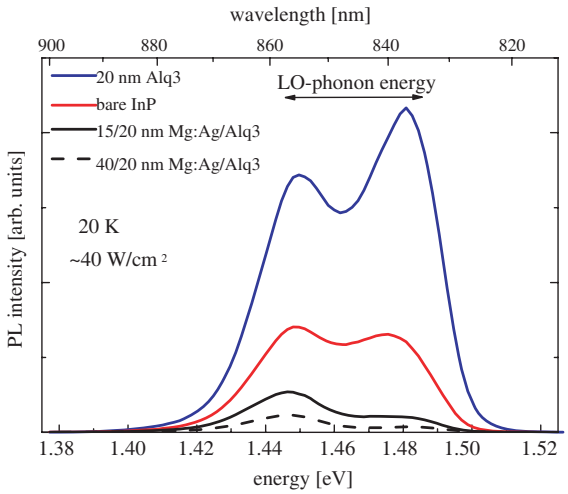

Figure 1: Photoluminescence spectra of bare, Alq_3 coated and plasmonic InP nanowires as labelled at 20 K. The excitation intensity of the He-Ne laser was 40 W/cm^2 for all NW ensembles.

Intensity-dependent PL spectra of zincblende AlGaAs/GaAs NWs show a strong and weak emission band at 1.515 and 1.47 eV at 15 K, which are attributed to the GaAs exciton transition and to an impurity related luminescence, respectively. Plasmonic AlGaAs/GaAs NWs with a ~ 10 nm thick Au coating but without Alq_3 spacer layer reveal a significant reduction of the PL intensity for both emission bands compared with the uncoated NW sample. Plasmonic NW samples with the same nominal Au coverage and an additional Alq_3 interlayer of 5 or 10 nm thickness show a noticeably stronger PL intensity which increases with rising Alq_3 spacer thickness. The observed behaviour suggests that again Förster energy-transfer from free GaAs excitons to plasmon oscillations in the gold film is mainly responsible for the PL quenching.

Controlled energy-transfer from NW excitons to plasmons in the deposited metal has the potential to compensate for metal losses in novel plasmonic devices.

Plasmonics towards the Industry: Sensing, Structural Colors and Solar Light Management

B. Gallinet
CSEM SA, CSEM Muttenz, Switzerland

Abstract— Metallic nanostructures interact strongly with light through surface plasmon modes and many application fields have been proposed during the past decade, including light harvesting to sensing and structural colors. However, their implementation for the industry requires the development of up scalable and cost effective manufacturing processes. The fabrication at wafer scale of plasmonic nanostructures and metamaterials using nano imprint lithography is reported. After structuring, one or several evaporations of various plasmonic materials are performed with a tilt angle with respect to the substrate, which increases the light interactions with the different metallic layers as well as enlarges the design possibilities. A step and repeat process is used to increase further the area of nanostructured surface. The measured optical properties of the fabricated structures show a very good agreement compared to numerical calculations using the rigorous coupled wave analysis and the surface integral method. These numerical calculations together which structural characterization, increase the process control and enable the design of the nanostructures for specific applications. In particular, nanostructures with a shape similar to split ring resonators and which support high order plasmonic modes showing Fano resonances are shown to be promising for sensing applications. Another kind of plasmonic substrates is reported, which shows unique color effects with a large palette of colorations. With a specific design, the structural colors are associated with a strong interaction between the polarizations which increases the complexity of the color effect rendered to the user. Finally, the potential of plasmonic nanostructures for the management of solar light is discussed.

Theory of Localized Plasmons for Multiple Metal Nanostructures

Masakazu Ichikawa
Department of Applied Physics, Graduate School of Engineering
The University of Tokyo, Japan

Abstract— Many theoretical studies of the localized plasmons in metal nanostructures have been reported until now [1]. We have also reported a theory of localized plasmons for metal nanostructures in random-phase approximation (RPA) [2] and have recently developed it to consider the retardation of the electromagnetic potentials [3]. In this presentation, a theory of localized plasmons in multiple metal nanostructures is reported, which is the development of the previous ones.

Considering the retardation of the scalar potentials and the local electron density $n(\mathbf{r})$, an effective scalar potential $\varphi_{\mathit{eff}}(\mathbf{r}, \omega)$ and an external scalar potential $\varphi_{ext}(\mathbf{r}, \omega)$ satisfy the following equation in the RPA at high-frequency condition (plasmon frequency region) [3]:

$$\varphi_{\mathit{eff}}(\mathbf{r}, \omega) = \varphi_{ext}(\mathbf{r}, \omega) + \int d\mathbf{r}_1 G_0(\mathbf{r} - \mathbf{r}_1, \omega)\, \rho(\mathbf{r}_1, \omega),$$
$$\because\ \rho(\mathbf{r}_1, \omega) \equiv -\frac{e^2}{m_e \omega^2} \nabla_1 \cdot [n(\mathbf{r}_1)\, \nabla_1 \varphi_{\mathit{eff}}(\mathbf{r}_1, \omega)], \tag{1}$$

where $G_0(\mathbf{r} - \mathbf{r}_1, \omega)$ is the retarded Green's function that satisfies the following Helmholtz equation.

$$\left(\nabla_{\mathbf{r}}^2 + \omega^2/c^2\right) G_0(\mathbf{r} - \mathbf{r}_1, \omega) = -4\pi\delta(\mathbf{r} - \mathbf{r}_1), \quad G_0(\mathbf{r} - \mathbf{r}_1, \omega) = \exp(i\omega/c \cdot |\mathbf{r} - \mathbf{r}_1|) / |\mathbf{r} - \mathbf{r}_1|.$$

$\rho(\mathbf{r}_1, \omega)$ in Eq. (1) is the induced electric charge density by the localized plasmon excitation. The local electron density $n(\mathbf{r})$ is expressed by $n(\mathbf{r}) = \sum_n n_0(\mathbf{r} - \mathbf{R}_n)$ for multiple metal nanostructures where $\mathbf{R}_n$ is the position of the each nanostructure. When the quasi-static approximation is used, neglecting the retardation ($c \to \infty$), the localized plasmon excitations in multiple metal nanospheres can be analytically studied. When the electron density is assumed to have a step function shape at the nanosphere surface ($r = a$), Eq. (1) can be analytically solved by using the normalized spherical harmonics and the following determinant equation is derived to calculate the localized surface plasmon frequency:

$$\det\left[\left(\omega^2 - \frac{\omega_p^2 l}{2l+1}\right)\delta_{ll'}\delta_{mm'}\delta_{ns} - \frac{\omega_p^2 l' a^{l'+1}}{(2l'+1)} B_{lm;\,l'm'}(\mathbf{R}_n - \mathbf{R}_s,\, a)(1 - \delta_{ns})\right] = 0,$$
$$\because\ B_{lm;\,l'm'}(\mathbf{R}_n - \mathbf{R}_s,\, a) = \int d\Omega_{\mathbf{r}} \left.\frac{Y_{lm}^*(\mathbf{r})\, Y_{l'm'}(\mathbf{r} + \mathbf{R}_s - \mathbf{R}_n)}{|\mathbf{r} + \mathbf{R}_s - \mathbf{R}_n|^{l'+1}}\right|_{|\mathbf{r}|=a}, \tag{2}$$

where $\delta_{ll'}$ etc. are the Kronecker's delta functions, ω_p is the bulk plasmon frequency, $\Omega_{\mathbf{r}}$ is the solid angle for $\mathbf{r}$ at $|\mathbf{r}| = a$, Y_{lm}^* and $Y_{l'm'}$ are the normalized spherical harmonics, and $\mathbf{R}_n$, $\mathbf{R}_s$ are the central positions of the metal nanospheres. The first term of Eq. (2) gives the surface plasmon frequency $\omega = \omega_p\sqrt{l/(2l+1)}$ for the individual nanosphere and the second term gives the frequency shift caused by the interaction between the multiple nanospheres. The calculation for the nanosphere dimer gives the red frequency shift that is proportional to $-(a/|\mathbf{R}_s - \mathbf{R}_n|)^2$ in the dipole approximation ($l = l' = 1$). The property of the red shift coincides with that of other studies [1, 4]. We also report the light emission from the nanosphere dimer, a formula of the localized plasmons for the periodic metal nanostructures using the Bloch's theorem and a method to consider the retardation of the scalar potentials using the structural Green's function method [5].

Abstract— Understanding the van der Waals interaction between plasmonic particles with diminutive geometric features is paramount to many microelectromechanical applications. However, modelling of this type is widely acknowledged as a difficult task because the plasmon modes supported by these systems are difficult to describe with traditional electromagnetic methods. In this talk, I will describe an efficient and accurate approach based on transformation optics [1] to investigate three-dimensional (3D) sharp plasmonic particles. This approach enables us to transform an apparently unsymmetrical plasmonic system to a more symmetrical partner with an identical spectrum and through which the electromagnetic properties can be classified and calculated analytically. For a pair of plasmonic tips and the tip-plane coupled system, we present details of this technique and discuss the characteristics of the plasmon modes and van der Waals forces [2]. The results are compared with the sphere-sphere and sphere-plane configurations [3, 4]. A deviation is observed for tips with a small cone angle.

Plasmonic and Metamaterial Band Theory: Fundamentals and Applications

Aaswath Raman, **Wonseok Shin**, **and Shanhui Fan**
Ginzton Laboratory, Stanford University, Stanford, CA, USA

Abstract— The past two decades have been extraordinary advances in the study and understanding of nanoscale photonic structures such as photonic crystals, plasmonic structures and metamaterials. As researchers have sought to fully characterize and explore the physical phenomena possessed by such nanophotonic structures, it has become increasingly necessary to understand how such structures behave over a broad range of frequencies. It is both of intrinsic and applied interest to develop an analytical, physical framework capable of describing the electromagnetic modes of all plasmonic and metamaterial systems in a general way: a plasmonic and metamaterial band theory.

The need to accurately calculate the eigen modes and band structures of such periodic structures numerically, and place analytic constraints on the modes of plasmonic systems whose constituent materials are typically dispersive and metallic, motivates the development of a rigorous plasmonic band theory. Beyond band structure computation, the development of a plasmonic band theory would also allow one to fully study and characterize important plasmonic/metamaterial device applications. In particular, there has been substantial recent interest in using plasmonic structures for active devices and sensing. Finally, the development of device applications is ultimately contingent on basic physical limits related to the use of dispersive materials such as metals in these systems. Understanding limits on the modal loss introduced by these metals is of vital importance.

In our work, we introduce a rigorous metamaterial band theory. We first demonstrate that the band structure of dispersive photonic crystals, plasmonic structures and optical metamaterials, in general, can be obtained by solving a standard matrix eigenvalue problem. In the case where the material can be approximated as lossless, the eigenvalue problem is Hermitian, which directly leads to an orthogonality-condition for modes at different frequencies. We next implement the band theory numerically using a finite difference scheme and demonstrate its effectiveness. We further build upon the band theory to construct a plasmonic perturbation theory that can generally treat the effect of small changes in any system parameter, whether geometric or material. In particular, we use the perturbation theory to predict modal frequency shifts due to changes in the dielectric constants of dispersive systems involving both metals and dielectrics. Finally, we prove rigorously that, for any electromagnetic mode of a plasmonic metamaterial structure, there exists an upper bound on its material loss rate. When the plasmonic material is described by a multi-pole Lorentz model, the upper bound is a frequency dependent weighted-average of the damping rates of the oscillators that underlie the poles. We validate this proof by full-field simulations of a variety of systems including periodic arrays of slot antennas.

Characteristics of Guided Modes in Plasmonic Metal/Aluminumquinoline Multilayer Waveguides

Abstract— We investigated the mode properties of planar plasmonic aluminum-quinoline (Alq_3) multilayer waveguides which have one single or three equally spaced nanometer-thin $Alq_3Mg_{0.9}$:$Ag_{0.1}$ composite metal-island layers in or near the center. The waveguides were grown by organic molecular beam deposition (OMBD) on 0.5 mm thick amorphous Pyrex® substrates at room temperature. An alloy of 90% Mg and 10% Ag ($Mg_{0.9}$:$Ag_{0.1}$) was used for the metal layers. Atomic force microscopy (AFM) on similarly thin Mg:Ag layers showed that the metal was deposited as clusters with layer filling factors ranging from 0.7 to 0.9.

Three of the $\sim$ 2.0 µm thick Alq_3 films had one single centered Mg:Ag layer each, nominal thickness of 8, 10 and 15 nm, respectively. In addition, a $\sim$ 2.0 µm thick stack of four Alq_3 layers (thickness of each: 500 nm) and three embedded Mg:Ag layers (thickness of each: 10 nm) was grown. Deviations from the nominal total growth thicknesses of the deposited films were determined using a profilometer prior to the optical investigation and were considered in the data evaluation. We used the m-line technique at a wavelength of 633 nm to investigate the effect of the inserted composite metal cluster layer(s) on the effective refractive indices n_{eff} of TM and TE modes and compared the results with a pure Alq_3 waveguide as reference. The effective refractive indices n_{eff} and field distributions of each mode were also calculated with a multilayer waveguide model.

We find that the effective refractive indices n_{eff} increase with the thickness of the inserted metal layer for odd TM modes, because these modes have an antinode at the position of the metal layer. Since even TM modes have a node at the metal layer, their refractive indices n_{eff} remain nearly unchanged. In TE modes, the metal layer forces a local minimum in the electric field distribution at the position of the metal film. The resulting field distribution of odd TE modes, which should have an antinode at the position of the composite metal layer, thus becomes similar to the field distribution of the adjacent next higher even TE mode (see Figure 1). This leads to lower effective refractive indices n_{eff} for odd TE modes compared to the pure Alq_3 reference. Even TE modes, which have a node at the location of the inserted metal film, have similar n_{eff} values as the pure Alq_3 reference. Accordingly, the metal resistivity losses are highest for odd TE modes, while they are less for even TE modes.

Our investigations suggest that strategically placed composite dielectric-metal or continous metal layers could be used to selectively increase the effective refractive indices of specific TM or TE modes, while at the same time decreasing the n_{eff} value of others. It is also possible to excite and/or attenuate certain TM or TE modes in a controlled way: This way mode selective attenuaters could be realized by inserting metal stripes into a dielectric waveguide during growth.

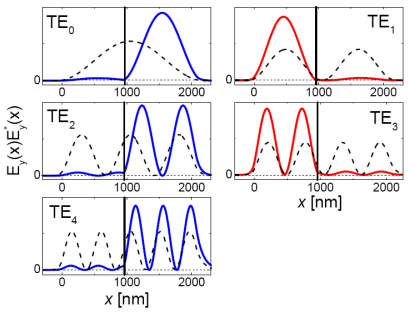

Figure 1: Calculated squared electric field distribution of guided TE modes in a plasmonic Alq_3 waveguide with a nominal 15 nm thick single Mg:Ag metal layer. The vertical line indicates the position of the composite metal layer with respect to the air/Alq_3 interface at $x = 0$. Calculated field distributions of TE modes in a pure Alq_3 reference waveguide are given as dashed lines.

Nanoantennas with Dual-wavelength Plasmonic Hotspots

Abstract— Plasmonic nanoantennas create strongly enhanced local fields when pumped resonantly as well as provide highly increased local densities of photon states. By coupling quantum emitters such as quantum dots, fluorescent molecules or atoms to specially designed nanoantennas, large fluorescence enhancement and effective emission control can be realized. Generally, the emission spectra of quantum emitters are different from their absorption analogues, which means, if we want to boost the absorption and control the emission simultaneously, at least two plasmonic resonances are needed for nanoantennas, one at the excitation wavelength and the other at the emission wavelength. Here we designed a novel nanoantenna with a dual-wavelength hotspot, which could be viewed as a combination of two different gap antennas and is featured by two different resonances sharing one plasmonic hotspot at the same gap region. One of the resonances at shorter wavelength is expected to be used for excitation enhancement, while the other one at longer wavelength used for emission control due to modified radiative decay rate. Another remarkable advantage of this nanoantenna is that by adjusting its shape (each gap antenna's arm length, width, orientation, etc.), each resonance's wavelength can be tuned separately. Finite-difference time-domain simulations (FDTD Solutions, Lumerical) of the antenna-emitter system were performed. For fabrication, chemically synthesized plasmonic nanoparticles were accurately moved and assembled by using an AFM tip to form this antenna. Finally, we used dark field scattering spectroscopy to characterize this dual-wavelength nanoantenna. This presented nanoantenna is a highly promising means for emission control of single quantum emitters.

Hydrodynamic Model for Nonlinear Plasmonics: From Nonlinear Mode Coupling to Supercontimuum Generation

Abstract— The electromagnetic response of a free-electron gas leads to the inherent nonlinear optical behaviour of nanostructured plasmonic materials enabled through both strong local field enhancements and complex collective electron dynamics [1]. In this presentation, we will overview our recent results on implementation of the hydrodynamic model for conduction electrons to describe a broad range of nonlinear effects in metallic nanostructures. It will be started with an illustrative hydrodynamic analytical approach, defining the nonlinear coupling of the plasmonic modes in metallic nanoparticles, particularly revealing an important role of the resonance symmetries [2]. In the further development, we will report our very recent numerical time-domain implementation of the hydrodynamic model, which enables non-perturbative studies of nonlinear coherent interactions between light and plasmonic nanostructures without any simplifications [3]. The effects originating from the convective acceleration, the magnetic contribution of the Lorenz force, the quantum electron pressure, as well as the presence of the nanostructure's boundaries are taken into account leading to the appearance of second, third and higher harmonics in the scattering field of a metallic nanorod (Fig. 1) [2]. We will also report supercontinuum generation in resonantly-tuned metallic nanospirals originating from the nonlocal effects [3]. The proposed time-domain method enables one to obtain a universal, self-consistent numerical solution free from any approximations, enabling investigations of nonlinear optical interactions with arbitrary shaped optical pulses, in contrast to the generally employed plane-wave CW pump assumption, opening unique opportunities to approach realistic experimental scenarios.

Three Dimensional Orientation and Rotation of Nanostructures Using Optical Torques

T. V. Raziman and Olivier J. F. Martin
Nanophotonics and Metrology Laboratory
Swiss Federal Institute of Technology Lausanne (EPFL), Lausanne-1015, Switzerland

Abstract— Light carries linear and angular momenta, and can impart these to nanoparticles, exerting optical forces and torques on them. The field of optical nanomanipulation has grown tremendously in the recent years, and the ability to trap nanoparticles and rotate and orient them in desired ways promises many practical applications. Here, we present a study on how optical torques can be used to orient plasmonic nanoparticles in desired directions as well as continuously rotate them about an axis. The electromagnetic response of plasmonic particles is simulated using the surface integral equation (SIE) method, and optical forces and torques are evaluated by integrating the Maxwell's stress tensor from the SIE surface currents directly.

A linearly polarised plane wave can exert a restoring torque on nanoparticles, orienting them both in the direction of propagation and perpendicular to it. We analyse how the restoring torques in the two directions can help achieve full three-dimensional orientation of particles. We find the equilibrium orientations of the particles and analyse how angular displacements away from these orientations tend to result in a stabilising or destabilising torque on them, making them orientations of stable and unstable equilibria, respectively.

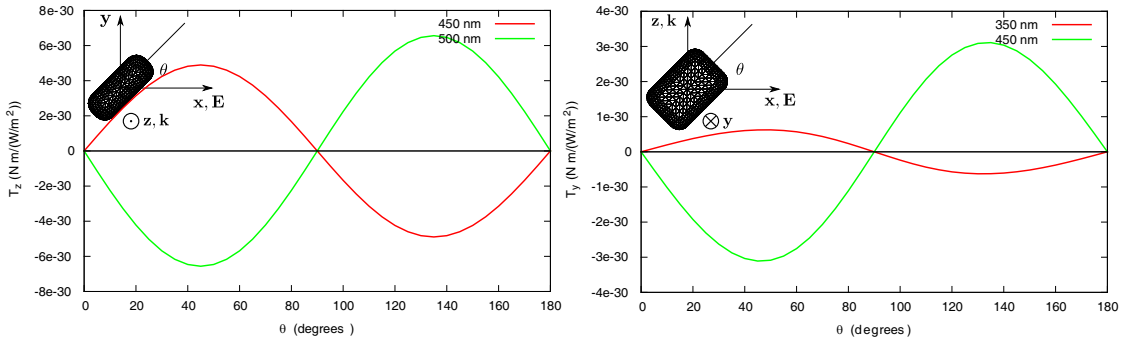

Figure 1: Optical torques on a silver cuboid ($L_x = 100\,\text{nm}$, $L_y = 40$ nm, $L_z = 70\,\text{nm}$) due to an x-polarised plane wave propagating in the z direction when given an angular displacement θ about (a) z axis and (b) y axis

As an example, consider the torques on a silver cuboid given an angular displacement about the z and y axes. For displacement about the z axis, as shown in Fig. 1(a), both $\theta = 0°$ and $\theta = 90°$ are equilibrium positions for both incident wavelengths of 450 nm and 500 nm. At 450 nm, a small displacement from 90° results in a restoring torque. As a result, the particle executes oscillations about 90°, and would settle to the equilibrium position in the presence of damping. On the other hand, displacement from 0° causes the particle to continue rotating in the same direction making it unstable. The opposite behaviour is seen at 500 nm with the stable equilibrium now occurring at 0°. A similar switch of stable equilibrium orientation is seen for displacement about the y axis as well, as seen in Fig. 1(b). We analyse the switching of the stable orientation as a function of wavelength, and explain the features in terms of the modes of the system. In addition, we show how circularly polarised waves can be used to continuously rotate nanoparticles.

Suppression of Light Scattering with ENZ-metamaterials

[4]Nonlinear Physics Center, Australian National University, Canberra ACT 0200, Australia

Abstract— Nearly perfect concealing of arbitrary objects in hyperbolic metamaterial acting as an alignment-free cloak is proposed. The scattering suppression relies on the combination of normal and additional modes simultaneously existing in a spatially dispersive material.

Suppression of scattering in a specifically design material environment leads to reduced detectability of objects, and may, ultimately, result in "invisiblity" if the scattering is absent. The concept of 'cloaking' was introduced in [1, 2] and gained considerable attention due to continuous demand to achieve invisibility for radar waves [3] and visible light [4, 5]. The general approaches for cloaking rely either on transformation optics concepts [1] or conformal optical mapping of complex electromagnetic potentials [2]. While the former generally results in the requirements of highly anisotropic (and sometimes singular) electric and magnetic susceptibilities of a medium of a cloak, the latter approach requires a position-dependent refractive index variation but is restricted for two-dimensional geometries by its nature.

Here we demonstrate cloaking of arbitrary shaped and arbitrary (not necessarily subwavelength) sized objects placed inside a layered metal-dielectric metamaterial. We show that a metamaterial realization has major influence on the cloaking phenomenon since the electromagnetic response of those plasmonic multilayers is substantially affected by spatial dispersion effects [6]. Investigation of the exact numerical model, taking into account material losses and finite dimensions of the metamaterial realization, shows the possibility of nearly perfect cloaking of arbitrary shaped bodies with the minimal variations of the phase front of the transmitted/reflected optical wave and highly suppressed scattering. Analysing the dipolar emission inside spatially dispersive layerd metamaterial by considering its spatial dispersion (Fig. 1(a)), we show that in contrary to the free space scenario the radiation patterns have flat uniform wavefronts (Fig. 1(b)). Beeing the 0-order approximation in the scattering analysis, the dipole paves a way for investigation more complex geometries. Figs. 1(c), (d) show the electromagnetic scattering in the empty cloak and the one with an object inside. The similarity between transmitted wave fronts verifies the validity of the general concept.

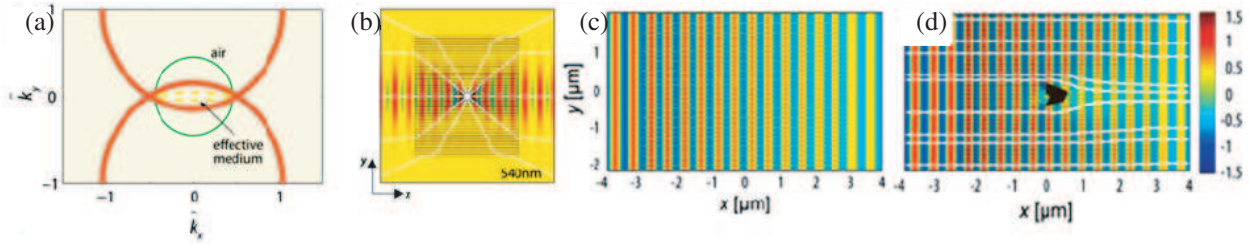

Figure 1: (a) Isofrequency contours for multilayered metamaterial (100 nm air and 20 nm Au) at $\lambda = 540$ nm. Red curves show propagation modes: (bright) main, (pale) additional. Green circle represents light cone in air. Yellow — isofrequency contours, simulated in the effective medium theory. (b) The electric field (y-component) distributions of the radiating y-polarized dipole situated in the centre of the metamaterial block of 15×4 μm size at the wavelength corresponding to the isofrequency contours in (a). Wave numbers k_x and k_y are normalized to the Brillouin zone boundaries $\pi/(d_a + d_g)$. White lines represent the power flow. (c) Electric field (y-component) distributions for the plane wave illuminating the empty cloak. (d) PEC object (larger than the wavelength) of an arbitrary shape inside the cloak.

In addition, the nearly perfect operation for 2D objects has been shown to be preserved for relatively long (longer than the wavelength) 3D arbitrary shaped objects. Moreover, other cloaking scenarios, interplay between local and nonlocal metamaterial dispersion, comprehensive analytical theory will be presented. The proposed type of cloaking may find use not only in the conventional concealing applications but also serve as a platform for 'cloaked detectors' schemes [7] where bulk and alignment free cloaks may significantly reduce the complexity of the realisation.

Abstract— In order to overcome the physical limits, the ways to realize high efficiencies close to the theoretical limit for solar-to-heat conversion in the solar radiation region have been studied. In terms of numerical calculations based on the spectral properties of multilayer stacks with different metal/dielectric materials and film thickness, the optical properties and thermal stability of a typical 6-layered metal/dielectric film structure are investigated in this work. A high optical absorption average of $> 98\%$ is achieved in the broad spectral range of 250–1200 nm with experiment results, in good agreement with our simulated results. The samples have a typical layered structure of: SiO_2(57.3 nm)/Ti(5.7 nm)/SiO_2(67.1 nm)/Ti(11.6 nm)/SiO_2(51.4 nm)/Cu($>$ 100 nm), deposited on optically polished Si or K9-glass substrates by magnetron sputtering. The sample of the 6-layered metal/dielectric film structure has an AM1.5G solar absorptance of 95.5% with the features of low thermal emittance of 0.136 at 700 K and good thermal stability, and will be potentially suitable for practical application in high-efficiency solar absorber devices in many fields.

Guided-mode Resonant Nanophotonic Devices: Physics, Design, Fabrication, and Characterization

Robert Magnusson, **Jae Woong Yoon**, **Manoj Niraula**, **and Kyu Jin Lee**
Department of Electrical Engineering, University of Texas — Arlington
Arlington, Texas 76019, USA

Abstract— Many innovative device concepts in nanoplasmonics and nanophotonics rely on intricate resonance effects generated with nanopatterned films. As incident light couples to the film, attendant resonance effects impose diverse spectral signatures on the output light. The guided-mode resonance (GMR) concept refers to quasi-guided, or leaky, waveguide modes induced in periodic layers. Whereas the fundamental GMR occurs in any diffraction regime, subwavelength architectures enable the most useful spectra. Even though these effects have been known for a long time, new attributes and application possibilities continue to appear. Wide parametric design spaces allow precise control of light amplitude, phase, polarization, near-field intensity, and light distribution on surfaces as well as within the device volume. The output spectra can be retrieved in either transmission or reflection. Applications such as laser mirrors, multiparametric biosensors, solar-cell absorption enhancement, tunable filters, narrowband nanoelectromechanical display pixels, nonlinear conversion, surface-enhanced Raman spectroscopy, slow-light control, leaky-mode nanoplasmonics, resonant Rayleigh reflectors, and many others have been suggested in the past.

In this paper, we review the physics of GMR device operation, illustrate their design with rigorous methods, discuss fabrication processes, and present results of physical and spectral characterization. We indicate the application potential of this field, discuss some past device examples, and provide new and emerging aspects. In particular, we present new wideband resonant reflectors designed with gratings in which the grating ridges are matched to an identical material thereby eliminating local reflections and phase changes. This critical interface therefore possesses zero refractive-index contrast; hence we call them "zero-contrast gratings." For simple gratings with two-part periods, we show that zero-contrast grating reflectors outperform comparable high-contrast grating reflectors with nearly 700-nm bandwidth achieved at 99% reflectance. We introduce a new class of reflectors and polarizers fashioned with dielectric nanowire grids that are mostly empty space. We provide computed results predicting high reflection and attendant polarization extinction in multiple spectral regions. Experimental results with Si nanowire grids yield ∼200-nm-wide band of total reflection for one polarization state and free transmission of the orthogonal state. Finally, resonance elements functioning as simultaneous spatial and spectral filters are introduced and substantiated with computed and experimental results that are in excellent agreement.

Tunable Graphene Absorber in the Visible Region Based on Plasmonic Metamaterials

Jinfeng Zhu[1], **Yijun Cai**[1], **Yanqiang Bai**[1], **and Qing Huo Liu**[2]

[1]Institute of Electromagnetics and Acoustics, Department of Electronic Science
Xiamen University, Xiamen 361005, China
[2]Department of Electrical and Computer Engineering, Duke University, Durham, NC 27708, USA

Abstract— Manipulation and enhancement of light absorption in graphene is a significant issue for applications of graphene-based optoelectronic devices. In order to achieve this purpose in the visible region, we have proposed a novel optical absorber for graphene inspired by the design principles of plasmonic perfect absorbers. Based on the design principles of metamaterial ideal absorbers, the reflectance and transmittance of the artificial structure must reach the minimum, which is determined by the match of wave impedance between air and the artificial medium. In an metal-dielectric-metal structure, there is no transmittance, and its reflectionless property depends on the electromagnetic coupling induced by a gap-plasmon guided mode, which is influenced by the size and separation period of metal nanoribbon, loss in the metal, and effects of dielectric spacers. Therefore, with regard to these factors, we investigate the optical absorption enhancing mechanism of single and multilayer graphene, and discuss the light manipulation approaches in the proposed nanostructure. The result shows the absorption spectra of graphene is sensitive to the polarization of incident light but almost independent of the incident angle. Furthermore, the peak position and bandwidth of graphene absorption spectra are tunable in a wide wavelength range through a specific structural configuration. The research reveals the potential implementation of plasmonic perfect absorbers for graphene absorption in novel nanophotonic devices, and provides a guide to design related nanostructures and devices.

Enhanced Linear and Nonlinear Behaviors of Graphene under Localized Surface Plasmon Resonances: Analyses with Boundary-integral Spectral Element Method

Jun Niu[1], **Ma Luo**[2], **and Qing Huo Liu**[1]

[1]Duke University, USA
[2]Wave Computation Technologies, Inc., USA

Abstract— Graphene has been considered as a promising alternative for silicon in the next generation advanced optoelectronic devices. Over the past few years, a considerable number of optoelectronic devices have been demonstrated based on graphene's linear optical performance. However, despite its outstanding quantum efficiency and fast carrier mobility, graphene's application in several categories of designs is still challenging. When designing graphene-based photodetectors around visible spectra, two typical limitations need to be overcome: The 2.3% optical absorption of floating single-atom layer graphene is poor for photo-responsivity. Additionally, graphene shows a considerably at absorption in the visible to near-infrared spectra, and thus does not provide a frequency selectivity.

As another crucial property, graphene's nonlinear optical behavior is also under intensive theoretical and experimental studies. Recent investigations show that single layer graphene's third-order nonlinear optical response is particularly strong. Previous four wave mixing experiment shows that the effective third-order susceptibility is in the order of $|\chi^{(3)}| \sim 10^{-15}\,\mathrm{m}^2/\mathrm{V}^2$. Moreover, although the centrosymmetric structure of graphene theoretically forbids the emission of second harmonic generation, this symmetry can be broken by its adjacent materials. However, few tools are available for numerically analyzing these interesting nonlinear phenomena within relatively complex designs.

In this work, effective light absorption engineering of graphene around visible spectrum by localized surface plasmon resonances (LSPR) is first proposed. Based on boundary-integral spectral element method (BI-SEM), we theoretically investigate the strategy of incorporating periodic gold nanoparticle (NP) cluster arrays with Bragg reflectors into the prototypes of graphene-based photodetectors. Numerical simulation shows that the proposed structures can effectively engineer the light absorption in graphene by tuning plasmon resonances. In the spectra of 300 nm to 1000 nm, a maximum light absorption of 67.54% is observed inside a graphene layer, while it is 41% within the visible spectra.

In the meantime, while the photo-responsivity can be improved via LSPR by confining a significant amount of energy inside the graphene layer, graphene's nonlinear optical field generation can also be dramatically enhanced. To study this interesting nonlinear interaction, we further investigated graphene's nonlinear performance with accurate numerical analysis. Based on BI-SEM, the optical fields at fundamental frequency and high order harmonic frequency are solved iteratively. For a complete nonlinear optical evaluation, both the backward and forward exiting power and the stored energy of the nonlinear fields are provided. With the spectral accuracy of BI-SEM, the proposed numerical method is able to solve the optical fields accurately with a relatively high convergence rate. Meanwhile, the flexibility of spectral element method also makes this scheme suitable for the simulation of more complex optoelectronic designs.

Strong Light-matter Interaction in Nano- and Micro-scale Heterostructures

B. S. Simpkins
Chemistry Division, Naval Research Laboratory, Washington, DC 20375, USA

Abstract— Inducing strong interactions between light and matter is at the heart of technologies such as photovoltaics, sensing, analytic spectroscopies, optical computing, and photo-catalysis for energy production or pollutant remediation. In this discussion, we review our efforts to design and probe (i) collective resonances and field distributions associated with visible and near-IR antenna arrays, (ii) strong polaritonic coupling between a Fabry-Perot cavity and molecular vibrational modes, and (iv) symmetryforbidden modes in loaded hybrid nanogap antennas.

We will first discuss cooperative effects in nano- and micro-scale resonators where we find universal coupling behaviors when data is scaled by antenna length and substrate index. In addition to the oftdescribed *radiative* to *evanescent* transition, a transition to a third regime, termed here as *near-field* coupling, is observed in which the extension of the resonant mode beyond the physical antenna end overlaps that of its neighbor. Arrays were integrated with an active dielectric layer in periodic square arrays of gold nano-squares patterned atop an aluminum nitride thin film on a gold substrate. The metal-insulator-metal metamaterial surfaces exhibit several strong absorption bands that correlate well with numerical simulations and are attributed to a grating-coupled transverse-electric slab-waveguide mode and a transverse-magnetic surface-plasmon polariton mode.

Next, we examine coherent coupling between an optical-transition and confined optical mode, which, when sufficiently strong, gives rise to new modes separated by the vacuum Rabi splitting. Such systems have been investigated for electronic-state transitions, however, only very recently have vibrational transitions been considered. Here, we bring strong polaritonic-coupling in cavities from the visible into the infrared where a new range of static and dynamic *vibrational* processes await investigation. We have experimentally and numerically described coupling between a Fabry-Perot cavity and carbonyl stretch ($\sim 1730\,\mathrm{cm}^{-1}$) in poly-methylmethacrylate. As is requisite for "strong coupling", the measured vacuum Rabi splitting of $132\,\mathrm{cm}^{-1}$ is much larger than the full width of the cavity ($34\,\mathrm{cm}^{-1}$) and the inhomogeneously broadened carbonyl-stretch ($24\,\mathrm{cm}^{-1}$). Agreement with classical theories provides evidence that the mixedstates are relatively immune to inhomogeneous broadening. Next, we investigate strong and weak coupling regimes through examination of cavities loaded with varying concentrations of urethane and demonstrate coupling to liquids using the C-O stretching band ($\sim 1985\,\mathrm{cm}^{-1}$) of $Mo(CO)_6$ in an aqueous solution.

Finally, we note that theoretical work has identified a new type of hybrid nanoresonator akin to a loaded-gap antenna, wherein the gap between two collinearly aligned metal nanorods is filled with active dielectric material. The gap optical load has a profound impact on resonances supported by such a "nanogap" antenna, and thus provides opportunity for (i) active modulation of the antenna resonance and (ii) delivery of substantial energy to the gap material. To this end, we have produced and characterized such nanostructures. In addition to conventional transverse and longitudinal resonances, these loaded nanogap antennas support a unique symmetry-forbidden gap-localized transverse mode arising from the splitting of degenerate transverse modes located on the two gap faces. This previously unobserved mode is strong (E^2 enhanced ~ 20), tightly localized in the nanoscopic ($\sim 30\,\mathrm{nm}$ separation) gap region, and is shown to red-shift with decreased gap size and increased gap dielectric constant. In fact, the mode is highly suppressed in air-gapped structures which may explain its absence from the literature to date. Understanding the complex modal structure supported on hybrid nanosystems is necessary to enable the multi-functional components many seek.

THz Characterization of ITO Films on p-Si Substrates

E. R. Brown[1], **W.-D. Zhang**[1], **H. Chen**[2], **and G. T. Mearini**[2]

[1]Department of Physics and Electrical Engineering
Wright State University, Dayton, OH 45435, USA
[2]Genvac Aerospace, Inc., 110 Alpha Park, Cleveland, OH 44143, USA

Abstract— This paper reports broadband THz transmission measurements and modeling of indium-tin-oxide (ITO) thin films on low-doped p-Si (CMOS-grade) substrates. ITO has long been of interest as a transparent ohmic-contact (TOC) material for infrared detectors and other optical applications. In recent years the ITO TOC has migrated into the THz region, along with interesting metamaterial-based component research. A key feature of ITO is that its bulk conductivity is in the semi-metallic range, $\sigma \approx 10^5$ S/m, compared to $\sigma > 10^7$ S/m in common (transition) metals, so that sheet resistances of around 377 Ω/sq can be obtained with thin-film thicknesses of ∼100 nm instead of the few-nm required of transition metals. However, the electrical properties of ITO depend on several material characteristics, such as the stoichiometry, and the effect on GHz-to-THz (RF) electrical conductivity is not well understood. In this study, two ITO films having thickness of 50 (#1) and 100 nm (#2), and DC sheet conductance 260 Ω/sq (3.85 mS/sq) and 56 Ω/sq (17.9 mS/sq), respectively, were deposited by ion-beam-assisted sputtering, and the THz conductivity was measured between 0.1 and 1.2 THz using a frequency-domain photomixing spectrometer. Fig. 1(a) shows the experimental configuration and (b) shows the transmission-line model used for analysis. Fig. 2 shows the modeled transmittance parametrized by the RF sheet conductance. The experimental transmission for film #2 is plotted in Fig. 3(a),

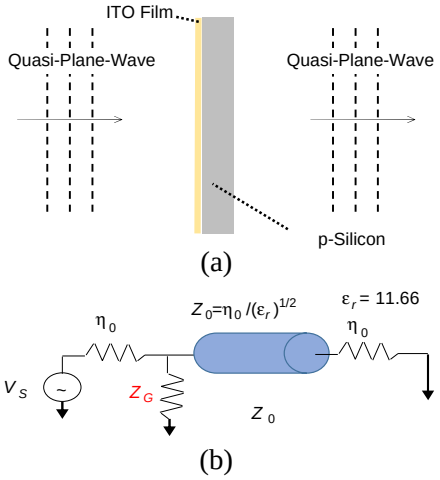

Figure 1.

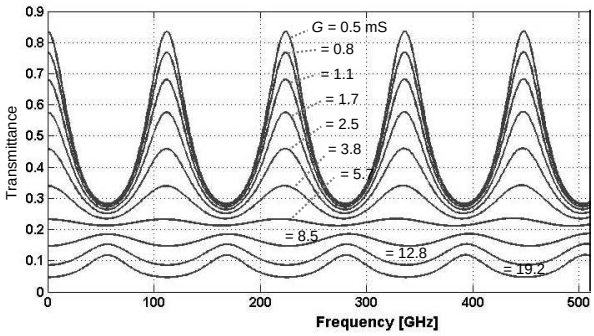

Figure 2.

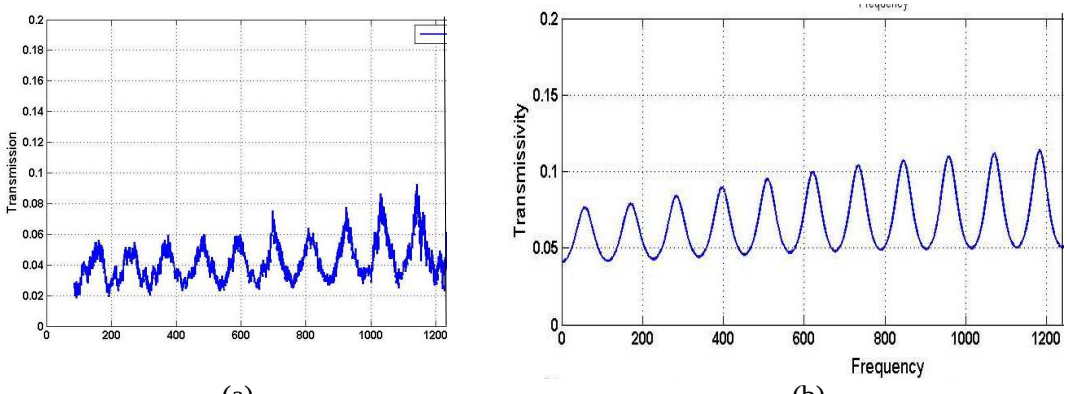

Figure 3.

and the modeled transmission in (b), calculated for the real part of the THz conductance equal to the DC value and the imaginary part dependent upon a Drudian scattering time of 3 fs. The experimental curve is considerably lower than the modeled, but most of the discrepancy can be explained by free-carrier absorption in the p-substrate. Similar agreement was obtained for film #1, suggesting that the Drude model is accurate in the ITO, at least up to 1.2 THz.

Nano-gap Induced Multi-resonant Metamaterials in the Visible and the Near IR

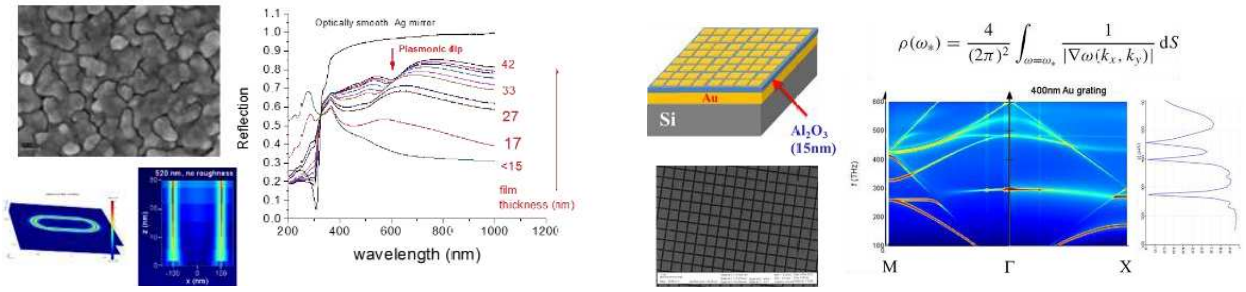
Abstract— Metamaterials have been of significant interest for nearly two decades for use in subwavelength light confinement and manipulation. Plasmonics allows for high field *E-M* field confinement through localized surface plasmons (LSP's) around well-defined geometric structures made of coinage metals. In addition, it is possible to create traveling modes using surface plasmon polaritons (SPP's) by using thin metal films. An area of high interest and common to both LSP's and SPP's involves the use of narrow gaps to induce light confinement. Recent work using Ag films deposited by atomic layer deposition have shown that the structural form of the Ag has a mosaic like pattern that is characterized by Ag islands that are separated by uniform gaps that are 4–6 nm wide and extend throughout the film thickness. These gaps have been shown to have very high fields with well-defined optical resonances in the visible, despite being randomly distributed. In addition, it has been shown that ALD-Ag can be deposited onto other geometries that would be used in plasmonics and yield dual resonant metamaterials. This form of Ag allows us to understand the impact of periodicity on light confinement in gap based metamaterials. Toward this end, we have used both theory and experiments, with lithographically patterned Au gratings with narrow gaps that would resemble a periodic version of ALD Ag. These structures allow us to have fine control over the resonances that is not possible in ALD Ag and to serve as a periodic model for the ALD-Ag geometry. Optically, they exhibit well defined resonances that can be impacted by the structure of the unit cell and the substrate that they are placed on. The high fidelity of the resonances enable us to more calculate the band structure and density of states of the system. The calculations show that gap based metamaterials have both localized and traveling modes. The localized modes have high densities of states and thus can survive randomization and still maintain a resonance. Simulations are then extended to ALD Ag using gap based model, such as rings of air embedded in Ag (coaxial). The results are similar to the model systems and indicate that a simple model of ALD-Ag as a periodic array of coaxial spoof material is accurate because of the low impact of randomization on the fundamental mode in periodic arrays of gaps. The results for both systems show high field localization and potential for applications where high light confinement is small regions is required. We will discuss the possible use of these structures for energy harvesting and other applications that require high light confinement in thin films.



Coupled Resonator Mediated Transmission of Light through Sub-wavelength Holes for Multispectral Imaging Applications

W. R. Buchwald and K. C. Kerby-Patel
University of Massachusetts Boston, USA

Abstract— The transmission of light through arrays of sub-wavelength holes in an optically thick metallic film is in general explained by the excitation of surface plasmon modes at the incident dielectric/metal interface allowing propagation of energy through the holes and into the far field via scattering. This effect is known to produce transmission resonances at wavelengths longer than what would be expected by simply considering classical electromagnetic waveguide theory In this work, it is shown through numeric simulation of 3 μm square holes, with an array period of 6 μm, that the addition of a 2.4 μm square metallic resonator, centered within the sub-wavelength hole, shifts the characteristic resonant frequency to longer wavelengths. In addition, a substantial reduction in resonance line-width is observed when a thick (3 μm) background metal and a thin (100 nm) resonator metal are used. Investigated over the wavelength range of 2 to 14 μm, full-width half-max values of 2.1 μm are observed for the thin background metal case, which produced a characteristic resonance at a wavelength of 9.7 μm. Increasing the Au background metal thickness to 3 μm shifted the transmission resonance to 8.7 μm along with a significant reduction in full-width half-max to 0.322 μm. By adjusting the period and resonator dimensions tuning of distinct spectral bands over the 7.0 μm to 14.0 μm range are achieved as a function of in-plane surface dimensions. Such engineered films are being investigated for use in multispectral imaging spectroscopic systems whereby a distinct spectral line could be allocated to each pixel of a LWIR imaging array enabling the direct detection and identification of certain pathogens or adverse chemical compounds in real time at video frame rates impacting cancer diagnosis and treatment as well as providing front line defense capability for homeland security applications.

Harmonic Double-resonance Cones in Hyperbolic Metamaterials

Abstract— The formation of double-resonance cones in nonlinear media with hyperbolic dispersion is discussed. We show that an electric dipole near the surface of the medium generates harmonic signals that propagate into two distinct volume plasmon-polaritons. We identify a harmonic component that propagates within its own peculiar resonance cone and a phase-locked, harmonic signal that is trapped under the pump's resonance cone. The large material anisotropy induces a significant angular divergence between the two volume plasmon-polaritons, which makes these structures suitable for subwavelength harmonic imaging microscopy. The effect is shown in a metamaterial made by a stack of metal-dielectric layers with subwavelength thicknesses. We use the Bloch theory to highlight the differences between double-resonance cones achievable with homogeneous hyperbolic media and those formed in discrete hyperbolic metamaterials.

MM-wave-to-THz Modulation with Graphene-oxide-silicon Etalon Structures

W.-D. Zhang[1], **P. H. Q. Pham**[2], **E. R. Brown**[1], **and P. J. Burke**[2]

[1]Department of Physics and Electrical Engineering
Wright State University, Dayton, OH 45435, USA
[2]Department of Electrical and Computer Engineering
University of California, Irvine 92697, USA

Abstract— This paper reports a millimeter-wave (MMW) amplitude modulator based on a graphene-oxide-silicon etalon structure. The device consists of an oxide-pre-coated high-resistivity silicon substrate with a monolayer graphene film sitting on top of the oxide. The structure is fabricated as a graphene-channel field-effect transistor (GFET) with source and drain contacts deposited on the graphene, and a gate contact on the opposite side of the silicon (backgate). Gate bias voltage changes the graphene sheet conductance which then modifies the transmission of radiation propagating perpendicular to the substrate. The transmission spectrum displays Fabry-Perot resonant peaks located at integer multiples of $f_0 = c/2nL = 112\,\text{GHz}$ where $L = 392\,\mu\text{m}$ is the silicon thickness, and $n = 3.41$ is its refractive index. A plane-wave transmission line model is used to predict the transmission as a function of graphene sheet conductance, and a large change of transmission (i.e., depth-of-modulation) is found to occur for incident frequency at or near the resonant peaks, i.e., 112 GHz, 224 GHz, etc.. The depth-of-modulation can reach $\approx 11\,\text{dB}$ if the sheet conductance is varied from 0.1 mS to 5.5 mS (Fig. 1, 112 and 224 GHz are overlapped). To test the performance, $\sim 1 \times 1\,\text{cm}$ graphene films were grown by

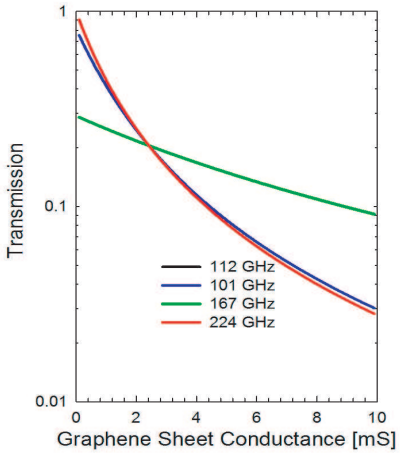

Figure 1.

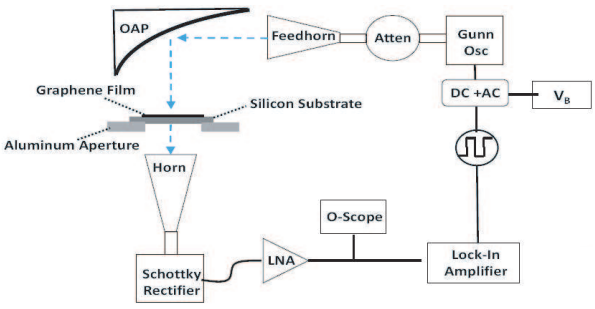

Figure 2.

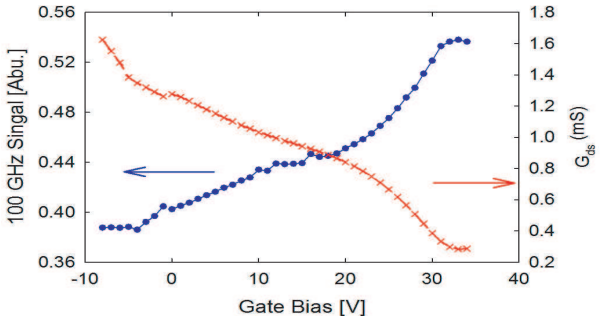

Figure 3.

CVD and transferred from copper to silicon through a polymethylmethacrylate (PMMA) "fishing" procedure. The experimental setup included a 101 GHz waveguide-mounted Gunn-oscillator as the source, and a Schottky-rectifier together with mode-matched feedhorn as the receiver (Fig. 2). The output signal from the Schottky rectifier is coupled to a 1000x-gain low-noise voltage amplifier. The model predicts good depth-of-modulation at 101 GHz, just slightly weaker than the maximum at 112 GHz (Fig. 1). This was tested experimentally (Fig. 3), where the depth-of-modulation was measured to be ~ 1.3 dB when the gate bias was varied from -4 V to $+34$ V. However, this is less than the predicted value — ~ 3.1 dB — calculated using the sheet-conductance change from 0.4 mS to 1.6 mS (Fig. 3). The discrepancy is attributed to inaccuracy of the transmission line model, which assumes a TEM mode radiation, while the experimental MMW beam is actually Gaussian. Nevertheless, there is room for improvement toward a practical MMW transmission amplitude modulator, approaching 10-dB depth-of-modulation, by obtaining greater change in the graphene sheet conductance with gate voltage, which may require a top gate rather than the backgate used here.

Distributed Brillouin Sensing Using Plastic Optical Fibers

Yosuke Mizuno, **Neisei Hayashi**, **and Kentaro Nakamura**
Tokyo Institute of Technology, Yokohama 226-8503, Japan

Abstract— Plastic optical fibers (POFs) can withstand large strain of up to several tens of percent and are regarded as one of the most promising candidates for the development of flexible fiber-optic sensors. We here provide an overview of the characterization of Brillouin scattering in POFs and its application to distributed large-strain sensing with a "memory" function. First, we review the first observation of Brillouin scattering in POFs at 1.55 μm, clarifying its fundamental properties, including a Brillouin gain coefficient, Brillouin threshold power, Brillouin frequency shift (BFS), and the BFS dependences on strain (relatively small strain and large strain) and temperature. These results indicate that Brillouin scattering in PFGI-POFs could be used to develop high-sensitivity temperature sensors and large-strain sensors. We also have a look at a new phenomenon named "BFS hopping", with which the BFS abruptly changes from 2.7 GHz to 3.2 GHz by applying large strain of up to 60% to POFs. It is shown that, after this effect, the BFS in POFs becomes more sensitive to temperature change and less sensitive to strain. Finally, we present our latest results on distributed strain and temperature sensing with a centimeter-order spatial resolution in a POF based on correlation-based technique. A 10-cm-long heated section of a 1.3-m-long POF is successfully detected with a theoretical spatial resolution of 7.4 cm and a sampling rate of 3.3 Hz (per measured point). We also discuss the influence of the POF characteristics (including BFS, Brillouin bandwidth, propagation loss, etc.) on the sensing performance.

Advances in Optical Fiber Reflectometry for Optical Access Network Diagnostics and Distributed Sensing

Xinyu Fan, **Qingwen Liu**, **Jiangbing Du**, **Lin Ma**, **and Zuyuan He**
State Key Laboratory of Advanced Optical Communication Systems and Networks
Shanghai Jiao Tong University, Shanghai 200240, China

Abstract— In this talk we will present the advances in research and development (R&D) activities of optical reflectometry in our laboratory.

A prototype ofphase-sensitive coherent optical time domain reflectometry (ϕ-COTDR) was developedfor the purpose of distributed vibration measurement. The performance is reported with the results of laboratorial tests and field tests. The frequency response of our prototype is 200 Hz at a measurement range of 40 km, and 1 kHz at a measurement range of 8 km. This prototype is believed to be eligible as being used as an important part of distributed vibration measurement applications such as a fiber fence security monitoring system, and a pipeline warning system.

Time-gated optical frequency domain reflectometry (TG-OFDR)is developed for the purpose of optical access network diagnostics. With the advantage of fully utilizing the frequency tuning range of the source and overcoming the spatial resolution degradation in long FUT, a spatial resolution of 2 m over a whole measurement range of 55 km was successfully obtained with a very simple scheme. We are now in the progress of developing it to a prototype for fault detection after the splitter of passive optical network (PON) scheme.

For high-spatial-resolution application, a broadly linearly-swept optical source based on optical comb and nonlinear fiber-optics is developed for being used in an OFDR scheme. With the high order sideband sweeping together with a four-wave mixing (FWM) phenomena to broaden the frequency sweep span 22-times, a spatial resolution of 0.75 cm is obtained with an original sweep span of only 638 MHz.

With the progress of the above introduced R&D activities of optical fiber reflectometry in our laboratory, we are trying to push the cutting-edge technologies be widely used in the industry.

Photonic Arbitrary Waveform Generation Using Optical Pulse Synthesizer and Its Applications

Ken Kashiwagi[1] **and Takashi Kurokawa**[1, 2]

[1]Tokyo University of Agriculture and Technology, Tokyo 184-8588, Japan
[2]National Astronomical Observatory of Japan, Tokyo 181-8588, Japan

Abstract— An optical frequency comb (OFC) is a light source whose spectral modes are equally spaced and is the topic of Nobel Prize in physics in 2005. Precise control of its spectral mode frequencies lead to diverse applications; distance measurement, profilometry, spectroscopy and optical frequency standard. A major generation technique propagates an intense pulse from a femto-second fiber laser through a highly-nonlinear fiber for spectral broadening. This approach can yield a broad spectrum, which typically has narrow mode spacing in an order from 10 to 100 MHz. On the contrary, the OFC with a mode spacing in a gigahertz range, which we call "multi-gighertz comb (MGC)", has advantages over the narrow-spacing OFC that each comb lines has higher powers and can be separated by gratings. We have studied optical pulse synthesis at high repetition rates using an MGC as a light source and an optical pulse synthesizer (OPS) as a device for frequency domain modulation onto the MGC. The OPS contains the all elements for the optical pulse synthesis on a single chip; an arrayed waveguide grating and multiple intensity and phase modulators. First, we introduce the pulse synthesis technique using the OPS and a variety of synthesized pulse waveforms. We demonstrate the generation of not only common types of pulses, Gaussian and sech^2 pulses, but also special types of pulses, parabolic, dark-soliton, and saw-tooth pulses. The synthesized pulses are used as a pump to induce optical nonlinearity in highly nonlinear fibers for signal processing and spectral broadening. Finally, we present our recent experimental results of ultra-fast wavelength conversion using a saw-tooth pulse for optical communication signals and a broadband MGC generation for an optical frequency calibrator of a spectrograph for an extra-solar planet finder.

High Sensitive Ammonia Gas Sensor Based on Graphene Coated Microfiber

Abstract— Ammonia is a kind of common poisonous gas in the atmosphere, thus ammonia gas sensor has a great demand in the fields of agriculture, chemical industry, medicine, etc.. The reported detection principles are mostly based on the electrochemical effect. However, miniaturized and electrical magnetic immune ammonia gas sensors become more and more important for severe environment.

Micro/nanofiber (MNF) featured with small size, tight optical confinement, low optical loss and large evanescent field transmission, is suitable for subminiature and passive photonic devices. In this paper, we propose an all-fiber miniature ammonia gas sensor based on graphene coated microfiber (GCMNF). Benefitting from the super-large specific surface area and fast electron transfer rate of graphene, the electrical properties and refractive index of graphene can be changed along with the number of ammonia molecules, leading to the variation of the transmission power of the GCMNF.

The graphene can be effectively coated onto the microfiber by light induced deposition which allows an interaction between graphene and the evanescent field of microfiber. Firstly, the graphene solution is confected by mixing 2 mg reduced graphene oxide powder with 20 ml anhydrous ethanol with a concentration of 0.1 mg/ml and then dispersed by an ultrasonic cleaner for 60 mins. Secondly, by using the flame-heating and taper-drawing technology, the microfiber with the waist diameter of $\sim 5\,\mu$m and the length of 10 mm is fabricated from a standard single mode fiber (SMF). Finally, make the microfiber dangle in the V groove and drip several drops of graphene dispersion until the microfiber is immersed into it. The light from high power EDFA is injected into the microfiber, and then the graphene particles start to be deposited onto the microfiber by thermal swirl and convection. Until the power remains unchanged, the ethanol evaporates completely. Consequently, the graphene coating process is finished. Before and after the deposition, we alternately use alcohol and deionized water to clean the microfiber many times to get rid of the dust and non-uniformly deposited graphene.

For the experimental demonstration of ammonia gas sensing, the GCMNF is fixed in the air chamber. Broadband light source injects into the GCMNF and the transmission intensity is detected by the optical power meter. Under the nitrogen atmosphere, the concentration of NH_3 injected into the chamber is changed from 0 ppm to 500 ppm by accurate control of the flow meter. We repeat the measurements for concentration rising and falling process, respectively. Experimental results indicate that the response time of GCMNF to NH_3 is only millisecond, and the sensitivity of the ammonia concentration is about 0.1352 dB/100 ppm through linear fitting of the experiment data. By employing the power meter with high resolution of 0.001 dB, high detection resolution of 0.74 ppm can be obtained. Furthermore, the sensitivity can be improved by decreasing the thickness of the coated graphene as well as the selective materials doping.

High Resolution Demodulation Platform for Large Capacity Hybrid WDM/FDM Microstructures Sensing System Assisted by Tunable FP Filter

Abstract— To increase the capacity of FBG sensing units in one single fiber, many methods have been taken to encode the FBGs such as the WDM, TDM, SDM schemes. In our previous work, we have reported a hybrid WDM/FDM sensing system by employing the simultaneous wavelength and frequency encoded microstructures as the sensing units along the fiber. The microstructure is composed of a pair of identical weak FBGs with certain spacing, resulting in the central wavelength of the FBG as the wavelength encoder and the cavity length of the FBG based Fabry-Perot Interferometer (FPI) related to the frequency encoder. However, the sensing system requires high resolution wavelength and frequency demodulation from the complex reflected spectrum, which the industrial optical spectrum analyzer cannot realize.

In this paper, we propose and demonstrate a flexible and high resolution demodulation platform for the hybrid WDM/FDM microstructures based on a tunable FP filter. The demodulation platform is constructed by an ASE light source, a circulator, a tunable FP filter, a photo detector, a NI FPGA card, a NI 16 bit AD/DA card and driving circuit for FP filter. The FPGA card is used to produce the driving signal of the tunable FP filter, and the driving circuit is employed to ensure steady output of the filter. The photo detector and the AD/DA card are adopted to gather the light signal reflected from the sensing units along the fiber. The transmission spectrum of the filter is very small, just like a delta function in wavelength domain. When the optical signal reflected from the fiber transmits through the FP filter, the output spectrum will be the convolution of the spectrum to be measured and the delta function. The tunable filter is driven by a ladder rising signal produced by the FPGA card, of which the central wavelength is determined by the driving voltage. Owing to the high resolution of AD/DA card, the step voltage of the driving signal is small enough to achieve high wavelength resolution. The light intensity data is collected during one step duration at a very high sampling speed and then is averaged to eliminate the perturbation of the filter and the detector noise. By recording the acquisition time, the light intensity data corresponding to the wavelength will be obtained, and then the full spectrum of signal reflected from all the sensing units along the fiber could be demodulated. Through wavelength grouping, spectrum FFT transformation, frequency filtering, and reverse FFT transformation, the spectrum of each microstructure can be separately demodulated. In order to accurately track the wavelength shift larger than one fringe in the interference pattern, we propose the curve fitting algorithm to get the envelope of it and then the wavelength shift of the envelope is considered to revise the wavelength shift of the interference fringe.

In order to test the performance of the demodulation platform, 16 microstructures of 4 WDM and 4 FDM are applied for experiment. The results demonstrate that each optical spectrum of the 16 sensing units can be extracted and retrieved separately, with a very high resolution up to 2.5 pm ranging from 1500 nm to 1590 nm at the high demodulation speed of 800 Hz. Due to the improvement in the wavelength resolution of the demodulation system, the capacity of the sensing units in one single fiber could be significantly enhanced.

Microfiber Resonators for Photonic Filtering and Sensing

Qizhen Sun[1, 2, 3], **Zhilin Xu**[1, 2], **Weihua Jia**[1, 2], **Haipeng Luo**[1, 2], **Yiyang Luo**[1, 2], **Deming Liu**[1, 2], **and Lin Zhang**[3]

Huazhong University of Science and Technology, Wuhan, Hubei 430074, China
[3]Aston Institute of Photonic Technologies, Aston University, Birmingham B4 7ET, UK

Abstract— Due to the promising properties of compact size, tight confinement, large evanescent field, high nonlinear effect and low transmission loss, optical microfibers have been emerging as a novel platform for exploring fiber-optic devices on micro-scale. In this paper, our recent progress in theory, fabrication of microfiber resonators and their applications in photonic filtering, lasing and sensing are discussed. Firstly, we present the microfiber based Fabry-Parot resonator, whose spectral filtering is composed of the interference fringes induced by multi-beam interference and reflection spectrum envelope induced by FBGs. The applications for tunable microwave generation and dual-parameters sensing are experimentally demonstrated. Secondly, we propose the "8" shaped resonator consisting of two microfiber Sagnac loop mirrors as the reflectors and a section of microfiber as the cavity. Owing to the high coupling efficiency induced by the large evanescent field of the microfiber, a broadband comb filtering spectrum with high extinction ratio and flat amplitude can be obtained, which has been applied in fiber ring laser to generate tunable multiwavelength lasing with high channel count. Finally, a compact tunable comb filter based on cascaded microfiber knot resonators (CMKRs) is designed, theoretically analyzed and fabricated by "Drawing-Knotting-Assembling (DKA)" technique On account of the Vernier effect, FSR broader than 63.682 nm and the Q value larger than 10^6 can be expected. In addition, sensitivity of 6523 nm/RIU and detection resolution up to 1.533×10^{-7} RIU for refractive index detection are realized, which can be widely used for chemical and biological detection, etc..

Precision Metrology with Frequency Combs over the Air: Time/Frequency Transfer and Spectroscopy

Nathan R. Newbury
National Institute of Standards and Technology, 325 Broadway, Boulder, CO 80305, USA

Abstract— The coherence, frequency accuracy, and broad optical bandwidth of frequency combs have enabled applications ranging from supporting optical clocks, to time/frequency metrology, to microwave generation, to precision molecular spectroscopy and beyond [1–4]. I will focus on two very different applications that both rely on frequency combs to provide higher precision and accuracy than conventional methods. Both applications require the use of two or more frequency combs and ultimately require operation outside the laboratory. Such applications are only possible with the continued evoluation of fiber-based frequency combs [5].

First, I will discuss coherent dual-comb spectroscopy. In dual-comb spectroscopy, the complex linear response of a sample is probed at each tooth of the frequency comb via massively parallel multi-heterodyne detection. In particular, we are focus on the use of dual-comb spectroscopy for atmospheric sensing over open air paths. Dual-comb spectroscopy (DCS) offers several favorable characteristics for intermediate-path sensing, including a coherent, collimated light source capable of traversing long path lengths (0.1–10 km), and simultaneous broad spectral coverage with extremely high resolution to enable coverage of the absorbing wavelength regions of several species with negligible instrument-derived distortion to the absorption spectrum. I will discuss a recent demonstration of the use of DCS for simultaneous, quantitative measurements of several greenhouse gas absorbers over a 2-km path above the NIST Boulder campus using near-infrared (1.5–1.7 μm) frequency combs.

The second application supports state-of-the-art optical clocks or oscillators, which have reached remarkable levels of stability and accuracy [6–9]. We have developed a technique to allow for comparison of two such optical clocks over a free-space link. This method essentially follows the conventional two-way time-frequency (TWTFT) technique but implemented in the optical domain rather than the rf domain. Through the two-way exchange of coherent optical pulse trains over turbulent, but nevertheless reciprocal, free-space links, one can completely cancel any timing noise associated with turbulence. Recent experiments conducted over a turbulent, 4-km free space link at the NIST Boulder campus have verified the low residual instability and high accuracy possible with this method [10]. With further development, this approach should enable the synchronization of two distant optical locks. This free-space approach can supplement current fiber-optic based approaches in situations when the remote clock is not located at the end of a deployed fiber link. In the future, such techniques might also support the use of optical clocks in satellite platforms.[1]

Abstract— In the last decade, research in high energy, short duration, pulsed fibre laser systems has yielded significant advances that have allowed fibre laser systems to compete with more established solid state lasers [1, 2]. Users of these products look for a number of qualities. High energy and short pulse duration are fundamentally important. Other design objectives include beam quality, wall plug efficiency, and thermal stability. We have recently demonstrated robust, passively mode-locked fibre laser designs that achieve these goals [3]. These devices use nonlinear amplifying loop mirrors (NALMs) for mode-locking, which allows for integrated all-fibre, all-polarisation maintaining (PM) cavity configurations that are inherently stable against environmental perturbations.

Here we report on our latest achievements in this area focussing on the excellent long term stability and adaptability of these sources. Fig. 1 shows our basic design fabricated using all-normal dispersion fibres and also equally import all-PM fibres making for a environmentally robust system. Our initial cavity worked at 1030 nm but we have also managed through appropriate choice of components, to obtain operation at 1060 nm.

A typical output spectrum is shown in Fig. 1(a). The pulses have a spectral bandwidth of about 3 nm, 0.34 nJ energy and a temporal duration of 5.8 ps. Using an external grating-pair compressor, we obtained comparatively clean pulses with 360 fs duration (FWHM) [see Fig. 1(b)]. The final figure in Fig. 1 shows the spectrum of our 1030 nm laser after over a period of 500 on-off cycles demonstrating both that it self-starts 100% of the time and that the resulting pulses are extremely reproducible.

We will discuss other extensions to our basic design allowing increased power, shorter pulses, altered repetition rate and operating wavelength etc.. These results emphasise the flexibility of our design and highlight what can be achieved using an all-fibre approach. Lastly we will discuss plans to further amplify these pulses to the multi-Watt level suitable for a range of industrial applications.

Abstract— Thulium-doped fiber lasers are becoming attractive laser sources in the spectral region around 2 µm with applications in material processing, biological imaging, atmospheric transmission and LIDAR for pollution monitoring. Among other applications belong pumping of solid state lasers (crystals, holmium-doped fiber), spectroscopy and efficient generation of super-continuum in the mid-IR range. Thulium fiber lasers operating at wavelengths around 2 micrometers are coherent light sources with a high slope efficiency reaching 70% and thus they are challenging the well-established ytterbium-doped fiber lasers operating at around 1 micrometer. Two-micrometer radiation sources have many advantages over the one-micrometer sources, e.g., better eye-safety, relaxed non-linear limits and often more efficient material processing.

In this paper we will review our recent progress in developing thulium-doped fibers. The fiber preforms were prepared by the modified chemical vapor deposition and solution doping techniques. Several approaches have been investigated in order to modify the the local environment of rare- earth ions in silica and to increase the quantum conversion efficiency of 3F4 level (upper level of the 2 µm transition) in thulium-doped silica fibers. We will review also the components for fiber lasers at around 2 micrometer that are based on fused biconical taper process. Several applications in fiber- based devices will be presented, namely in monolithic configuration of the laser cavity and broad band amplified spontaneous emission sources. Special attention will be given to the mode-locked femtosecond fiber laser with graphene-based saturable absorber.

Stretched-pulse Operation of an All-fiber Thulium/Holmium Doped Fiber Laser

Brian R. Washburn
Department of Physics, Kansas State University, 119 Cardwell Hall, Manhattan, KS 66506, USA

Abstract— Thulium/holmium doped fibers are promising gain sources for fiber based lasers in the near-infrared at 2 µm [1]. The combination of high gain and wide gain bandwidth (1.7–2.1 µm) make Tm/Ho doped fibers an attractive source for the production of femtosecond duration, high peak power pulses. Recently, we have demonstrated solitonic [2] and stretched-pulse [3] operation of a mode-locked thulium/holmium doped fiber laser. Positive net-cavity dispersion was obtained using a high numerical aperture fiber in the laser cavity that exhibits normal group-velocity dispersion [4, 5]. The laser dynamics as a function of the net cavity dispersion was experimentally observed. We clearly observe the transition from stretched-pulse to solitonic operation as the length of high numerical aperture fiber was reduced. The optimized laser bandwidth was 30 nm centered at 1.94 µm with a corresponding pulse duration of 450 fs. High numerical aperture fibers can be also used to simultaneously compensate both the second and third-order dispersion allowing for even shorter pulses to be generated.

One motivation for developing mode-locked Tm/Ho lasers is the generation mid-infrared (3–10 µm) ultrashort pulses and frequency combs. Mid-infrared laser sources have long been sought after for many important applications such as medical diagnostics, molecular identification, or gas monitoring. Furthermore, due to the success of using direct frequency comb-based spectroscopy in the visible and near-infrared [6] there is a strong desire to push phase-stabilized frequency combs to the mid-infrared to cover molecular fingerprint region from 2.5 µm to 12 µm. These applications will require robust and portable systems so fiber lasers are a better choice than their solid-state counterparts. Unfortunately, the strong mid-infrared absorption of fused silica fibers and the limited available of non-silica based gain fibers make it difficult produced mid-infrared pulses directly from a fiber laser. An alternative method is use a low mid-infrared loss, nonlinear fiber to extend the wavelength a pulsed near-infrared fiber laser to the mid-infrared. Chalcogenide or fluoride glass fibers could be used since they have low mid-infrared loss and high nonlinearity. Here, we investigate using the mode-locked Tm/Ho doped fiber laser to generate short, mid-infrared pulses and the possibility of using this laser as a source for a mid-infrared frequency comb. High peak power pulses produced by the Tm/Ho doped fiber laser will seed nonlinear spectral broadening in a ZBLAN fiber. By solving the nonlinear Schrödinger equation we demonstrate that the Raman soliton formation produce power-tunable, nearly transform-limited pulses centered in the mid-infrared.

Abstract— Ultrafast mode-locked fiber lasers, owing to their high peak power and short pulse widths, have driven applications in imaging, industrial machining and nonlinear optics. Taking these systems to the mid-infrared wavelengths (2–20 µm) allows access to other fields such as sensing and frequency comb based metrology, due to molecules absorbing light strongly at these wavelengths. However the performance of mode-locked fiber lasers in the mid-infrared has been limited with no demonstration of femtosecond scale pulses, and little evidence for a direct pulse measurement [1, 2]. At best an intensity autocorrelation of a 6 ps pulse was measured [3], but it did not reveal the true pulse shape or any phase information. Here we demonstrate the first modelocked fiber laser operating at wavelengths > 2.1 µm, producing 497 fs pulses with a peak power of 6.4 kW, with the electric field completely characterized using a Frequency Resolved Optical Gating (FROG) technique. This marks the first femtosecond-level fiber laser in the mid-infrared and highlights fluoride lasers as a strong candidate for ultra-fast mid-infrared sources.

This fiber laser was mode-locked by the use of nonlinear polarisation rotation (NPR) inside the ZBLAN fiber. The cavity (Fig. 1(a)) consisted of 3 µm of erbium doped ZBLAN fiber (7 mol.%) operating in a ring cavity, consisting of polarisation optics to act as an effective saturable absorber for mode-locking. NPR modelocking was achieved in the standard way [4] where a train of pulses was produced at 56.7 MHz, having a strong rf-beat signal with a signal to noise ratio of 73 dB. In order to unambiguously characterise the pulses we built a FROG measurement system based on the second harmonic generation from the mode-locked pulses through a $AgGaS_2$ crystal. By spectrally resolving the frequency-doubled light a spectrogram was constructed (Fig. 1(b)). Using standard algorithms the complete temporal and spectral fields were retrieved (Figs. 1(d), (e)), which revealed a pulse width of 497 fs and a calculated peak power of 6.4 kW. The retrieved spectrogram was in good agreement with the measured (Fig. 1(c)) as described by the low FROG algorithm error of 1.8×10^{-4}. Not only was this the shortest pulse produced from these fiber lasers, it was also the first ambiguity-free measurement of the pulses that retrieved the phase information, revealing characteristics such as pulse chirp. These fluoride fibre lasers will be one of the key sources of ultrafast mid-infrared laser radiation.

Abstract— We report nonlinear measurements of SiGe waveguides in the mid-IR performed in the picosecond and femtosecond regime and compare the results to numerical calculations. Nonlinear properties of SiGe waveguides in the mid-IR are extracted. We discuss the potential of SiGe alloys to become the platform of choice for nonlinear Mid-infrared integrated photonics (for operation between 2 and 12 µm).

The interest in expanding the spectral window of operation of group IV photonics towards the mid-infrared (mid-IR), which corresponds to wavelengths between 2 and 12 µm, is rapidly growing. The strong appeal of this particular spectral range derives from a vast range of potential applications such as chemical and biological sensing, active imaging, tissue ablation, secure free-space communication, and multiwavelength light sources [1, 2]. The mid-IR region has also been welcomed as a promising future regime for silicon based nonlinear photonic devices. The nonlinear loss phenomenon of two-photon absorption, that limits nonlinear optical applications in the near-infrared region, vanishes at these wavelengths [2, 3], thus opening the door to photonic devices with new capabilities such as parametric waveguide amplifiers with positive net gain [4]. However, it has recently [5], been shown that, under some experimental conditions, e.g., using picosecond pulses, nonlinear losses in the mid-IR can still be significant. The free carriers generated by multi-photon absorption can have a strong impact through free-carrier absorption (FCA) and thus limit some applications for which a strong nonlinear response is required, as for example supercontinuum generation [5].

The silicon-on-insulator (SOI) material platform has attracted significant interest to implement on-chip integrated waveguides operating in the mid-IR thanks to the possibility of a CMOS compatible fabrication process. However, the increasing absorption of the silica cladding layer of the SOI at wavelengths longer than 3.5 µm may limit the useful wavelength range of this material platform. It is therefore crucial to explore other material platforms. In this context, SiGe alloys on Si are seen as an attractive alternative platform to SOI for applications in the mid-IR due to their expected lower propagation losses and higher nonlinear response [6, 7].

Recently [8, 9], we reported SiGe/Si waveguides with propagation losses as low as 0.5 dB/cm at a wavelength of 4.75 µm. Here, in collaboration with CEA-LETI, RMIT Melbourne and the laser physics center of ANU Canberra we experimentally investigate the nonlinear response of these SiGe waveguides in the mid-IR including nonlinear transmission and self-phase modulation (SPM) using picosecond and femtosecond optical pulses centered at wavelengths between 3 and 5 µm [10].

Diverging and Converging Beam Diffraction by a Wedge. Part II: Plane Wave Spectral Solutions and Complex Ray Solutions

M. Katsav[1], **E. Heyman**[1], **and L. Klinkenbusch**[2]

[1]School of Electrical Engineering, Tel Aviv University, Tel Aviv 69978, Israel

Abstract— This two-part paper is concerned with calculating the diffraction of a two dimensional (2D) beam by a perfect conducting wedge. Specifically, we are interested in the case where the incident beam is converging as it hits the wedge. In a recent paper [1], we have used the complex source (CS) method to analyze the problem of beam diffraction by a wedge, but as discussed in Part I of this paper [3], the solution in [1] applies only for the case where the incident beam is diverging as it hits the wedge.

Following [2], we have explored in Part I [3] the application of the CS approach to the case where the incident beam is converging as it hits the wedge. We have utilized the multipole expansion of the conventional Green's function and have shown that it can be extended to the address the converging beam case but only if the CS coordinates are defined in a particular way. Specifically, we have determined the proper value of the CS coordinates for the diverging or for the converging beam cases so that the complex multipole expansion yields physically meaningful solutions.

In the present paper we establish the validity of the results in [3] by comparing them to solutions obtained via two alternative approaches: a plane wave spectrum approach and a complex ray tracing approach. In the former, the field of the incident converging beam is synthesized using the CS approach in conjunction with the plane-wave spectral analysis, and the diffracted field is then calculated using a multipole expansion approach. The exact solution obtained via this spectral technique is then compared with an asymptotic solution obtained via CR tracing augmented with nonuniform/uniform complex ray diffraction. The CR solution includes also selection rules that delineate the CR lit and shadow zones for the diverging or converging beam cases.

Phase Behaviour of an Azimuthally Magnetized Two-layered Ferrite-dielectric Circular Waveguide

Mariana Nikolova Georgieva-Grosse[1] and Georgi Nikolov Georgiev[2]

Abstract— The circular waveguides, entirely or partially filled with ferrite of azimuthal magnetization are apt for the development of nonreciprocal digital phase shifters, operating in the normal TE_{01} mode, since they can provide differential phase shift when switching the remanent magnetization of their anisotropic load between its two stable states [1–13]. For certain combinations of parameters the multilayered ferrite-dielectric structures could afford an increased value of this important quantity [1, 2, 4–6, 8, 13]. Due to the complexity of the tasks, however, still the phase behaviour of these configurations is not sufficiently clarified.

This purpose of this paper is the calculation and investigation of the phase characteristics of a two-layered circular waveguide, containing a coaxially positioned azimuthally magnetized ferrite cylinder, surrounded with an isotropic dielectric toroid, in contact with the transmission line wall that supports normal TE_{0n} modes. The boundary-value problem approach is employed. The complex Kummer confluent hypergeometric and the real Bessel and Neumann functions [14, 15] are accepted as wave functions for propagation in the ferrite and dielectric medium, resp. A procedure is worked out, making use of the numerically found purely imaginary roots of characteristic equation of the structure, yielding the aforesaid characteristics for both signs of ferrite magnetization in normalized form. In view of the great number of parameters involved, to facilitate the examination, the relative permittivities of both strata are assumed equal. A family of phase pictures of the geometry is computed and presented as a function of the ferrite cylinder to waveguide radius ratio ρ. As expected, the phase behaviour of the structure under study is much more complicated than those of the circular and coaxial waveguides filled with ferrite solely [7, 12]. Particularly, for both signs of off-diagonal ferrite tensor element α envelope lines exist at which the phase characteristics terminate. Hence, in contrast to the simpler ferrite configurations [7, 12], the propagation may occur in bounded frequency bands both for $\alpha < 0$ and $\alpha > 0$. This is a results of the appearance of the $L_{\pm}$ numbers, linked with the roots of characteristic equation [16]. For all values of ratio ρ the curves for negative lie above those for positive magnetization. For the pertinent normalized phase constants $\bar{\beta}_-$ and $\bar{\beta}_+$, answering to chosen normalized guide radius $\bar{r}_0$ and $|\alpha|$ ($|\alpha| < 1$), it holds $\bar{\beta}_- > \bar{\beta}_+$. The structure may produce positive differential phase shift $\Delta\bar{\beta} = \bar{\beta}_- - \bar{\beta}_+$ in a wide area of change of both $\bar{r}_0$ and $|\alpha|$. There are values of the latter, however, for which no $\Delta\bar{\beta}$ is provided. To the left of cutoff there is a backward-wave region where $\Delta\bar{\beta}_-$ is a double-valued function of $\bar{r}_0$ [9]. For certain values of parameters a magnetically controlled cutoff exists.

A Nonlinear Boundary Condition for Continuum Models of Biomolecular Electrostatics

J. P. Bardhan[1], **D. A. Tejani**[1], **N. S. Wieckowski**[1], **A. Ramaswamy**[1], **and M. G. Knepley**[2]

Abstract— Understanding the behavior of biomolecules such as proteins requires understanding the critical influence of the surrounding fluid (solvent) environment — water with mobile salt ions such as sodium. Unfortunately, for many studies, fully atomistic simulations of biomolecules, surrounded by thousands of water molecules and ions are too computationally slow. Continuum-solvent models based on macroscopic dielectric theory (e.g., the Poisson equation) are popular alternatives, but their simplicity fails to capture well-known phenomena of functional significance. For example, standard theories predict that electrostatic response is symmetric with respect to the sign of an atomic charge, even though response is in fact strongly asymmetric if the charge is near the biomolecule surface. In this work, we present an asymmetric continuum theory that captures the essential physical mechanism — the finite size of solvent atoms — using a nonlinear boundary condition (NLBC) at the dielectric interface between the biomolecule and solvent. Numerical calculations using boundary-integral methods demonstrate that the new NLBC model reproduces a wide range of results computed by more realistic, and expensive, all-atom molecular-dynamics (MD) simulations in explicit water. We discuss model extensions such as modeling dilute-electrolyte solvents with Debye-Huckel theory (the linearized Poisson-Boltzmann equation) and opportunities for the electromagnetics community to contribute to research in this important area of molecular nanoscience and engineering.

Metamaterials for Medical Implants to Enhance Compatibility with Magnetic Resonance Imaging (MRI)

Giorgio Bonmassar
Harvard Medical School, AA. Martinos Center, Massachusetts General Hospital
Building 149, 13th Street, Charlestown, MA 02129, USA

Abstract— Pacemakers, spinal cord stimulators, cochlear implants, and deep brain stimulators (DBS) and other electrical implants are becoming increasingly available as a treatment option to patients suffering from a wide range of diseases. Despite their remarkable success, one of the significant limitations of these medical devices is the limited compatibility with magnetic resonance imaging (MRI), which a standard diagnostic tool in medicine. A major concern when performing MRI examinations in patients with electrically conductive implants is the increase in induced currents ("antenna effect") along conductive leads in the body that are exposed to the radiofrequency (RF) waves of the MRI. The increase in current flow into the tissue at the point of contact with the lead (i.e., the electrodes), causing a large amount of RF energy to be absorbed in the tissue, which in turn causes surges in temperatures that can lead to serious injury [1, 2]. In this work we present a design based on metamaterials to decreases the antenna performance and the induced currents along the wire. The new implant exposed to an RF field can be represented with a hybrid model composed of an antenna attached to a transmission line, which consists of resistive traces with sharp changes in conductivity to maximize reflections, followed by a load such as an electrode connected to the tissue. According to our model [3], the equivalent antenna (i.e., the entire metamaterial) receives the electromagnetic field and injects it into the first port (i.e., layer) with impedance Z_1 of such a network. A portion of the power transmitted to the first port of the metamaterial lead is reflected back as a result of an impedance mismatch between the first port and the antenna, while a remaining portion is supplied to the second layer of the metamaterial lead. The impedance of this second port is intentionally mismatched to reflect the greatest amount of power back to the implantable pulse generator (IPG) or pacemaker and away from the electrode that is in contact with the tissue.

In the case of our metamaterial, we will present solutions to the following Pocklington's integral equation:

$$\begin{aligned} &\int_0^{L_2} I(z)\left(\frac{\boldsymbol{\partial}^2}{\boldsymbol{\partial}\mathbf{z}^2}+k^2\right)\frac{e^{-jkR}}{R}dz' + \int_{L_2}^{L_1+L_2} I(z)\left(\frac{\boldsymbol{\partial}^2}{\boldsymbol{\partial}\mathbf{z}^2}+k^2\right)\frac{e^{-jkR}}{R}dz' \\ =\ & -j\omega\varepsilon_w(z)\left(\|\mathbf{E}_{\mathbf{B}_1}(\mathbf{z})\| - \frac{I(z)}{L_w(z)\sigma_w(z)}\right) \end{aligned} \tag{1}$$

where $\sigma_w(z)$, $\varepsilon_w(z)$ and $L_w(z)$ are respectively equal to σ_1, ε_1 and L_1 when $L_2 \geq z \geq L_1 + L_2$ and equal to σ_2, ε_2 and L_2 when $z < L_2$. The solution $I(z)$ represents the current density field inside our lead implant, with the specific design goal to decrease the antenna performance and the induced currents along the wire. The analytic solution was compared to the numerical solution and confirmed that the metamaterial produced a lower inductance, which corresponded to a shorter equivalent antenna length and lower induced currents.

Coherent Helical Undulator Radiation in Resistive Waveguide

M. Ivanyan, T. Vardanyan, A. Tsakanian, and V. Tsakanov
CANDLE Synchrotron Research Institute, Yerevan 0040, Armenia

Abstract— The circular polarized intense radiation produced in helical undulators of advanced synchrotron light sources and free electron laser has an essential value for structural biology and molecular biophysics studies. The properties of the undulator radiation in free space and in the perfectly conducting walls waveguides have been extensively studied during the last decade. An important feature of the undulator radiation in waveguide is the radiation discrete spectrum conditioned by the excited waveguide modes. Actually, the waveguide modifies the continious spectrum of undulator radiation into a number of sharp peaks, each corresponding to an excited waveguide mode. The selected modes can be enhanced by proper choice of the undulator and waveguide parameters thus improving the undulator radiation source performance. However, in a real finite conductinmg wall metallic waveguide the properties of the radiation are changed due to boundary impedance.

In this paper, the helical undulator radiation in circular waveguide with finite conducting walls in surface impedance boundary conditions is studied. The solution of Maxwell equations are searching by the help of Fourier transformation of source and radiation fields and their expansion into modes of the resistive circular waveguide with impedance boundary conditions. The dispersion relations for the waveguide eigenvalues are given and the unknown amplitudes are determined using the orthogonality of the modes in impedance boundary condition approximation. The explicit forms of the point-charge longitudinal and transverse wake functions along the helical orbit are obtained. For the charge longitudinal distribution the particles within the bunch interact with the radiated electromagnetic fields that can be evaluated in terms of the wake potentials. The low frequency part of the wakefields formes the coherent part of the radiation, while the high frequency part leads to energy modulation within the bunch. The beam coherent radiation and particle energy modulation for various charge distributions are studied using the longitudinal wake function. An impact of the waveguide walls finite condcutivity to the helical undulator radiation performance is analysed.

High-power Short Pulse Compression: New Methods for Physical and Engineering Analysis

Merey Sautbekova[1], **Seil Sautbekov**[1], **Yuriy Sirenko**[1, 2], **and Alexey Vertiy**[1]

Abstract— One section in the book [1] is devoted to the model synthesis of resonant quasi-optical devices. An approach developed therein, has been originally described in [2] as applied to microwave energy compressors. The approach includes the following steps: estimation of the functional capabilities of isolated components, matching these capabilities with the functionality of the unit as a whole, construction of the corresponding mathematical model, electrodynamic analysis and synthesis of the unit and its components with due regard for optimization of the designed device. Mathematically, we deal here, as a rule, with open boundary value or initial boundary value problems, i.e., the problems whose domain of analysis is infinite in one or more directions. An efficient technique combining the time-domain and frequency-domain methods has been proposed to solve this kind of problems. The basic idea was to use the so-called exact absorbing conditions (EAC) in the finite-difference or finite-element algorithms and to invoke the analytical results obtained from the time-domain analysis of open resonators. These rigorous methods allow one to analyze the corresponding initial boundary value problems in bounded spatial domains and for long time intervals and to obtain reliable numerical data describing the transient processes under resonant conditions.

It is these methods that are best suited for reliable and precise analysis of the energy storage process in an active compressor, which is a high-Q resonant system excited by long quasi-monochromatic pulses, as well as of resonant and distributed energy switches. We have also proposed to apply this technique to the study of the compression of frequency-modulated pulses propagating long distances in the dispersive guiding structures like passive compressors. The proposed algorithms are based on exact analytical representations for the so-called 'transport operators' — diagonal convolution operators in the space of evolutionary bases of signals. The use of the FFT (fast Fourier transform) accelerated schemes is of great aid in their numerical realization.

The developed methods and algorithms have been implemented in the special-purpose software packages for 2-D (and partially — for 3-D) simulation and analysis of energy compressors and resonant radiators of high-power short radio pulses with arbitrary types of (i) cross-uniform regular waveguides for passive compression, (ii) storage units (waveguide and open resonators with metal, semitransparent, and frequency-selective mirrors), and (iii) switches (distributed grating-type switches for compressors on multimode waveguides and for resonant radiators, interference and resonant switches for compressors with single-mode output waveguides) for active compression.

Our approach as applied to formation and radiation of high-power short radio pulses we discuss in detail in this communication. We consider briefly the models that have been employed in the numerical experiments based on the EAC method too. Detailed discussion of these models and certain associated analytical results can be found in [1, 3].

Multi-objective Optimization Applied to RF and Photonic Components

Jogender Nagar, **Douglas H. Werner**, **and Pingjuan L. Werner**
Department of Electrical Engineering
The Pennsylvania State University, University Park, PA 16802, USA

Abstract— This study shows the potential of multi-objective optimization in the design of RF and photonic components. Multi-objective optimizers provide a visualization of the trade-offs between multiple conflicting objectives, allowing the designer to choose between a set of quasi-optimal solutions. Robustness and convergence efficiency are crucial for these optimizers to have real-world applications. In this study, three unique multi-objective algorithms will be compared in the analysis of a variety of RF and photonic components, including a microstrip patch and optical lens.

Introduction: Single-objective genetic algorithms have long been a critical tool in the design and analysis of electromagnetic components [1]. Real-world designs often have a large number of conflicting trade-offs, most notably performance vs. cost. The traditional single-objective approach requires the designer to make assumptions about the best way to combine these objectives, and the result is a single solution. In contrast, multi-objective optimizers require no assumptions and provide the designer with a set of solutions highlighting the design trade-offs involved [2]. This gives the designer an insight into the underlying physics of the problem, and provides them with the flexibility to choose the best design for a given application.

Multi-objective Optimization Applied to Electromagnetism: Electromagnetic simulations often require a large amount of time, making the convergence efficiency and parallelization of an optimization algorithm critical to its feasibility for real-world design applications. In addition, the cost functions are often noisy and extremely sensitive to the design parameters, making robustness another critical factor. Many unique algorithms have been proposed for multi-objective optimization, notably BORG [3], MOCMA [4] and MOEAD [5]. The convergence efficiency, ease of parallelization and sensitivity to parameters are compared for a variety of difficult problems, including an aperture-coupled stacked microstrip patch and GRIN lens.

Conclusion: Multi-objective optimizers provide a new design paradigm which has the potential to give RF and photonics designers a great degree of flexibility and insight. A study of these optimizers shows very promising results, but room for improvement as well.

Concerning the Circular- and Square-loop Antennas Mounted over a Ground Plane of Finite Extent

A. A. Ayorinde[1], **S. A. Adekola**[1, 2], **and A. Ike Mowete**[1]

[1]Department of Electrical and Electronics Engineering

[2]Department of Electrical and Electronics Engineering
Niger Delta University, Wilberforce Island, Yenegoa, Nigeria

Abstract— As a natural sequel to an earlier presentation [1], which compared the performance features of equal perimeter circular- and square-loop antennas located over finite ground planes, this paper, using the same formulation, examines the same performance characteristics, but this time, with the antennas being of equal cross-sectional areas; and with loop heights varying between 0.05λ and 1.00λ at the operating (center) frequency of 1.25 GHz. Computational results for the antennas' input characteristics reveal that whereas they share virtually identical input resistance profiles, input reactance for the square loop has values that are in general, lower than those for the circular loop, for the entire range of 'height above ground plane' considered. Results for the E- and H-plane radiation field patterns indicate that when the loops are located at heights beyond 0.3λ above the finite ground plane, the front lobes become distorted; an observation supported by the profiles of the forward directive gain, which display the 'notch filter response' behavior. Furthermore, the results suggest that acceptable front-to-back ratio performance can only be maintained if loop heights above the ground plane are kept below 0.3λ.

Integrated Matrix-form of the Boundary Conditions for Electromagnetic Field in Anisotropic Media

Bing Zhou[1] **and Graham Heinson**[2]

[1]Department of Geosciences, The Petroleum Institute, Abu Dhabi, UAE
[2]Geology & Geophysics, The University of Adelaide, Australia

Abstract— Boundary conditions of electromagnetic fields at the interface between two media are generally expressed as two separate equations:

$$(\mathbf{F}^+ - \mathbf{F}^-) \times \mathbf{n} = \mathbf{0}, \qquad (\boldsymbol{\alpha}^+ \cdot \mathbf{F}^+ - \boldsymbol{\alpha}^- \cdot \mathbf{F}^-) \cdot \mathbf{n} = -\Delta I^{\pm}. \tag{1}$$

Here $\mathbf{F} \in \{\mathbf{E}, \mathbf{H}\}$ stands for electromagnetic field intensity, $\boldsymbol{\alpha} \in \{\boldsymbol{\sigma} + i\omega\boldsymbol{\varepsilon}, \boldsymbol{\mu}\}$ defines physical properties of the media, $\Delta I^{\pm} \in \{\Delta J^{\pm}, \Delta M^{\pm}\}$ is the net electromagnetic current on the interface and $\hat{\mathbf{n}}$ is the interface normal. Eq. (1) shows that the boundary values $\mathbf{F}^{\pm}$ at a contact of two anisotropic media become the two implicit functions of the interface normal ($\mathbf{n}$) and tensors of electric permittivity ($\boldsymbol{\varepsilon}$), conductivity ($\boldsymbol{\sigma}$) and magnetic permeability ($\boldsymbol{\mu}$). This paper demonstrates that the two separate and implicit boundary equations can be combined as the following integrated explicit matrix-form

$$\mathbf{F}^{\mp} = \mathbf{C}_{\boldsymbol{\alpha}}^{\mp}\mathbf{F}^{\mp} + \left(\Delta I^{\mp}/\Delta_{\boldsymbol{\alpha}}^{\pm}\right)\mathbf{n}, \tag{2}$$

where the matrix have either the normal version

$$\left(\mathbf{C}_{\boldsymbol{\alpha}}^{\mp}\right)_{ij} = \delta_{ij} + n_i n_k \left(\alpha_{kj}^{\mp} - \alpha_{kj}^{\mp}\right)/\Delta_{\boldsymbol{\alpha}}^{\mp}, \qquad \Delta_{\boldsymbol{\alpha}}^{\mp} = n_i \alpha_{ij} n_j. \tag{3}$$

or tangential version

$$\left(\mathbf{C}_{\boldsymbol{\alpha}}^{\mp}\right)_{ij} = \tau_{1i}\tau_{1j} + \tau_{2i}\tau_{2j} + n_i \left[Q_1\left(\boldsymbol{\alpha}^{\mp}\right) n_j + Q_2\left(\boldsymbol{\alpha}^{\mp}\right)\tau_{1j} + Q_3\left(\boldsymbol{\alpha}^{\mp}\right)\tau_{2j}\right], \tag{4}$$

where

$$Q_1\left(\boldsymbol{\alpha}^{\mp}\right) = \Delta_{\boldsymbol{\alpha}}^{\mp}/\Delta_{\boldsymbol{\alpha}}^{\pm}, \quad Q_2\left(\boldsymbol{\alpha}^{\mp}\right) = n_i\left(\alpha_{ij}^{\mp} - \alpha_{ij}^{\pm}\right)\tau_{1j}/\Delta_{\boldsymbol{\alpha}}^{\pm}, \quad Q_3\left(\boldsymbol{\alpha}^{\mp}\right) = n_i\left(\alpha_{ij}^{\mp} - \alpha_{ij}^{\pm}\right)\tau_{2j}/\Delta_{\boldsymbol{\alpha}}^{\pm}. \tag{5}$$

Here $\{\boldsymbol{\tau}_1, \boldsymbol{\tau}_2\}$ are two perpendicular tangential vectors of the interface. Eq. (2) reveals that the boundary values of electromagnetic fields are linked by a 3×3 boundary matrix which depends on the interface topography $\{\mathbf{n}, \boldsymbol{\tau}_1, \boldsymbol{\tau}_2\}$ and the model property tensors $\{\boldsymbol{\sigma}, \boldsymbol{\varepsilon}, \boldsymbol{\mu}\}$. In addition, we demonstrate the mathematical equivalency of these different versions, as well as their synthetic examples of a hill and a ridge model in geo-electromagnetic analysis, and we highlight their advantage of being a simpler and more straightforward method of applying electromagnetic boundary conditions.

Optimization of Metamaterials for Microwave Devices

B. Vial and Y. Hao
School of Electronic Engineering and Computer Science, Queen Mary University of London
London E1 4NS, UK

Abstract— We report the design of an all-dielectric cloaking device using topology optimization and provide a quantitative assessment of its performances in the microwave regime. The physical mechanism leading to the cloaking effect is investigated through a modal analysis. We also discuss potential improvements and applications of optimization methods, including bandwidth enhancement and dispersion engineering.

Optimization Technique Applied to Cloak Design: Invisibility cloaks obtained analytically by Transformation Optics (TO, [1]) require extreme material properties (anisotropic, spatially varying permittivity and permeability). Such complex properties are not available in nature and have been achieved based on the use of metamaterials with microstructure much smaller than the wavelength. Those devices rely on resonances with narrow-band and lossy response and are difficult to realize in practice, which calls for other approaches for invisibility cloaks.

Recently, gradient-based topology optimization have been proposed to realize all-dielectric cloaks with low index contrast [2, 3]. We apply this idea to the design of a cloak made of ABS ($\varepsilon = 2.69 - 0.02i$) for TE polarization working at 10 GHz. It is designed to cloak an ABS dielectric cylinder of radius $r = \lambda$. The results are presented together with a quantitative analysis of the performances of the cloak [4]. In addition, we study the cloaking mechanism through modal analysis, and show that it is different from the one at stake in TO-based cloaks.

We finally discuss potential improvements the optimization technique, and its potential applications such as bandwidth enhancement, angular tolerance and dispersion engineering.

Broadband Microwave Absorber Utilizing Metamaterial and Magnetic Absorbing Material

Tianlong Wu, **Wei Li**, **Jin Yang**, **Wei Wang**, **and Jianguo Guan**
State Key Laboratory of Advanced Technology for Materials Synthesis and Processing
Wuhan University of Technology, Wuhan 430070, China

Abstract— The bandwidth of microwave absorbing materials is important for the practical applications [1]. However, the traditional magnetic absorbing materials (MAMs) cannot simultaneously show high magnetic loss and good impedance matching in the whole frequency range of 2–18 GHz because of the magnetic resonance nature and Snoek's limit [2]. On the other hand, it is also hard for metamaterial absorbers (MAs) to achieve a wide absorption bandwidth because of the resonant absorption nature. In this presentation, by combing the broadband absorption property of the MAMs in high frequency and easily adjustable advantages of the MAs, we proposed a two-layer hybrid absorber that the top layer of the non-planar MA stands on the bottom layer of the MAM. In this bilayer hybrid absorber, the MA layer offers strong absorption for low frequency waves while allowing high frequency waves to propagate through without reflection. The bottom MAM layer then strongly absorbs the high frequency EM waves. Through combining different functionalities into the composite design, a broadband, high efficiency, light-weight, and easily tunable absorber is obtained [3]. To further broaden the absorbing bandwidth and reduce the thickness, we then advanced a crisscross two-layer composite absorber by two identical polarization sensitive MAs. The lower frequency is firstly absorbed by the bottom layer MA as TE absorbing mode and the higher frequency is consumed by the top layer MA as TM absorbing mode. Consequently, the total reflection is reduced (less than 10%) in a wide frequency range as broad as 3–40 GHz. In our works, a simple patterning method is also proposed to drastically broaden the absorption bandwidth of a conventional MAM. In such a patterned absorber, the broadband strong absorption is mainly originated from the simultaneous incorporation of $\lambda/4$ resonances and edge diffraction effects. Simulated and experimental results reveal an ultra-broadband microwave absorber with more than 90% absorption in the frequency range of 4–40 GHz which has a thin thickness of 3.7 mm [4]. Besides, we have designed a bran-new planar composite absorber by embedding metamaterial (MM) in the MAM. By optimizing the structure and shape of the MM to eliminate or weaken the coupling effect between the MM and the MAM. So the composite absorber possess flexible and adjustable characteristics of the MM at low frequencies, while retaining the broadband absorbing in high frequencies of the MAM. Significantly, the thickness of this planar composite design is much smaller than the multilayer configuration to broad the absorbing band. So, integrating MM with MAM reveal a promising and flexible method to greatly extend or control the absorption bandwidth of absorbers. By changing the properties of the MM and the magnetic MAM as well as their arrangement, more electromagnetic hybrid absorbers can be made to accommodate diverse intended applications.

Abstract— We demonstrate the condition of unitary transmission between uniaxial epsilon-near-infinity (ENI) media with double infinite components. We propose that broadband uniaxial ENI metamaterials at microwave frequencies can be realized by alternatively stacking thin metallic plates and air. Making use of the unitary-transmission condition and broadband ENI metamaterials, a sharp bending device in rectangular waveguide working for broadband electromagnetic waves is demonstrated.

Self-guided One-way EM Wave by Chain of Gyro-magnetic Rods

Rui-Xin Wu, **Zhen Li**, **Qing-Bo Li**, **and Yin Poo**
School of Electronic Science and Engineering
Nanjing University, Nanjing 210093, China

Abstract— Magnetic photonic crystals (MPCs) are of great interest in recent years for their many unique characteristics, which will lead to great potential applications in microwave and optics engineering. One-way self-guided propagation for which electromagnetic waves are guided along the edge of the MPC without any other cladings [1], is one of the most attractive characteristics of magnetic photonic crystals. Most of the one-way self-guided transmission is based on MPC slabs made of gyro-magnetic rod array [1–3]. The underline mechanisms are topological electromagnetic (EM) edge states [2], or magnetic surface plasmon (MSP) resonance [3].

As the edge stats is localized on the interface of MPC, we will show here that even for a single layer of gyro-magnetic rods, i.e., a chain of rods, can support self-guided one-way propagation of EM waves. We investigate two types of rod chain: one is of zigzag form, another has straight-line one. The variation of band structures from MPC to rod-chains proves the existence of edge modes in gyro-magnetic rod-chains. Both simulated and measured results show that the two forms of rodchain have broadband frequency range of one-way transportation that is robust to the wave channel bending.

The rod-chain configuration provide a new way to the applications of one-way waveguides, which has deep sub-wavelength transverse dimension and very flexible to form arbitrary shapes of oneway waveguide. An example is given. These characteristics make the rod-chain very attractive for practical applications.

Hyperbolic Polaritons for Near-field Optical Imaging

Lian Shen, **Zuojia Wang**, **and Hongsheng Chen**
The Electromagnetics Academy at Zhejiang University, Zhejiang University, Hangzhou 310027, China

Abstract— We study the behavior of hyperbolic polaritons — an alternative form of light propagation with effective wavelength that is much shorter than $\lambda_0/2n$ — in hyperbolic materials. We find that the wave vector refraction of hyperbolic polaritons at different hyperbolic medium interface obeys the Snell's law which is an effective way to manipulate waves at deep subwavelength scale. In particular, we develop a bilayer lens by combining Type I and Type II hyperbolic materials with proper thickness for realizing near-field imaging. Such approach constitutes a further important step towards practical applications of optical imaging.

Broadband Focusing: On-chip Demultiplexers for SPPs and Guided Modes

Tao Li, **L. Li**, **Q. Q. Cheng**, **and S. N. Zhu**
National Laboratory of Solid State Microstructures
College of Engineering and Applied Sciences, Nanjing University, Nanjing, 210093, China

Abstract— Recent advances have pushed the optical design from the macro scale to micro/nano scales, in order to meet the requirement of compact photonic integration. One of the important techniques in optical intercommunication is the wavelength division multiplexing (WDM), by which the information carried by the optical signal can be multiplexed with large capacity. Plasmonics does provide such a solution in routing the optical field in very compact area, and great successes have been achieved in manipulating the surface plasmon polariton (SPP) field. Among them, SPP focusing is a basic and useful function that can be adopted to many nanophotonic devices. Here, I would introduce a recently developed in-plane Bragg diffraction method in manipulating the SPP beam [1, 2], by which a broadband SPP focusing was successful achieved [3]. Taking good usage of the broadband focusing, a plasmonic WDM was proposed and realized with a typical wavelength resolution about 12 nm. Although this resolution is not very good, this device has a relative bandwidth (more than 100 nm) and compact footprint. More importantly, this method provides people a new and general method in steering the SPP and guided modes. As consequences, it is extended to manipulate the guided modes in metal/insulator/insulator hybrid waveguides. According to different mode indices (as well as propagation wave numbers), multi-modes of a same free spaces wavelength (633 nm) inside the hybrid waveguide were clearly separated by this focusing design [4]. Therefore, an compact mode division mulitiplexer (MDM) was achieved. From another viewpoint, both the WDM for SPPs and MDM for guided modes, can regarded as the integrated spectrometers, which are very important components in the on-chip integration for the photonic sensing and detection.

Performance Comparison of Phase-corrected and Classical 1D Electromagnetic Band Gap Resonator Antennas

Basit Ali Zeb, **Muhammad Usman Afzal**, **and Karu P. Esselle**
Centre for Electromagnetic and Antenna Engineering
Department of Engineering, Macquarie University, Sydney, Australia

Abstract— Electromagnetic band gap resonator antennas (ERA), also known as Fabry-Perot cavity antennas or 2D Leaky-Wave antennas, are planar high-gain antennas that employ a resonant cavity formed between a partially reflecting superstructure (PRS) and a fully reflecting ground plane. The cavity is fed by a small less-directive antenna. Since the pioneering work of Von Trentini in 1956 [1], several research groups have investigated techniques to improve the performance figures of ERAs such as antenna bandwidth, peak directivity/gain, sidelobe levels and aperture efficiency. Our recent investigations indicated that many ERAs have non-uniform aperture phase distributions, or phase errors, which can be a limitation in achieving the optimal antenna performance. This motivated us to correct these phase errors [2] to achieve nearly uniform aperture phase distribution, and hence to significantly increase the antenna performance, particularly directivity and sidelobe levels. In this paper, we present a qualitative comparison of one phase-corrected ERA and a classical ERA with the help of full-wave numerical simulations in CST MWS. The antenna configurations are shown in Fig. 1. For this study, we used a simple probe-fed microstrip patch as the feed antenna. The example phase-corrected ERA utilises an all-dielectric phase correcting structure (PCS) [2] placed on top of the base ERA, which itself has one unprinted quarter-guided-wavelength-thick superstrate layer placed half a wavelength distance above the PEC ground. The classical ERA consists of a 1D EBG structure [3] (also known as a Bragg reflector), i.e., a stack of identical dielectric slabs (two or more) placed quarter of a wavelength distance apart with alternate layers of low and high permittivity material (air-dielectric-air). The key results and performance parameters are compared in Table 1. A 9.4 dB increase in antenna directivity, lower sidelobe levels and better aperture efficiency are achieved for ERA with PCS over the classical 1D ERA with one slab. The phase-corrected ERA is suitable for wideband applications that require directivity greater than 20 dB. For very narrowband applications, classical 1D ERA with 3 slabs is suitable.

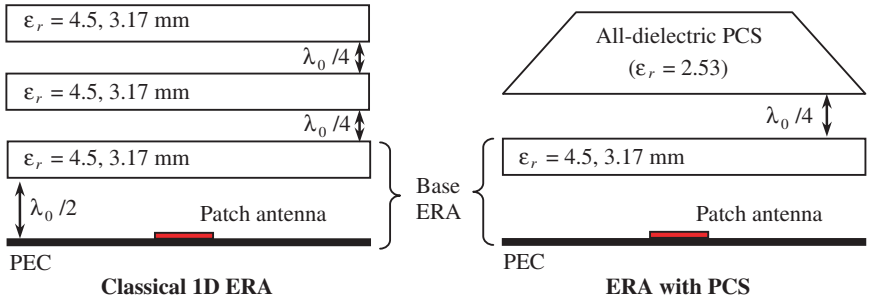

Figure 1: Configurations of the two ERAs under study.

Table 1: Performance comparison of two different ERAs. Design frequency is $f_0 = 11.1$ GHz.

		Classical 1D ERA					ERA with PCS
		1 Slab	2 Slabs	3 Slabs	4 Slabs	5 Slabs	
Peak Directivity (dBi)		12.5	20.8	24.3	22.6	18.3	21.9
3 dB Directivity Bandwidth (%)		11.2	3.1	2	1.2	0.8	8
Sidelobe level (dB)	*E*-plane	−9.8	−16.1	−20.0	−13.7	−10	−16
	H-plane	−19.2	−24	−20.2	−13.7	−9	−20
3 dB Beamwidth (deg)	*E*-plane	34.2	12.3	9.6	10.2	11	13.9
	H-plane	35.4	11.9	9.9	9.8	10.1	13.6
Aperture Efficiency (%)		4	23	44	44	11	28
Total Antenna Height (mm)		∼ 16	∼ 27	∼ 37	∼ 47	∼ 57	∼ 60

Abstract— Wireless microwave technology with large bandwidth are always required in high-capacity communication, precise measurement, and high-resolution radar. The large bandwidth can be achieved by use of wireless microwave in high-operational frequency such as millimeter-wave or terra-hertz bands. Additionally, there are availability spectrum of the millimeter-wave/terra-hertz bands and promising to open for new advanced applications. However, the bands have large propagation loss in the air and metal cables. The drawback can be compensated for by adopting radio-over-fiber (ROF) technology, where the wireless microwave is modulated to lightwave and propagated through low loss optical fibers. Furthermore, the large area can be covered by installing small wireless cells with optical fiber connection. Therefore, a converter from electrical and optical signals is required in the high-speed ROF technology. The electrical-optical converter can be composed of microwave antennas and optical modulators. Recently, microstrip patch antennas and electro-optic (EO) modulator using planar structures were developed for microwave/millimeter-wave bands. The antenna size becomes very small for high operational frequency. Precise tuning is also required for effective resonance. Therefore, a new device structure are investigated for high operational frequency.

In this paper, we propose a new electrical-optical converter using electric-field-coupled (ELC) metamaterial antennas on an EO modulator for wireless millimeter-wave/terra-hertz applications. By irradiation wireless millimeter-wave/terra-hertz signals, strong millimeter-wave/terra-hertz electric field can be induced on the ELC metamaterial antennas. The induced millimeter-wave/terra-hertz electric field can be used for EO modulation when a lightwave propagates into an optical waveguide located under regions of the induced wave/terra-hertz electric field. The proposed device has compact structure and passive operation with no external electrical power supply. Analysis in microwave and optical modulation of the proposed electrical-optical converter and its fabrication process in experiment are discussed and reported in detail for operational frequency of 100 GHz.

Broadband Perfect Absorption of Ultrathin Conductive Films

Sucheng Li, Weixin Lu, and Bo Hou
College of Physics, Optoelectronics and Energy
Collaborative Innovation Center of Suzhou Nano Science and Technology
Soochow University, 1 Shizi Street, Suzhou 215006, China

Abstract— Absorption of microwave by metallic conductors is typically inefficient, albeit naturally broadband, due to the huge impedance mismatch between metal and free space. Reducing metal to ultrathin profile may improve the absorption efficiency, but is still bounded by a maximal 50% limit induced by the field continuity. Here, we experimentally show that broadband, perfect (100%) absorption of microwave can be realized in a single layer of ultrathin conductive film when it is illuminated coherently by two oppositely incident beams. Inheriting the intrinsic broadband feature of metal, the complete absorption is frequency-independent in the spectrum which spans 6–18 GHz in our microwave experiments and may range from kilohertz to gigahertz frequencies in theory. Remarkably, it occurs in films with thicknesses that are at the extreme subwavelength scales, $\sim \lambda/10000$ or less.

Furthermore, the coherent illumination ($\Delta\varphi = 0$) requires a zero-path-delay interferometer for the two counter-propagating coherent beams. The critical interfering condition guarantees a constructive interference of the electric fields and simultaneously a destructive one of the magnetic fields at the film position at every frequency, which eliminates the dispersive coupling in conventional interfering absorber designs and can be equivalently regarded as a frequency-independent magnetic boundary.

Negative Refraction of Natural Composite Based on Graphene Barium Ferrite

Karen Oganisian and Wieslaw Strek
Institute of Low Temperature and Structure Research Polish Academy of Science
Okolna 2, Wroclaw 50-244, Poland

Abstract— In recent decades an interest with the negative refraction materials (metamaterials) increased due to their exotic features such as reversed geometrical optics, Doppler shifts, Cerenkov radiation etc.. There are many different classes of metamaterials but one feature is common for all of them — they have an artificial origin. The natural negative refraction materials may solve the main problem of their fabrication. Here we present the possibility to obtain negative refraction in natural physic-chemical synthesis of graphene ferrite composition which can be simply applied in industrial scale.

The structure, dc magnetic and electromagnetic properties of graphene barium hexoferrite-$BaFe_{12}O_{19}$ obtained by a hot pressing were examined by X-ray diffraction, scanning electron microscopy, dc magnetization and the capacitance and inductance measurements in the frequency range between 10 and 1 GHz.

It was found that the graphene plates were stacked parallel to each other forming the dense layered quasi-2D percolated structure along the samples as result of high pressure treatment. The barium ferrite nanoparticles were inhomogeneously distributed in graphene host. The dc magnetization loop was characterized by conventional ferromagnetic ordering with relatively high coercivity and remanence. In turn, electromagnetic investigations revealed electric and magnetic resonances near 500 MHz and 100 MHz, respectively. The resonances were accompanied by changes of the sign of permittivity and permeability. Moreover the region with simultaneously negative ε' and μ' was extended up to several GHz.

The observed resonances may be associated to the pressed graphene features because both such resonances were detected in the pure graphene samples. Recently we have observed the strong electric resonance in pure graphene samples that may be explained by the creation of 2D plasmons due to strong coupling between a quasi-2D structure of graphene and perpendicular oriented TE mode of incident wave. Such a strong interaction may arise from the modification of Fermi energy in graphene by an external electromagnetic field. On the other hand it also can be related to Drude relaxation on graphene plates.

However, in pure graphene, magnetic resonance do not change the sign of permeability. Whereas in graphene ferrite composition, magnetic impurities reduce permeability "background" due to barium ferrite ferromagnetic resonance which appears at lower frequencies. Therefore even weak magnetic resonance of graphene may changes the sign of permeability to negative.

Following well known definition the refractive index $n = \sqrt{\varepsilon\mu}$ is negative when the real parts of ε and μ are negative simultaneously in the overlapped frequency range. Thus, it was found that the refraction of graphene ferrite nanocomposite was negative from 500 MHz up to several GHz.

In summary the nanocomposite of graphene barium ferrite obtained by a hot pressing revealed both negative permittivity and permeability in the overlapped frequency range suggesting on negative refraction in the broad frequency region from 500 MHz up to several GHz.

Abstract— In modern life, global population is continuously exposed to electromagnetic radiation emitted by mobile phones, computers, radars, smart meters and medical technology equipment etc. In the last 10 years, use of mobile phone worldwide has increased by almost 200% resulting in 4.65 billion users in 2014. This rate is further increasing at approximately 5% annually [1]. Because mobile phone use is so widespread, public concerns about the possible health effects of mobile phones receive a lot of coverage in the media. Intensive international research has found no conclusive or convincing evidence that mobile phones are damaging to health in the short or long term. However, in May 2011, the World Health Organization (WHO) classified RF radiation as 'possibly carcinogenic for humans, based on an increased risk for glioma, a type of brain cancer' [3].

There is an increasing need to study and evaluate the impact of weak RF at cellular and molecular levels. Recent reports confirm that even weak RF induces modulating effects on various biological systems [2, 3]. This study aims to improve our understanding of impact of low power RF radiation (4G mobile network frequencies) on enzymatic reactions. The selected enzymes play crucial roles in the biological processes. L-Lactic dehydrogenase is extensively present in blood cells and heart muscles, and is a marker of common injuries and disease. Catalase enzyme can be found in all living organisms, it is important for protecting a cell from oxidative damage by reactive oxygen species (ROS). This *in vitro* study evaluates the effects of low power RF on kinetics of LDH and Catalase enzymes irradiated at the frequencies of 2.1, 2.3, and 2.6 GHz and two powers of 17 and −10 dBm using the commercial Transverse Electro-Magnetic (TEM) cell. The experimental findings reveal that RF exposures at the particular studied parameters can induce changes in the enzymes' kinetics, which in turn lead to modulation of rate of change in corresponding reactions these enzymes catalyze. The results of experimental evaluation are presented and discussed in the paper. This study will contribute towards identifying guidelines for safety measures of RF exposures.

Abstract— Energy supply to a biological system excites and sustains a state far from thermodynamic equilibrium which is a basic condition of life. Distribution of charges in biological molecules and structures and exceptional electric polarity of biological objects suggest excitation of coherent electromagnetic field (EMG) generated by polar vibrations [2]. Microtubules in the cytoskeleton of the living cell are the generating structures [5]. Resonant frequencies of individual microtubules were recently investigated in a systematic fashion in the frequency range from 1 kHz to 20 GHz. Two frequency bands were disclosed: One band has resonant frequencies 10–30 MHz, the other 100–200 MHz. Generation of EMG is conditioned by electric polarity, nonlinearity of vibrations, and energy supply to microtubules. Mitochondria provide energy supply, establish a strong static electric field and ordered water around them resulting in low damping of oscillations [3]. Energy of the generated EMG is transformed into physical forces and useful work for biological needs and provides interactions, transport, organization, synchronization of dynamic processes and information transfer. The brain activity, central control function, instinct of self-preservation, and consciousness are assumed to depend on electrodynamic processes, mainly of quantum nature.

Basic items of biological electromagnetic activity were formulated in the form of postulates to set up a solid foundation for further theoretical and experimental studies in a new interdisciplinary field–physical biology [6]. First postulates concern existence of the endogenous coherent electromagnetic field, generating structure, and supporting organelles: The field is generated by microtubules, which are nonlinear oscillating structures, and the supporting organelles are mitochondria. Other postulates describe function of the electrodynamic field in biological cells and the brain. The last postulate concerns pathological states of the electrodynamic field, in particular, in cancer development. Therefore, cancer process is a pathological state of disturbed energy processing system including generation of the EMG [4]. Besides postulated functions the generated electrodynamic field should carry out other essential functions of life.

Cancer is a pathological breakdown of coherent energy states in living cells, in particular, of generated electromagnetic field. After mutation of genome the power plants of the cell, mitochondria, are attacked. Oxidative metabolism is deformed by closing the sugar way. This link of cancer transformation was discovered by O. Warburg [7]. As a result of this link damping of the electric polar vibrations and electromagnetic field is increased. Due to damping coherence of oscillations is diminished and in the phenotype of the Warburg effect (the reverse Warburg effect) the power of the electromagnetic field decreased (increased), and frequency of oscillations increased (decreased) with respect to healthy cells in the tissue. Due to frequency changes interaction between healthy and cancer cells are not attractive [1]. The cancer cells perform invasive motion into their surroundings and then initiate metastastic process. The main part of the cancer process is of physical nature. The transformation pathway of cancer will be shown.

Abstract— The effects of weak magnetic fields on the production of reactive oxygen species from (ROS) intracellular superoxide ($O_2^{\bullet -}$) and extracellular hydrogen peroxide (H_2O_2) were investigated *in vitro* with rat pulmonary arterial smooth muscle cells (rPASMC). We observe a decrease in $O_2^{\bullet -}$ and an increase in H_2O_2 concentrations in the presence of a 7 MHz radio frequency (RF) at 10 μT_{RMS} and static 45 μT magnetic fields. We propose that $O_2^{\bullet -}$ and H_2O_2 production in metabolic processes occur through singlet-triplet modulation of semiquinone flavin ($FADH^{\bullet}$) enzymes and $O_2^{\bullet -}$ spin-correlated radical pairs. Spin-radical pair products are modulated by the 7 MHz RF magnetic fields that presumably decouple flavin hyperfine interactions during spin coherence. RF flavin hyperfine decoupling results in an increase of H_2O_2 singlet state products, which creates cellular oxidative stress and acts as a secondary messenger that affects cellular proliferation. This study demonstrates the interplay between $O_2^{\bullet -}$ and H_2O_2 production when influenced by RF magnetic fields and underscores the subtle effects of low-frequency magnetic fields on oxidative metabolism, ROS signaling, and cellular growth.

Principles and Methods of EMF Safety Maintenance by Individual Protective Means

I. V. Bukhtiyarov, N. B. Rubtsova, S. Yu. Perov, O. V. Belaya, and T. A. Kravtsova
FSBSI "Research Institute of Occupational Health", Moscow, Russian Federation

Abstract— According the principles of electromagnetic safety one of way of this problem solving is protective mean use. There are 2 main directions of protective means: collective and individual. Collective protective means in dependence of EMF frequency range decrease EMF value by means of EMF reflection or absorption. Individual protective means (protective suits) use as a rule in cases of static electric field, power frequency (50/60 Hz) electric field and radiofrequency (RF) EMF occupational exposure. The methods of these protective suits testing are developed in different countries. Great difficulties are connected with correct evaluation of RF EMF individual protective means protective characteristics.

There is presented the method of RF EMF protective suit (PS) safety properties evaluation. Safety properties of modern PS are based on EMF reflection, which ensures shielding effect. PS is made of electro-conductive materials; all elements are connected to produce a "cover" around a human body, which allows reducing the EMF values to permissible levels.

The testing of protective suit is carried out by special setup use. EMF are emitted by means of RF generator connected with antenna through amplifier. Special setup includes human body phantom (head, trunk and extremities) and measuring probe connected to personal computer by optic fiber. Phantom is placed in spatially homogeneous EMF for all body parts. EMF measurement is carried out in three control points (head, breast and groin) at fixed distances from RF EMF source in two phantom positions: in front and back to the RF EMF source (with and without PS).

The results obtained by suggested approach allow determining PS protection level (in dB), and develop recommendations for construction upgrade.

Furthermore, the obtained data of shielding effectiveness suggest that there is the relationship between protective properties and RF EMF values. Proposed method of PS shielding effectiveness evaluation can help analyze those relationship in future studies.

Experimental Study of Digital Enhanced Cordless Telecommunication Devices Electromagnetic Field Possible Hazard Health Effects

N. B. Rubtsova, S. Yu. Perov, O. V. Belaya, and E. V. Bogacheva
FSBSI "Research Institute of Occupational Health", Moscow, Russian Federation

Abstract— Radiofrequency electromagnetic field (RF EMF) wireless personal telecommunication devices may be the reason of increased adverse human health effects. The most of recent studies analyze the possible health hazards of cellular phone EMF only.

The goal of research was to investigate the Digital Enhanced Cordless Telecommunication (DECT) EMF biological effects to animal behavior and reproduction function. EMF exposure parameters: frequency 1890 MHz, continuous wave (CW), power density 250 $\mu W/cm^2$ (exposure time 2 hours/day; 5 days/week; 4 weeks) and 500 $\mu W/cm^2$ (3 hours/day; 5 days/week; 4 weeks). The objects: white rats male (190–210 and 340–360 g). Each exposed group had sham exposure. The evaluated parameters: weight (body, spleen, adrenal glands, testis), behavioral parameters (open filed test), the function of reproduction system (epididymis sperm count, sperm osmotic resistance).

Exposure value 500 $\mu W/cm^2$: significant decrease of rats' behavioral parameters after 5 days; decrease of behavioral parameters, sperm osmotic resistance, spleen and testis weights after 10 days; decrease of sperm osmotic resistance and body weight after 20 days. Exposure value 250 $\mu W/cm^2$: significant decrease of rats' sperm osmotic resistance after 20 days of exposure and after 2 postexposure weeks, as well as significant decrease of adrenal glands weight and epididymis sperm count after 2 postexposure weeks.

There were carried out the simulation EMF exposure experiment. The simulation helps to find the dependency interrelation between power density, power exposure and specific absorption rates.

The results showed that exposure to CW EMF at 1890 MHz with 500 and 250 $\mu W/cm^2$ may lead to adverse health effects on reproductive system of male rats; and using of DECT devices may be evaluated as possible human health risk factor.

Numerical Field Calculations for Assessment of Electric Field Strength Arising in Human Body Tissues Caused by Magnetic Field Exposure

Reinhard Doebbelin, Stefan Foerster, Lars Middelstaedt, and Andreas Lindemann
Otto-von-Guericke-University Magdeburg, Germany

Abstract— Application of high currents in industrial processes is accompanied by intense magnetic fields in the vicinity of such equipment and so in the workplace area of operators.

The International Commission on Non-Ionizing Radiation Protection (ICNIRP) is a respected institution which has been engaged in analysis of human field exposure and definition of limit values for a lot of years. Considering the guidelines concerning the limitation of exposure to time-varying fields published by ICNIRP in 1998 and 2010, the EU issued a directive on the minimum health and safety requirements regarding the exposure of workers to the risks arising from electromagnetic fields (EMF) in 2013. According to these rules, limits exist for parameters of the in-situ electric field (named basic restrictions/exposure limit values) and for affecting (external) electric and magnetic fields (named reference levels/action levels). Compliance of an exposure situation with the limits for the affecting field can be checked by means of measurements. However, the limits for the electric field arising in relevant tissues of the human body represent the, in the end, decisive criterion for the field exposure assessment. The reference levels for the external field were derived from the basic restrictions in a relatively conservative way. Therefore, especially in technological high-current applications, it can be useful to perform a field exposure assessment considering compliance with the basic restrictions. Nowadays, the determination of the in-situ electric field strength occurring in the body tissues can be done by means of numerical field calculations using appropriate software and an anatomically-based human body model including the required characteristics of the body tissues. Such numerical field calculations were carried out for exposure situations at resistance welding equipment using high-amperage welding currents in the kA range. An example of the modelled arrangements is depicted in Fig. 1. By means of the applied simulation program *EMPIRE XCcel*$^{\text{TM}}$. the simulation space including the magnetic-field generating welding circuit, the human body model (model *Duke* of the *Virtual Family*, established by IT'IS Foundation, Zurich, Switzerland) and air is discretized into cells in the form of cuboids. The mentioned simulation software uses the finite differences time domain technique to solve the Maxwell equations. This way, the field parameters of all cells are updated at each time step and finally the resulting electric field strength values in all relevant regions of the body model and the corresponding tissues are determined. This is illustrated in

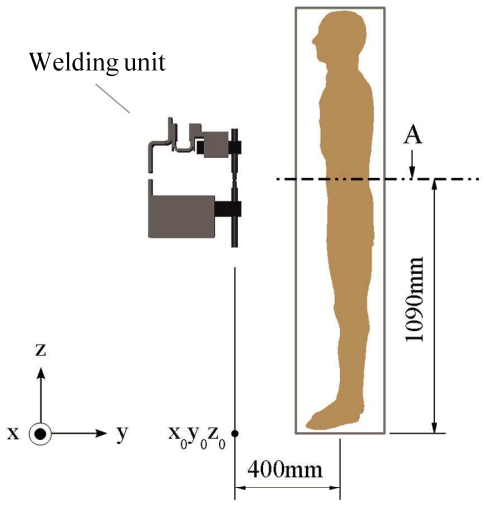

Figure 1: Example for positioning of the human body model in front of the welding circuit of resistance welding equipment.

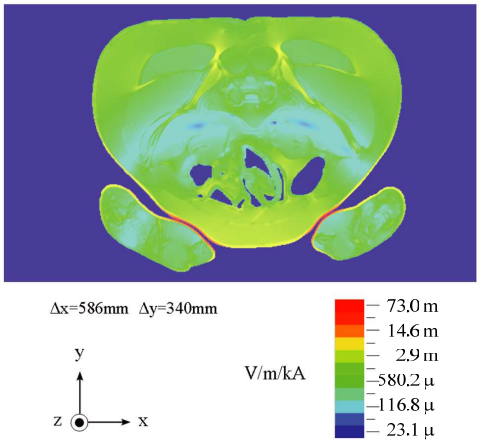

Figure 2: Distribution of electric field strength in sectional plane A of the body model indicated in Fig. 1, frequency 50 Hz.

Fig. 2 by means of a sectional view (field strength values normalized to a welding current of 1 kA).

Details of the field calculation procedure and arising possibilities to assess exposure situations occurring in industrial praxis shall be illustrated in the paper.

Abstract—

Introduction: Interactions between electromagnetic (EM) fields or currents and living cells constitute a recurrent subject of interest for several decades, and their effects have been profusely discussed [1], especially for the frequency bands currently encountered in everyday life of humans. In a more restrictive domain, large number of studies have been done, focused on EM modelling of a bacteria medium, in order to predict the EM field penetration and inner induced currents in living microorganisms. Relevant information to be collected deals with level and frequency of the EM signal that may affect the development of the considered cells. The former because non-thermal effects are nowadays suspected to exist, altering cell's metabolism, the latter because it is well known that the spectral response of the living cell impedance exhibits some dispersion in relation with cell membrane behaviour and shield effects [2].

It appears that these parameters may be strongly sensitive to shape, dimensions and orientation of bacterial cells in relation to the applied electric field orientation. The present paper aims to examine this problem and brings a streamlined lighting. This is done through the elaboration of a simplified equivalent electric circuit, supported by a prior COMSOL^{TM} analysis and a stochastic approach.

Analysis: The bacterium selected to test our approach is *Escherichia coli* DH5α. A first model, suitable for the required level of resolution, may be a 2 ± 1 µm long and 0.5 ± 0.2 µm wide cylinder filled with physiological fluid and surrounded by a dielectric membrane of thickness 50 nm. The medium is considered also as a physiological fluid. Figure 1 shows the COMSOL^{TM} model, with possible orientations for the external applied electric field, assuming that the field is provided through the application of an AC voltage between two plane parallel electrodes. A simplified equivalent circuit, similar to those explicited in the literature [2], can then be extracted from COMSOL^{TM} computation, where capacitance and resistor values depend on size and orientation (Figure 2). Next, the equivalent circuit for the overall medium, containing the suspended bacterial cells, is deduced, taking into account the concentration and the orientation of bacteria, as well as the electrodes/medium interface.

Results: As an example of interesting result, Figure 3 shows the admittance of a bacterium longitudinally oriented with the electric field. It reveals the well-known shield effect at lower frequencies. The final paper will relate other relevant parameters as inner current in the micro-organism. Variations according to the size and orientation of bacteria will be detailed for both uniform and non-uniform media, supported by a stochastic analysis.

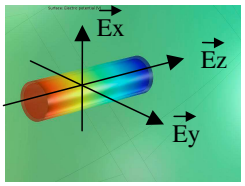

Figure 1: COMSOL^{TM} Model of E. Coli.

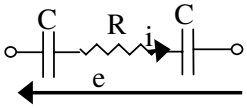

Figure 2: Equivalent circuit for one bacterium, to be inserted in the overall circuit representing the bacterial medium. C and R values are orientation-dependent.

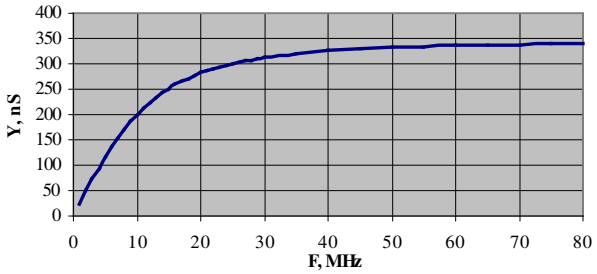

Figure 3: Frequency behaviour of the admittance of E. Coli.

Abstract— With the development of high field magnetic resonance imaging (MRI) scanners ($\geq$ 3 T), there has been a concern about possible heating effects of radio-frequency (RF) coils used in MRI. To ensure RF safety, International Electrotechnical Commission set limits both for the whole body specific absorption rate (SAR) and local SAR. In a clinical MRI scan, however, only whole-body SAR is controlled. Full-wave electromagnetic simulations with anatomic models reveal that it is possible to highly exceed local SAR limits even if whole-body SAR is kept below the specified limits. Moreover, such worrisome results are also obtained for 1.5 T scanners which have been used for about 30 years with no known incidents of hazards due to excessive heating.

To be able to explain such a dilemma, we aim to compare simulations with experimental findings. For this purpose, we obtained whole body MRI scans of a sheep and constructed its anatomical models using Mimics software. The resolution of the image set obtained using T1 weighting is 1.56 mm $\times$ 1.56 mm $\times$ 1.56 mm. For the part including brain and neck, we segmented skin, fat, brain, bone, muscle tissues, and air. We used cavity fill, multiple slice edit, extrude, and boolean operations for some tissues but most of the time manual segmentation is required particularly to differentiate air and bone since their gray-scale colors are quite close to each other. After obtaining 3D model, we performed further validation to correct erroneous segmented slices. We also performed smoothing and wrapping processes to In Figure 1, we depict a sagittal slice of the original MR image, a partial model constructed using skin, fat, and muscle tissues, and a more detailed anatomical model consisting of six tissues. Simulations pertaining to SAR and temperature increase of these models will be obtained from the Sim4Life software and will be contrasted to experimental results.

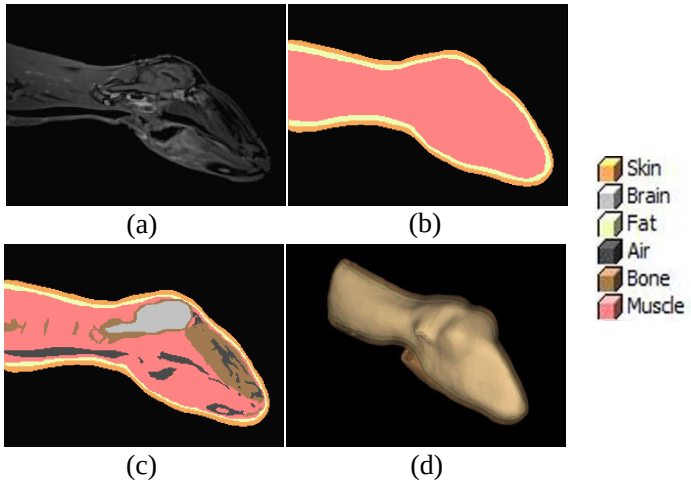

Figure 1: The process of constructing the anatomical model of a sheep: (a) Sagittal MR image, (b) partial model consisting of skin, fat, and soft tissue (muscle), (c) more detailed model with six tissues, and (d) 3D image of the anatomical model.

The Use of Quasi-phantom Measurements for Characterization of Vertigo Hazards Caused by Static Magnetic Fields Exposure of Magnetic Resonance Workers

Jolanta Karpowicz
Central Institute for Labour Protection, National Research Institute (CIOP-PIB)
Czerniakowska 16, Warszawa 00-701, Poland

Abstract— There are many reports from workers involve in various activities near magnets of magnetic resonance scanners (radiographers, nurses, technicians, cleaners, etc.) that during activities near or inside magnet tube they experienced vertigo, sometimes strong enough to significantly disturb their work. In 2014 International Commission on Non-ionizing Radiation Protection (ICNIRP) published guidelines for limiting exposure to electric fields induced by movement of the human body in static magnetic field and by time-varying magnetic fields below 1 Hz — in order to prevent vertigo and phosfenes. The ICNIRPs reference level to protect against effects in peripheral nervous system due to movement in static magnetic field and due to time-varying magnetic field of 0–1 Hz exposure is 2700 mT/s (2.7 T/s), and basic restriction was set at 2,000 mT (2 T). It triggered scientific debate if such measures of exposure hazards are sufficient, because magneto-mechanical interaction with the exposed body is not reflected in mentioned limits.

The aim of presented studies was to characterize the vertigo hazards near magnetic resonance scanners by expanded set of exposure parameters (including phenomenon of induced electric field and magneto-mechanical interaction mechanism). The 3-axis Hall probe connected to the pocket data logger was used in quasi-phantom measurements near 1.0; 1.5 and 3.0 T scanners. The significant differences in the exposure parameters between components of various polarization in magnetic field affecting worker (vertical, sagital, transverse). The new approach developed to characterize complex pattern of exposure may help to understand better what mechanism of interaction between static magnetic field and human body play dominating role in vertigo developing.

Abstract— This first study conducted by the University of Guadalajara, the Pediatric National Social Security Medical Center, the Hospital Civil de Guadalajara and the General Hospital of Guadalajara, shows the geographical and temporal distribution of 274 cases of children suffering from Leukemia in 6 municipalities in the metropolitan area of Guadalajara (2014). In Mexico, geographical information systems (GIS) have been rarely implemented to monitor spatial assessments of leukemia. We present an analysis of the spatial distribution of acute leukemia among children from 0 to 16 years of age in the metropolitan zone of Guadalajara, Mexico using individual case Hospital data from the three main hospital facilities attending this population.

Methods: Using the approach of spatial epidemiology DBSCAN and 1-dist, cases of leukemia obtained from the databases of hospitals resulted in "clusters" or groups of cases/100,000 inhabitants. Cancer cases were grouped according to an internationally recognized morphology-based.

Results: The results shows 24 cases/100,000 inhabitants for leukemia (acute lymphoblastic leukemia) LLA and 4.4 cases/100,000 inhabitants for leukemia AML (acute myeloid leukemia). These results were outside of international references. The values are usually 3–5 cases/100,000 for LLA and 0.8 cases/100,000 for AML.

Conclusions: Although the etiology of most childhood leukemias is unknown, there is a significant correlation between spatial disease cluster with an unusual elevated disease incidence rate and the high voltage distribution network and the wireless communication network. Studies in the literature have focused on childhood leukemia because of its relative large incidence among children compared with other malignant disease, its apparent tendency to cluster, and the public concern over locally elevated leukemia incidence.

Experimental Assessment of Influence Factors of Body Shadow Effect in Dosimetry Measurements in Indoor Enclosures

S. de Miguel-Bilbao[1], **J. Roldán**[2], **J. Blas**[3], **and V. Ramos**[1]

[1]Health Institute Carlos III, Telemedicine and e-Health Research Unit, Madrid, Spain

University of Valladolid, Valladolid, Spain

Abstract— The use of wireless systems, such as WLAN spreading to a wide range of sectors, ranging from domestic households, to administrative as well as industrial and healthcare environments, with a broad and transverse application scope. The number of personal devices that operate in the frequency band of 2.4 GHz is spreading in enclosed environments. Personal exposure meters (PEMs) are used for measuring exposure to electromagnetic fields (EMF), and are typically worn by the user during the measurement campaigns. The immediate proximity of the user underestimates EMF exposure levels in the registered data. This alteration is known as body shadow effect (BSE). Regulations about the protection of human exposure to non-ionizing radiation provide thresholds to assure the health and protection of the human beings. These thresholds have been fixed taking into account unperturbed data provided by scientific studies, so these thresholds must be compared with objective and undisturbed data. This study describes the procedure of design of an experimental protocol of measurement of the E-field levels in indoor enclosures to avoid the influence of the BSE. The designed protocol isolates the treatment of the BSE from other intrinsic uncertainties of the exposure assessment from WLAN devices, such as the discontinuous transmission. The quantification of this uncertainty is performed by the duty factor, defined as the relation between the effective information transmission and the total duration of the transmission. Simulations have been performed means of a software prediction tool in order to estimate the measured E-field levels obtained with the designed experimental method.

Electromagnetic Scattering by Random Media and Rough Surfaces

Measuring the Optical Extinction of Aerosol Particles with Digital Holography

Matthew J. Berg, Nava R. Subedi, and Perter A. Anderson
Department of Physics & Astronomy, Mississippi State University
355 Lee Blvd., Mississippi State, MS 39762, USA

Abstract— This work will present a new technique to measure an aerosol particle's extinction cross section. The concept relies on digital holography, where the interference pattern of a particle's scattered and incident light is recorded optoelectronically to yield a digital hologram. Much information about a particle's physical character can be extracted from such holograms. For example, a silhouette-like image of the particle can be obtained via a simple Fourier-transform-based operation. This talk will show how the digital hologram can also yield the value of the extinction cross section for single and multiple nonspherical particles. Given the simplicity of the measurements involved, such capability could have important applications to quantify extinction by complex-shaped aerosol particles, such as mineral dust, and could do so *in situ*.

Analysis of Layered Dielectric Capped Wedge for RCS Reduction

Hulya Ozturk[1] and Korkut Yegin[2]

[1]Department of Mathematics, Gebze Technical University, Kocaeli 41400, Turkey
[2]Electrical and Electronics Engineering Department, Ege University, Izmir 35100, Turkey

Abstract— Conducting wedge is a canonical structure in electromagnetic scattering problems. Applications of scattering from wedge geometries range from reflector designs to aerial vehicles. Due to wide range of applications, plane wave scattering due to a wedge shape has been studied extensively in the past. However, wedge capped with dielectric layers with the intention of RCS reduction has been overlooked. We first took a canonical wedge infinite in z-direction (longitudinal) and covered this wedge with dielectric layers of varying thicknesses and dielectric properties including conductive loss. Then, scalar Helmholtz equation in two dimensions is formulated for each solution region and a matrix of unknown coefficients are arrived at for problem solution. For different wedge shapes and dielectric layer properties, corresponding RCS values are computed in one- and two-dimension. We observed that if certain conditions are met, RCS can be reduced from that of uncovered perfect electric conductor wedge. We also formulated the RCS reduction as a single objective optimization problem to observe the interdependence of wedge parameters to RCS values. Since wedge shapes are particularly useful in unmanned aerial vehicles, airplanes, and missile structures, the analysis which was carried in two-dimensions (infinite in longitudinal direction), is further expanded for simplistic shapes in three dimensions using computer-aided electromagnetic scattering programs. These numerical solvers also permit solutions for coated wedge geometries where it is possible to compare the effectiveness of coating to dielectric capped wedge configurations. Both analytical and simulated results will be presented in detail to express the degree of agreement and to validate the proposed concept on 3D shapes.

A Perturbative Solution to Plane Wave Scattering from a Rough Dielectric Cylinder

Rahul Trivedi and Uday K. Khankhoje
Department of Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India

Abstract— Scattering of electromagnetic waves by vegetation such as tree trunks, branches and leaves is a significant contributor to radar scattering. At low microwave frequencies, modelling the tree trunk as a smooth cylinder is usually sufficient to accurately capture it's effect on the incident radiation. However, at higher frequencies, the surface roughness begins to play an increasingly important role in the scattering properties of the tree trunk. Numerical methods such as the integral equation method can be used to compute the scattered fields for a rough cylinder, however, their use is limited by the large computation time involved.

We present a second order perturbative analysis of scattering of a plane electromagnetic wave from a stochastically rough cylinder. The rough cylinder surface is described by a stochastic process, $h(\phi, z)$, which denotes the radial distance of a point on the rough surface at azimuthal coordinate ϕ and z-coordinate z from the mean smooth cylinder of radius a. We analytically solve Maxwell's equations to obtain a perturbative expression to second order for the scattered fields:

$$\begin{aligned}\mathbf{E}^{sca}(\mathbf{r}) \;=\; \mathbf{E}_0^{sca}(\mathbf{r}) + \sum_{m=-\infty}^{\infty} \int_{-\infty}^{\infty} \alpha_m(\mathbf{r};k)\tilde{h}_m\left(k - k_0\cos\alpha\right) dk \\ + \sum_{m=-\infty}^{\infty}\sum_{p=\infty}^{\infty} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \beta_{m,p}(\mathbf{r};k,k')\tilde{h}_m\left(k' - k_0\cos\alpha\right)\tilde{h}_p\left(k - k'\right) dkdk' \qquad (1)\end{aligned}$$

where $\tilde{h}_n(k) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_0^{2\pi} h(\phi,z)\exp(-j(n\phi+kz))d\phi dk$, the incident field is assumed to propagate along $\mathbf{k}_i = k_0(\hat{z}\cos\alpha + \hat{x}\sin\alpha)$, and $\mathbf{E}_0^{sca}(\mathbf{r})$ is the scattered field due to a *smooth* cylinder of radius a. Closed form expressions for the functions $\alpha_m(\mathbf{r};k)$ and $\beta_{m,p}(\mathbf{r};k,k')$ are derived from the Maxwell's equations and the boundary conditions at the rough cylinder surface. Clearly, Eq. (1) can be used to evaluate the ensemble average of the scattered field and other derived quantities (such as the scattering cross section), if the autocorrelation function of the random process $R(\phi,z) = \overline{h(\Phi,Z)h(\Phi+\phi,Z+z)}$ is known. Our method therefore allows the direct calculation of the statistical properties of the scattered fields in terms of the statistical properties of the rough cylinder surface, significantly reducing the computational time involved as compared to the other numerical methods that can be employed for analysing the same problem.

We also investigate the validity of our analysis by numerically comparing it with a method-of-moments based solution of the same problem. For simplicity, we assume that the cylinder surface is only *azimuthally* rough, i.e., $h(\phi,z)$ is independent of z, and that it is exponentially correlated:

$$R(\phi) = \overline{h(\Phi)h(\Phi+\phi)} = h_0^2\exp\left(-|\phi|/\phi_0\right)\forall\in(-\pi,\pi] \qquad (2)$$

h_0 being the root mean square roughness and $l = a\phi_0$ being the correlation length of the rough surface. This numerical validation gives us a region of validity in terms of bounds on h_0 and l within which the perturbative solution is sufficient to describe the scattered fields due to the rough cylinder.

Multispectral Light Scattering Imaging and Multivariate Analysis of Airborne Particulates

Stephen Holler[1], **Charles Skelsey**[2], **and Stephen D. Fuerstenau**[3]

Abstract— Light scattering patterns from non-spherical particles and aggregates exhibit complex structure that is only revealed when observing in two angular dimensions. However, due to the varied shape and packing of such aerosols, the rich structure in the two-dimensional angular optical scattering (TAOS) pattern varies from particle to particle. We examine two-dimensional light scattering patterns obtained at multiple wavelengths using a single CCD camera with minimal cross talk between channels. The integration of the approach with a single CCD camera assures that data is acquired within the same solid angle and orientation. Since the optical size of the scattering particle is inversely proportional to the illuminating wavelength, the spectrally resolved scattering information provides characteristic information about the airborne particles simultaneously in two different scaling regimes. The simultaneous acquisition of data from airborne particulate matter at two different wavelengths allows for additional degrees of freedom in the analysis and characterization of the aerosols. Whereas our previous multivariate analyses of aerosol particles has relied solely on spatial frequency components, our present approach attempts to incorporate the relative symmetry of the particle-detector system while extracting information content from both spectral channels. In addition to single channel data, this current approach also examines relative metrics. Consequently, we have begun to employ multivariate techniques based on novel morphological descriptors in order to classify "unknown" particles within a database of TAOS patterns from known aerosols utilizing both spectral and spatial information acquired. A comparison is made among several different classification metrics, all of which show improved classification capabilities relative to our previous approaches.

Evaluation of the Angular Spectrum of Scattered High Frequency Radio Waves in the Anisotropic Collision Magnetized Ionospheric Plasma

G. V. Jandieri[1], Zh. M. Diasamidze[2], M. R. Diasamidze[3], and I. Nemsadze[4]

[2]Physics Department, Batumi Shota Rustaveli State University, Georgia
[3]Department of Exact and Natural Sciences, Batumi State Maritime Academy, Georgia
[4]Physics Department, Batumi Shota Rustaveli State University, Georgia

Abstract— This paper represents incline incidence of high-frequency radio wave on the magnetized collision ionospheric plasma slab in the ray (-optics) approximation taking into account boundary conditions using the Snell's low. Fourth order dispersion equation is derived for the mean field of scattered radio waves including components of the second rank dielectric permittivity tensor of the magnetized plasma. Set of stochastic differential equations is obtained for the fluctuating electric field vector. Second order statistical moments of the phase and amplitude fluctuations of high-frequency electromagnetic waves are investigated taking into account both electron density and external magnetic field fluctuations. Polarization effects for the ordinary and extraordinary waves are taken into account. The obtained results are valid for arbitrary correlation functions of fluctuating plasma parameters in the near and far zones from a slab. The influences of both anisotropy factor and angle of inclination of prolate irregularities with respect to the external magnetic field on the statistical characteristics of scattered radio waves: Stokes parameters, broadening of the spatial spectrum of scattered radiation, displacement of its maximum, angle of arrivals in the principle and perpendicular planes are investigated analytically and numerically for both anisotropic Gaussian and power law spectral functions characterizing electron density fluctuations on different ionospheric layers. Interaction effect of waves is considered on the basis of the dispersion equation at different angles of incidence on plasma slab. Phase portraits of the correlation functions of the amplitude and phase fluctuations were constructed for different spatial parameters characterizing given problem taking into account external magnetic field fluctuations. Numerical calculations were carried out at different distances between observation points and parameters characterizing anisotropic irregularities having different characteristic spatial scales. The obtained results are of interest and will have application in satellite communication and ionospheric monitoring stimulating investigation of ionospheric irregularities.

Stochastic Geometry for Electromagnetic Scattering Modeling

Frédéric Gruy
Ecole Nationale Supérieure des Mines
158 Cours Fauriel, 42023 Saint-Etienne, Cedex 2, France

Abstract— Electromagnetic scattering by particles consisting in a homogeneous material has been studied a lot by means of Maxwell equations that are numerically solved. Solutions depend on the morphology of the particles; the morphology of the particle is revealed at the boundary conditions. In the case of a homogeneous material a relationship between the scattering properties, the optical indices of the material and the surface characteristics can be expected. The need of fast calculations is important for industrial applications, even if the accuracy is lower. Fitting the accuracy of the calculation with the accuracy of the measurement is sufficient. Moreover the use of relevant descriptors for the particle geometry can simplify the correspondence between optical and geometrical properties. In the past some optical approximations have been developed for the calculations for soft materials, e.g. Rayleigh-Debye-Gans approximation for small particles, Van de Hulst approximation for large particles. In these cases phase function and scattering cross section explicitly contain geometrical parameters like the distance between two points inside the particle, the chord length, etc.. On the other hand Fraunhoffer diffraction for large and optically hard particles is often related to the projected area of the particle. As a consequence there may exist a relationship between the optical properties and the statistical distribution of such geometrical parameters. In this sense the chord length distribution (CLD) seems to be a good candidate to optically describe a particle. This paper:

- reminds how the optical properties are related to these distributions,
- presents the way to estimate the distributions,
- presents some examples of distributions (for spheres, ellipsoids, cylinders, facetted crystals),
- reminds some mathematical properties of these distributions,
- presents some rules to reconstruct rapidly the CLD for convex particles,
- compares the exact and approximated calculations of the scattering cross section.

Plasmons and Charge Noise at Composite Surfaces

C. Henkel[1] and B. Horovitz[2]

[1]Institute of Physics and Astronomy, University of Potsdam, Germany
[2]Department of Physics, Ben Gurion University, Beer Sheva, Israel

Abstract— We discuss the scattering of photons, plasmons, and electrons at a rough metallic surface. Our motivation are experiments with surfaces that are not perfectly characterized, covered with adsorbates or hosting localized charge states. For example, the randomly varying work function (patch potentials) of an amorphous metal actually shows fluctuations; these can be measured in the MHz band with charged particle traps at sub-millimeter distances. Our goal is to develop a microscopic model and to identify strategies to reduce this noise. Another experimental signature is the dispersion of the surface plasmon resonance at large parallel momentum. It is well known since the work of Feibelman [1] that the slope of the dispersion relation is sensitive to the response of the electron density in the near-surface region.

Our model builds upon previous work on a kinetic theory where bulk and surface electrons are coupled via non-specular scattering at a rough surface [2]. We use the relevant conservation laws for hydrodynamic fields (density, current) to complement material relations in the bulk with boundary conditions. This yields, for example, a modified dispersion relation for surface plasmon polaritons. The electromagnetic response problem for fields incident upon the surface is solved and yields electric and magnetic fluctuation spectra in conjunction with the fluctuation — dissipation relation [3]. We analyze in particular the average Lorentz force in a high-density conductor that may give a significant temperature dependent correction to the work function. The goal is to establish the spectral density of the thermal Lorentz force and to compare with frequency- and temperature-dependent data for surface charge noise from miniature ion traps.

ACKNOWLEDGMENT

This work is supported by the DIP programme of the *Deutsche Forschungsgemeinschaft* within the project "IANV Hybrids".

Resonant Electromagnetic Scattering in Anisotropic Layered Media with Random Fabrication Errors

Emily A. McHenry
Mathematics Department, Louisiana State University, Baton Rouge, Louisiana

Abstract— The excitation of an electromagnetic guided mode (occurring at a frequency embedded in the continuous spectrum of the underlying Maxwell operator) of a slab structure by an exterior source field elicits anomalous scattering behavior, particularly resonant field amplification and sharp variations in energy transmission and reflection across the slab (known as Fano resonance). This resonance phenomena is utilized by optical devices that require the precise tuning of the width and central frequency of a resonance, including lasers, filters, and light-emitting diodes. However, these characteristics are sensitive to random fabrication errors that occur during the production process. In this talk, we will quantify quantify the sensitivity of resonant characteristics to these material imperfections.

In [4] a slab structure that supports a spectrally embedded guided mode was constructed using the properties of anisotropic layered media. Into this regime, we introduce random perturbations of the dielectric and magnetic tensors ϵ and μ across the slab; the random perturbations are controlled by a small parameter σ:

$$\begin{aligned}\epsilon(z) &= \epsilon_0(z) + \sigma\xi(z)\\ \mu(z) &= \mu_0(z) + \sigma\eta(z),\end{aligned}$$

where ξ and η are random variable matrices. The effect of the random perturbations on the resonant characteristics of the slab is analyzed through the poles of the scattering matrix $\tilde{S} = (TP_- - P_+)^{-1}$, where $P_\pm$ are the projections in $\mathbb{C}^4$ onto the two-dimensional rightward $(+)$ and leftward $(-)$ Bloch modes of the ambient (nonrandom) medium. Representing the scattering matrix in this way, the random variation of a pole is obtained through perturbation analysis of the analytic eigenvalue $\lambda(\boldsymbol{\kappa}_\parallel, \omega)$ of the matrix $(T_0(I + \sigma M))P_- - P_+$, where $T_0(I + \sigma M)$ denotes the transfer matrix T up to the first order in σ.

The transmission and reflection coefficients are obtained by projecting the scattering matrix to the propagating harmonics of the ambient medium. The result has the form

$$S(\boldsymbol{\kappa}_\parallel, \omega; \sigma) = \frac{1}{\lambda(\boldsymbol{\kappa}_\parallel, \omega; \sigma)} \begin{bmatrix} b_1(\boldsymbol{\kappa}_\parallel, \omega; \sigma) & a_2(\boldsymbol{\kappa}_\parallel, \omega; \sigma) \\ a_1(\boldsymbol{\kappa}_\parallel, \omega; \sigma) & b_2(\boldsymbol{\kappa}_\parallel, \omega; \sigma) \end{bmatrix}.$$

The eigenvalue λ, reflectances a_j, and transmittances b_j vanish simultaneously at the guided mode point $(\boldsymbol{\kappa}_\parallel^0, \omega^0; 0)$. A rigorous description of transmission anomalies in the nonrandom lossless case is given in [1–3]. We will extend this analysis to establish the properties of transmission anomalies as random variables, particularly the mean and variance of the heights and locations of the sharp peaks and dips in the Fano lineshape.

Patterning Highly Oriented Pyrolytic Graphite for Efficient Broad-band Absorption

Julian Evans, **Yaoran Sun**, **and Sailing He**
Center for Optical and Electromagnetic Research, Zhejiang University, China

Abstract— Highly absorbing materials have many applications in astronomical observation, photothermal solar light harvesting, and thermal photonic devices. Many groups use vertical aligned carbon nanotubes to create such materials, which require complicated growth processes and large thicknesses. Highly Oriented Pyrolytic Graphite (HOPG) can be structured using ICP-etching to produce significantly thinner, more robust materials that have potentially comparable performance for a variety of applications. In this talk I will describe a method using gold nanoparticle masks to produce 400 nm tall nanocone structures that allow for broadband absorption of greater than 95% for wavelengths ranging from 400 nm–1600 nm. The density and size of nanocones can be easily tuned by varying the density of nanoparticle masks and etching conditions. Using polyethylene glycol capped spheres, we've achieved nearly complete coverage of the surface with the nanocone structures through a simple spin coating process. Computer simulations indicate that surface coverage and height are the critical parameters for achieving high absorptivity and that the overall pattern of nanocone arrangement and polydispersity are less critical in material performance.

A Study of Periodic Multilayered Structure in Fractional Dimension Space and Euclidian Space

M. J. Mughal[1] and Safiullah Khan[2]

[1]COMSATS Institute of Information Technology, Islamabad, Pakistan
[2]Ghulam Ishaq Khan Institute of Engineering Sciences and Technology, Topi 23640, Pakistan

Abstract— In this paper, Transfer Matrix Method and modified Maxwell equations are used to find the general expressions for reflection and transmission coefficients of periodic multilayered structure. The structure is placed in D dimension space where D is integer for Euclidean space and non-integer for Fractional space. Characteristics of these structure are studied when an electromagnetic wave strikes on it at both normal and oblique incident angle. The final expressions are the function of frequency, dimension and incident angle. Numerical results for multilayered periodic strong chiral — strong chiral structure are presented. This study provides motivation to investigate the electromagnetic waves propagation in multilayered structures at fractional boundaries.

Summary: Advances in the metamaterials (MTM) has significantly attracted the attention of researchers. Multilayered structures composed of composite materials are being widely used in applications such as antenna designing, lens designing, frequency selective surfaces etc. [1–3]. Since, metallic structures have losses associated with it, metamaterial structures are used to achieve desirable outcomes. Until recently, frequency, incident angle and constitutive parameters behaviour were studied but with the introduction of fractional calculus, effect of dimension can also be studied. Irregular surfaces, porous media, and complex structures can be modelled with fractional calculus [4].

In this paper strong chiral — strong chiral multilayered structure placed in D dimension space is presented for analysis as shown in Figure 1. The general incident, reflected and transmitted fields are [4],

$$\mathbf{E}_i = \left[E_{i\parallel}\left(\hat{x}\cos\theta_i + \hat{z}\sin\theta_i\right) + E_{i\perp}\hat{y}\right] e^{-jk_F(-x\sin\theta_i)}(k_F z\cos\theta_i)^n \left[H_n^{(2)}(k_F z\cos\theta_i)\right], \tag{1}$$

$$\mathbf{H}_i = \frac{1}{\eta}\left[E_{i\parallel}\hat{y} - E_{i\perp}\left(\hat{x}\cos\theta_i + \hat{z}\sin\theta_i\right)\right] e^{-jk_F(-x\sin\theta_i)}(k_F z\cos\theta_i)^{nh} \left[H_{nh}^{(2)}(k_F z\cos\theta_i)\right], \tag{2}$$

$$\mathbf{E}_r = \left[E_{r\parallel}\left(\hat{x}\cos\theta_r - \hat{z}\sin\theta_r\right) + E_{r\perp}\hat{y}\right] e^{-jk_F(-x\sin\theta_r)}(k_F z\cos\theta_r)^n \left[H_n^{(1)}(k_F z\cos\theta_r)\right], \tag{3}$$

$$\mathbf{H}_r = \frac{1}{\eta}\left[-E_{r\parallel}\hat{y} + E_{r\perp}\left(\hat{x}\cos\theta_r - \hat{z}\sin\theta_r\right)\right] e^{-jk_F(-x\sin\theta_r)}(k_F z\cos\theta_r)^{nh} \left[H_{nh}^{(1)}(k_F z\cos\theta_r)\right], \tag{4}$$

$$\mathbf{E}_t = \left[E_{t\parallel}\left(\hat{x}\cos\theta_t - \hat{z}\sin\theta_t\right) + E_{t\perp}\hat{y}\right] e^{-jk_F(-x\sin\theta_t)}(k_F z\cos\theta_t)^n \left[H_n^{(2)}(k_F z\cos\theta_t)\right], \tag{5}$$

$$\mathbf{H}_t = \frac{1}{\eta}\left[E_{t\parallel}\hat{y} + E_{t\perp}\left(\hat{x}\cos\theta_t + \hat{z}\sin\theta_t\right)\right] e^{-jk_F(-x\sin\theta_t)}(k_F z\cos\theta_t)^{nh} \left[H_{nh}^{(2)}(k_F z\cos\theta_t)\right] \tag{6}$$

where $n = \frac{|3-D|}{2}$ and $nh = \frac{|D-1|}{2}$. Hankel function of the second kind and Hankel function of the first kind represents the forward travelling wave and backward travelling wave respectively. Transfer Matrix Method (TMM) is applied on Equations (1)–(6) and electric and magnetic field expressions for strong chiral medium, to compute field expressions on either side of the structure. The final expression is of the following form,

$$\begin{bmatrix} E_{i\parallel} \\ E_{i\perp} \\ E_{r\parallel} \\ E_{r\perp} \end{bmatrix} = [T] \begin{bmatrix} E_{t\parallel} \\ E_{t\perp} \end{bmatrix} \tag{7}$$

$$[T] = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \\ a_{31} & a_{32} \\ a_{41} & a_{42} \end{bmatrix} = [M_1][P_A][T_1]^m[M_2] \tag{8}$$

$$[T_1] = [M_{AB}][P_B][M_{BA}][P_A] \tag{9}$$

where $[T]$ is the transfer matrix and it relates the field on either side of the structure. Figures 2 and 3 show the reflectance at normal and oblique incidences, respectively (for simplicity only reflectance is shown here).

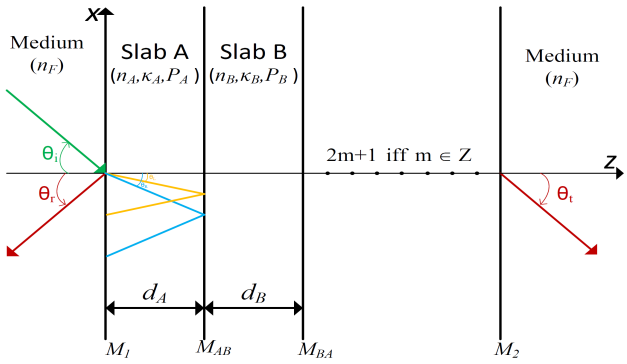

Figure 1: Five layered metmaterial structure placed in D dimension space.

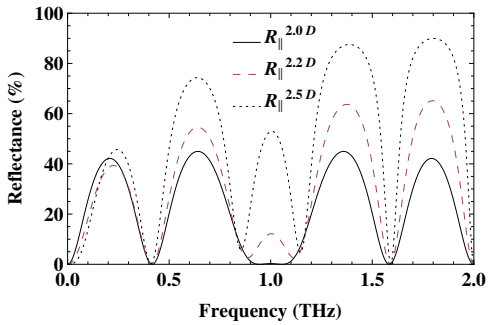

Figure 2: Reflectance for five layered SC-SC structure. $n_A = 0.8$, $n_B = 0.6$, $\kappa_A = 1.2$, $\kappa_B = 1.0$, $|n_A|d_A = |n_B|d_B = \lambda_0/4$, $\theta_i = 0°$.

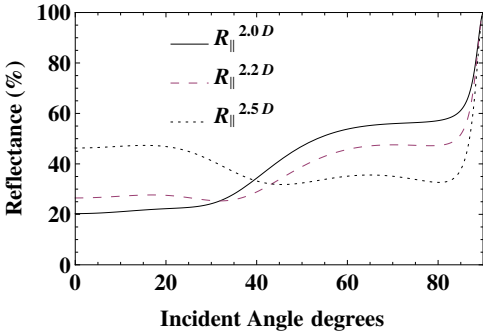

Figure 3: Reflectance for five layered SC-SC structure. $n_A = 0.8$, $n_B = 0.6$, $\kappa_A = 1.2$, $\kappa_B = 1.0$, $|n_A|d_A = |n_B|d_B = \lambda_0/4$, $f/f_0 = 0.5$.

Quantum Thermodynamics: An Information Theoretical Viewpoint

Mauro Paternostro
Centre for Theoretical Atomic, Molecular, and Optical Physics
School of Mathematics and Physics, Queen's University Belfast, BT71 NN, Belfast, UK

Abstract— Thermodynamics is one of the pillars of physical, chemical and biological sciences. It is able to predict the occurrence and efficiency of complex chemical reactions and biological processes. In physics, the conduction of heat across a medium or the concept of the arrow of time are formulated thermodynamically. In information theory, the definitions of information and entropy are given in thermodynamical terms. Even more, the tightness of the link between information and thermodynamics can be deduced from the thermodynamic interpretation of the landmark embodied by Landauers erasure principle, Jaynes principle of maximum entropy, or the exorcism of Maxwell's demon operated using information theoretical tools. Another example is the analysis of the spectrum of blackbody radiation made by Planck, which triggered the quantum mechanical revolution. However, science and technology have evolved immensely from the early days of the quantum era, allowing us to witness quantum effects that could only be dreamed of decades ago. Our capabilities to control and guide processes at the microscopic scale has reached outstanding levels of dexterity. Yet, a series of tantalising questions arise: what happens to the principles of thermodynamics when we deal with the quick dynamics of small quantum systems brought dramatically out of equilibrium? Can we formulate in a thermodynamical way the working principles of quantum devices designed to perform transformations analogous to "canonical" thermo-machines? In this talk I will present a framework that is able to show the emergence of thermodynamics out of genuinely quantum processes enforced in quantum many- body systems, thus establishing a tight link between thermodynamics and quantum critical phenomena. I will discuss how work can be extracted from intricate (mesoscopic) quantum motors to ensure engines performances overcoming any classical counterpart and suggest tantalising connections between the irreversible quantum entropy produced across a process and the establishment of quantum correlations among the constituents of a quantum device.

Steady Many-body Entanglement Induced by an out of Thermal Equilibrium Environment

Bruno Bellomo[1, 2] **and Mauro Antezza**[2, 3]

[1]Observatoire des Sciences de l'Univers THETA, Institut UTINAM, UMR CNRS 6213

[3]Institut Universitaire de France, 103, bd Saint-Michel F-75005 Paris, France

Abstract— This work concerns the manipulation of quantum systems by engineering the properties of the environment they interact with. It is based on recent studies regarding the properties of the radiation field produced in a given configuration when macroscopic bodies are kept at different temperatures [1]. Indeed, it has been shown that the interaction of small atomic systems (one or two atoms) with a field produced in a configuration kept out of thermal equilibrium may permit a strong manipulation of the atomic dynamics [2–5].

Here we study an ensemble of more than two two-level quantum systems (qubits) interacting with a common electromagnetic field in proximity of a dielectric slab whose temperature is held different from that of some far surrounding walls (see Fig. 1). We show that the dissipative dynamics of the qubits driven by this stationary and out of thermal equilibrium (OTE) field, allows the production of steady many-body entangled states, differently from the case at thermal equilibrium where steady states are always non-entangled. By studying up to ten qubits, we point out the role of symmetry in the entanglement production, which is exalted in the case of permutationally invariant configurations. In the case of three qubits, we find a strong dependence of tripartite entanglement on the spatial disposition of the qubits, and in the case of six qubits, we find several highly entangled bipartitions where entanglement can, remarkably, survive for large qubit-qubit distances up to 100 µm [6].

Our analysis points out the potentialities of rich yet simple configurations involving macroscopic bodies held at different temperature, which are within experimental reach. They may permit the production and manipulation of steady multipartite entanglement, resistant for large inter-qubits distances, offering then new tools possibly exploitable for quantum computational tasks. All this is obtained without any further external actions on the qubits, being the result of the qubits dissipative dynamics itself. These protocols are then intrinsically robust to environmental effects and do not need of initializing the total system in a given configuration.

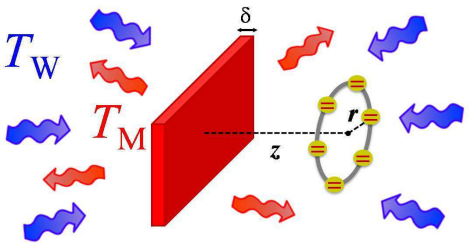

Figure 1: Several qubits close to a slab at temperature T_M different from the temperature of some far surrounding walls, T_W.

Tightening the Second Law of Thermodynamics for Restricted Baths

Karen V. Hovhannisyan, Martí Perarnau-Llobet, and Paul Skrzypczyk
ICFO-Institut de Ciencies Fotoniques, Mediterranean Technology Park
Castelldefels, Barcelona 08860, Spain

Abstract— The most operationally meaningful formulation of the second law of thermodynamics is the so called maximum work principle: The maximal work one can extract from a system attached to a bath is given by the difference of initial and final free energies of the system. The law is universal: It does not depend on the details of the bath. Yet, while working with small systems, we face different kinds of limitations connected to the fact that the bath is not infinite or it cannot be engineered to have correct macroscopic spectrum, etc.. A fundamental question then would be whether one can put additional limitations on the extractable work which will respect the new constraints but will still be independent on the other details of the bath. In case of fixed dimensionality of the Hilbert space of the bath we find general dimensionality-dependent bounds on the corrections to free energy difference formula. We further study another kind of limitation where it is not the dimensionality that is bounded but the fine tuning in the bath. We do so by considering an ensemble of identical spins as a bath. There we prove that the lack of fine tuning is compensated by taking the continuum limit and we find the scaling of the corresponding correction term. The role of correlations built up between the system and the bath and within the bath is also studied.

Finite Temperature Reservoir Engineering and Entanglement Dynamics

Abstract— For the vast majority of experimentally controllable and measurable quantum systems, interaction with the environment leads to a decoherence process that rapidly and irreversibly destroys the quantum properties of the studied system. Decoherence impedes the large scale applications of quantum mechanics, as quantum information and quantum metrology. Such unavoidable coupling between a system and an inaccessible environment privileges so-called pointer states. When interaction with the reservoir prevails over the system's free Hamiltonian, the specific properties of the system — environment coupling determine the steady, or more stable states of the considered system. Decoherence owes its bad reputation to the fact that, for experimentally relevant situations, these steady states usually do not display nonclassical properties. However, quantum reservoir engineering showed that decoherence can be rendered compatible with the preservation of quantum properties. Indeed, by judiciously engineering the effects of exotic system — reservoir couplings, quantum states with useful quantum properties, such as entanglement or quantum coherence, can turn out to be the steady states of the decoherence process. Reservoir engineering can be used to protect interesting quantum states from decoherence, even in the case where a "natural" reservoir is present. As a matter of fact, an engineered reservoir can dominate a system's dynamics, turning the total system's steady state arbitrarily close to its own steady state, that can be controllably chosen.

The experimental implementation of reservoir engineering became achievable with the rapid technological development of quantum devices. Recent experimental results demonstrate the production of steady maximally entangled states through controlled dissipation in trapped ions and superconducting systems. Most theoretical proposals and experimental realizations are focused on engineering zero temperature reservoirs, since they can lead to the production and protection of pure states.

The steady state of a finite temperature reservoir is mixed. Finite temperature reservoir engineering can lead to the production and protection of mixed states with interesting entanglement properties, a problem that remains unexploited in the literature. Nevertheless, there are a number of interesting and unusual entanglement properties that engineered thermal reservoir can help to reveal and fully exploit for applications. One example is thermal entangled states, states that are separable at zero temperature, but entangled at finite temperature. They are the eigenstates of a strongly interacting spin system coupled to a reservoir that, due to the strongly interacting Hamiltonian, is non-local, i.e., it acts in many spins at the same time. Experimental observation of thermal entanglement is possible in strongly interacting many body systems. However, in such systems, entanglement cannot be extracted and used as a resource for quantum based protocols. Moreover, the system-reservoir Hamiltonian is fixed by the specific material under study, and cannot be engineered and controlled.

In the present contribution, we provide theoretical proposals leading to finite temperature reservoir engineering which are well adapted to the state-of-the art of different set-ups successfully used to demonstrate quantum protocols. We detail these ideas for a trapped ion systems. Extending the proposed ideas to other set-ups, as superconducting qubits and photons, is also possible, but will not be detailed here.

The Best Quantum Thermoelectric at Finite Power Output

Robert S. Whitney
Laboratoire de Physique et Modélisation des Milieux Condensés (UMR 5493)
Université Grenoble 1 and CNRS, Maison des Magistères, BP 166, Grenoble 38042, France

Abstract— Carnot efficiency is only achievable at zero power output. We ask what is the maximum efficiency at some given finite power output. It appears that this question is ill-defined in classical thermodynamics, but can be answered with a quantum theory.

We use the Landauer-Buttiker scattering theory to find this maximum efficiency for heat engines and refrigerators made of thermoelectric quantum systems. We initially find the exact maximum efficiency for two-terminal systems without energy relaxation [1]. We then use phenomenological models to explore whether this maximum can be exceeded by two-terminal systems with relaxation [2], or by three-terminal systems. We have not yet found a system which can exceed the maximum efficiency given in Ref. [1], although open questions remain.

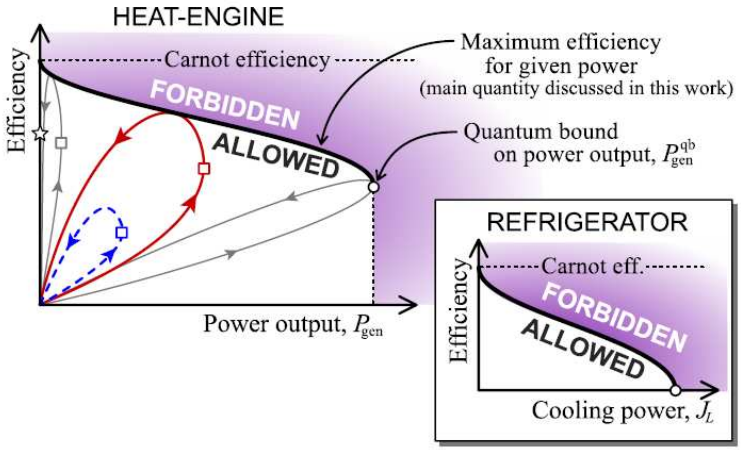

Figure 1: Taken from Ref. [2]. The thick black curves are qualitative sketches of the maximum efficiency as a function of heat-engine power output (main plot), or refrigerator cooling power (inset), with the shaded regions being forbidden. The colored loops (red, grey and blue) are sketches of the efficiency versus power of *individual* heat-engines as we increase the load resistance.

Non-adiabaticity and Irreversible Entropy Production

F. Plastina
Dipartimento Fisica, Universita' della Calabria, Arcavacata di Rende (CS) 87036, Italy

Abstract— The out-of-equilibrium thermodynamic properties of closed quantum systems driven by a change in a control parameter and undergoing a unitary transformation have been the subject of an intense research activity. We study the work actually done on the system and compare it with the adiabatic one, that would be performed following an ideal adiabatic protocol. The non-adiabatic part of the work, usually called *inner friction*, can be used to reveal irreversibility in the process and it is intimately linked to the non-equilibrium entropy production. Indeed, it is related to the heat exchanged in a specific thermalization process that would occur after the end of the adiabatic transformation, and it can be expressed as the relative entropy between the actual state of the system and the ideal equilibrium one. Furthermore, it is associated to a specific fluctuation relation for the entropy production, which allows the inner friction to be expressed in terms of its cumulants. We apply this formalism to various cases of experimental relevance, including a qubit and an harmonic oscillator. In such cases, we show explicitly that the inner friction is linked to the speed at which the thermodynamic transformation is performed and to the diabatic transitions that occur in the system.

Critical Casimir Forces

S. Dietrich[1, 2]

[1]Max Planck Institut für Intelligente Systeme, Germany
[2]Institut für Theoretische Physik IV, Universität Stuttgart, Germany

Abstract— Long-ranged correlations in a fluid near its critical point lead to clearly identifiable effective forces acting on confining walls. The corresponding universal scaling functions are discussed for different boundary conditions and geometries. The theoretical predictions are compared with high precision experimental data for He^4 and He^3/He^4 wetting films near the superfluid phase transition as well as with synchrotron scattering data from classical binary liquid mixtures. Direct measurements and applications for colloidal suspensions are discussed.

Critical Casimir Forces & Many-body Effects

Andrea Gambassi
SISSA — International School for Advanced Studies and INFN
via Bonomea 265, Trieste 34136, Italy

Abstract— In 1948, Hendrik Casimir predicted that two uncharged conducting surfaces in vacuum attract each other due to the quantum fluctuations of the electromagnetic field which are spatially confined by these surfaces. The classical analogue of this effect was theoretically investigated by Michael Fisher and Pierre-Gilles de Gennes in 1978 and it originates from the confinement of thermal fluctuations in fluids near continuous phase transitions, such as the demixing of a mixture of two liquids. The equilibrium force of these fluctuations — the so-called critical Casimir force — has been recently measured and it can be harnessed for controlling soft matter and colloids at the micrometer scale. Due to its very same nature, this force is non-additive and therefore many-body effects have to be expected. In the talk I will discuss the current status of their investigation.

Photonic Control of Thermal Emission for Radiative Cooling

Aaswath Raman, **Linxiao Zhu**, **and Shanhui Fan**
Ginzton Laboratory, Stanford University, Stanford, CA, USA

Abstract— From a thermodynamic standpoint, one can improve the efficiency of any energy conversion process by having access to both a higher-temperature heat source and a lower-temperature sink. While the Sun has been actively exploited as a renewable source of the former, relatively little work has gone into exploiting a lower-temperature sink that we have access to radiatively: the cold of outer space. At its highest level our work shows how a photonic approach to control far-field thermal radiation can allow us to efficiently exploit the 'heat sink' of the universe at all hours of the day to improve energy efficiency and conversion processes.

From a practical point of view, cooling is a significant end-use of energy globally and a major driver of peak electricity demand. At night, electricity-free cooling below ambient air temperature has been demonstrated using a technique known as radiative cooling or night-sky cooling, where one uses a device exposed to the sky to radiatively emit heat to outer space through a transparency window in the atmosphere between 8–13 μm. Peak cooling demand however occurs during the daytime. Daytime radiative cooling below ambient under direct sunlight has not previously been achieved because sky access during the day results in heating of the radiative cooler by the sun.

In this talk, we will discuss how a photonic approach to the control of far-field thermal emission from a surface is both formally necessary for optimal radiative cooling, and enables new technological possibilities. We first introduce the theoretical requirements necessary for daytime radiative cooling and derive the upper bound of performance possible by a thermal emitter. This bound is constrained by the second law of thermodynamics and is only attainable using a selective emitter. We show moreover that the optimal selective emitter for radiative cooling varies as a function of the operating temperature below ambient.

We then present results of the first experimental demonstration of daytime radiative cooling, where we achieve a temperature of nearly 5°C below the ambient air temperature under direct sunlight. Using a thermal photonic approach, we design and fabricate an integrated photonic solar reflector and thermal emitter consisting of 7 layers of HfO_2 and SiO_2 that reflects 97% of incident sunlight while emitting strongly and selectively in the mid–infrared atmospheric transparency window. Even when exposed to direct solar irradiance of greater than $850\,W/m^2$ on a rooftop, the photonic radiative cooler achieves an average of 4.9°C below ambient air temperature over, and has a cooling power of $40.1\,W/m^2$ at ambient.

Finally, we will discuss both the theory behind, and an experimental demonstration of, a photonic approach to passively maintain solar cells at lower temperatures through radiative cooling, while maintaining their solar absorption.

Heat Transfer and Thermodynamics of Thermal Radiation in the Near and Far Fields

Gang Chen, **Vazrik Chiloyan**, **Poetro L. Sambegoro**, **Jonathan K. Tong**, **Yi Huang**, **Wei-Chun Hsu**, **and Svetlana V. Boriskina**
Department of Mechanical Engineering
Massachusetts Institute of Technology Cambridge, MA 02139, USA

Abstract— This talk will discuss two aspects of thermal radiation. One is on the limit of radiative heat transfer in the near fields. When the spacing between two surfaces is less than the dominant wavelength of thermal radiation, heat transfer between the two surfaces can significantly exceed the blackbody limit. In the past, we have demonstrated experimentally that near-field thermal radiation can far-exceed the far-field blackbody limit and the experimental results are in agreement with the Rytov's fluctuating electrodynamics description. However, in the limit when two surfaces are in contact, heat transfer is described in terms of heat conduction and phonon transport. We develop an approach using lattice dynamics and the microscopic Maxwell equations to bridge the theories of conduction and radiation. We will also update recent experiments on near field heat transfer between different materials. We will then move on to discuss next the thermodynamics of thermal radiation, focusing on entropy of thermal radiation and its consequences on the limits of various energy conversion processes, and the extraction of the near field thermal radiation to the far field.

Abstract— A frequency selective surface (FSS) usually operates as a spatial filter for the incoming electromagnetic waves with different operating frequencies, polarizations, and incident angles [1]. Based on its special characteristics, an FSS are widely used in applications of target invisibility and interference reduction [2, 3]. It is highly desirable that an FSS can achieve high performance (such as high selectivity and wide stopband characteristics) with simple fabrication process. Although most of single-layered FSSs have simple topologies and can be easily fabricated, it is very difficult for a single-layered FSS to realize high selectivity and wide stopband characteristics [4, 5]. On the other hand, three-dimensional (3D) frequency selective structures can achieve the above mentioned high performance [6, 7]. However, the fabrication process will be complex due to their complicated topologies.

In this work, a double-layered FSS with quasi-elliptic bandstop filtering response is presented. The proposed FSS consists of two cross dipole arrays printed on both sides of a substrate respectively and a number of via holes connecting these cross dipoles, as shown in Fig. 1. With appropriately tuning the locations of the via holes and the length ratios of the dipoles and via holes, a wideband bandstop filtering response can be obtained, as shown in Fig. 2. Furthermore, two transmission zeros and two transmission poles are achieved in the operating frequency band, thus resulting in high selectivity. Moreover, the present structure has simple topology and can be easily fabricated with high accuracy. Experimental verifications will be carried out in the near future.

Some Novel Applications of Frequency Selective Surfaces (FSSs)

Raj Mittra
EMC Laboratories, Pennsylvania State and Central Florida Universities, USA

Abstract— Frequency Selective Surfaces find a wide variety of applications as components in electromagnetic devices, as for instance in high-performance radomes and frequency re-use systems for satellite communications, among others. In this paper we will discuss two other uses of FSSs, namely as screens for mobile phones that are designed to mitigate the SAR (Specific Absorption Rate) problem in mobile phones, and as substrates or superstrates for off-the-shelf dielectric materials to alter their permittivities to desired values specified by the user.

The SAR problem stems from the fact that a large share ($\sim 80\%$) of the RF power radiated by cellphone antennas end up being absorbed by the human head when the phone operates close to a human head, as it typically does in normal use. Attempts to reduce the radiation in the back direction of the phone, where the hea is typically located, have not been very successful to-date. The paper will describe, as one of the novel applications of the FSS, how we can selectively reduce the SAR at higher end of the frequency spectrum covered by cellphones designed for 4G and LTE frequency bands — where it is most needed because it exceeds the threshold deignated by the FCC at higher frquencies.

Next the paper will discuss another non-traditional application of the "FSS-type" screens. In this application the FSSs-type screens are printed on off-the shelf dielectric materials to tweak their permittivity values to those specified by the user, but are unavailable from a vendor for such materials. Such materials are often called for in the design of low profile lenses and in broadband reflectarrays. We will describe how the FSS-type screen is used to artificially synthesize dielectric materials for the applications mentioned above, as well as for other antenna applications.

Before closing we mention that FSSs used for the two applications mentioned above are often referred to as Metamateials, which we believe is a misnomer. In any case, we employ the reflection the reflection and transmission characteristics of the FSS screen for our purposes, and we neither evaluate nor utilize the effective medium properties of the FSSs we employ in our designs.

An Active Mono-layer Phase Switched Screen

Jonathan M. Rigelsford and Radhwan J. Mahmoud
Department of Electronic & Electrical Engineering
The University of Sheffield, Mappin Street, Sheffield S1 3JD, United Kingdom

Abstract— The classical single layer phase-switched screen (PSS) described by Chambers and Tennant [1] was designed as a radar absorbent material that can attenuate the incident waves. Their design comprises an active frequency selective (FSS) layer suspended above a conducting ground plane. The phase shift is achieved by switching the FSS between its transmissive and reflective states.

In this work we present an active mono layer PSS in which the conducting ground plane has been removed, additionally allowing it to perform as a conventional FSS. An advantage of this design is that the mono-layer PSS is thinner than conventional designs and can be designed to have some level of optical transparency. A section of the active mono-layer PSS is illustrated in Figure 1. It consists of two dimensional arrays of rectangular metallic patches that have a length of L and a width of W. Each strip is horizontally separated with its adjacent one by a distance of d and connected via PIN diodes on short interconnecting arms. The rectangular patches are vertically separated from each other by 1 mm and are electrically connected using capacitors. The PIN diodes are reverse biased by applying voltage at each end of the horizontal arrays.

When diodes are switched ON, they will short the patches together and make the surface has low impedance and the layer will act as a reflector. However, when they are OFF, they will isolate the strips from each other which will cause the surface to have high impedance. At the operational frequency, both switching cases have the same magnitude of reflection coefficients but a negative phase to the other. By switching the diodes rapidly and periodically with a switching frequency (f_s) between these two impedance states, binary phase modulation to the incident signal will be performed with reallocation of its energy out of its band acting as an absorber.

Figure 2 shows reflection and transmission results for a mono-layer PSS designed to operate at 2.7 GHz. At this frequency it can be seen that the state of the PIN diodes (ON — low impedance,

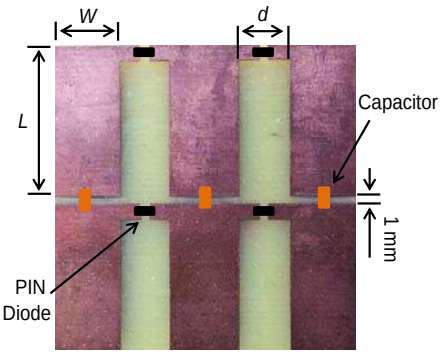

Figure 1: A section of the active mono-layer PSS prototype.

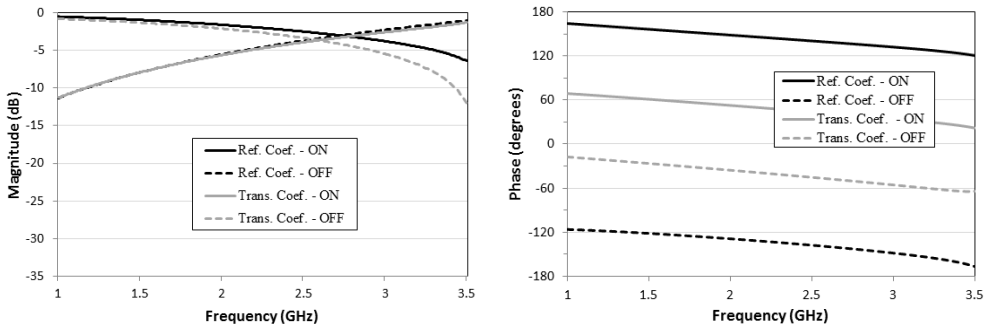

Figure 2: A section of the active mono-layer PSS prototype.

or OFF — high impedance) has minimal effect on the magnitude of the reflection and transmission coefficient. In this case (Figure 2(a)) all four parameters are approximately -3 dB and so the mono-layer acts purely as a PSS and is neither preferentially reflective nor transmissive. Out of the frequency band of operation, the surface can be switched between reflective or transmissive states. Figure 2(b) shows that a phase difference of 90° can be achieved between the two switching states for both the reflection phase and transmission phase.

The full paper will demonstrate further results and performance analysis of the designed mono-layer PSS

A Multilayer Meander Line Structure for Dual Band Orthogonal Circular Polarization Selectivity

D. Sjöberg
Department Electrical and Information Technology, Lund University, Sweden

Abstract— In the context of multiple beam antennas for the emerging broadband satellite market, accurate control of circular polarization is of interest. In order to efficiently reject out-of-band signals, a combination of orthogonal polarizations and different frequencies are employed in a four-color scheme to cover the earth surface. A desirable component in this kind of system is a dual band circular polarization structure [1], the function of which is to reflect one handedness of polarization at frequency f_1, and transmit the other polarization. At another frequency f_2, the operation should be switched. The ratio f_2/f_1 should typically be in the order of 1.5–2.

Such a structure can be realized by a multilayer meander line concept as presented in [2]. The concept is based on consecutive meander line sheets, rotated with respect to each other corresponding to their separation in the normal direction. For a nominal wavelength $\lambda_1 = c/f_1$ and sheet spacing d, this means each sheet is rotated clockwise by an angle φ_1 determined by $\varphi_1/2\pi = d/\lambda_1$, leading to re ection of right hand circular polarization (RHCP). This leads to an interesting harmonic at a wavelength $\lambda_2 = c/f_2$: when $\varphi_2 = \pi - \varphi_1 = 2\pi(d/\lambda_2)$, the structure is rotated counter-clockwise resulting in re ection of LHCP. This provides the dual band operation of the structure.

In the presentation I will give examples of such designs, explaining how the number of layers and other geometrical parameters affect the performance of the design, measured in terms of return loss, insertion loss, and axial ratios around or less than 1 dB. The conceptual harmonic property deduced in the previous paragraph will be shown to produce a viable design after applying some full-wave optimization.

A New Frequency Selective Surface Geometry Design at the Unlicensed 2.4 GHz and 5.8 GHz ISM Bands

Mesut Kartal[1] and Bora Döken[2]

[1]Department of Electronics and Communications Engineering
Istanbul Technical University, Maslak, Istanbul 34469, Turkey
[2]Vocational School, Istanbul Technical University, Maslak, Istanbul 34469, Turkey

Abstract— The usage of wireless devices within buildings at ISM bands is growing rapidly in recent years. Mutual interferences within the adjacent wireless devices degrade the system performances. Securing personal data is also becoming another important problem between the adjacent devices. Transforming existing building walls to a band stop frequency selective surface can an efficient solution for such problems. This work is proposed to design band stop frequency selective surface for interference mitigation and network security within the buildings in the unlicensed 2.4 GHz and 5.8 GHz ISM bands.

Frequency selective surfaces (FSS) are periodic structures which have filter characteristics depending upon their geometries when interacting with electromagnetic waves. Band stop FSSs and their isolation capabilities have been investigated by different researchers for WLAN security and interference mitigation in indoor environment. According to given results, FSSs are capable of providing radio isolation of minimum 10 dB between the two adjacent rooms at both ISM bands. These researches also showed that wireless signals in indoor environment have a wide range of incidence angles. Although the 2.45 GHz and 5.8 GHz ISM bands have been investigated sufficiently for FSS designs, there are not many works in the literature which stops the both ISM bands at the same time. In this work, an attenuation of 10 dB on the transmission (S_{21}) parameter is desired for 2.4 GHz and 5.8 GHz ISM bands while providing maximum transparency at broadcast frequencies for wide range of oblique incidence angles and for all polarizations.

One of the most important factors influencing the response of FSS is the periodic element geometries, geometrical and electrical parameters of these geometries and the gaps between these periodic elements. Unit cell dimensions and the gaps between the unit cells should be small in terms of the wavelength of the resonance frequency to avoid earlier onset of grating lobes and greater variation of the first resonant frequency with angle of incidence. Meandering of the excited metal patch is used to reduce unit cell sizes in our work. The advantages of fractal geometries and convoluting the array elements are being taken.

Simulation and optimization processes are performed by Ansoft HFSS software. Equivalent circuit (EC) models of these FSSs geometries are used to define the relationship between the geometrical parameters of the periodic elements and their frequency responses.

In this work band stop FSS is designed for interference mitigation and network security within the buildings in the unlicensed 2.4 GHz and 5.4 GHz ISM bands. To achieve a stable frequency response for wider oblique incidence of angles a new element geometry is introduced. Satisfying results are obtained for oblique incidence angels from normal to 70° for all polarizations. Achieved attenuation levels are below −20 dB for TE and TM polarizations and for all incidence angles. Besides, the thickness of this structure is 1 mm which gives the possibility of using this design as a structural surface material for blocking ISN signals.

In-building Propagation Control Using Passive Elements Installed in a Corridor

Christopher J. Davenport and Jonathan M. Rigelsford
Department of Electronic & Electrical Engineering
The University of Sheffield, Mappin Street, Sheffield S1 3JD, United Kingdom

Abstract— The use of comb reflection frequency selective surfaces (CR-FSS) to reduce specular scatters and re-direct signal in alternate directions has previously been researched [1]. Although work has been done to understand how the scattering characteristics change relative to incidence angle [2], the application of such surfaces in in-building simulations has not been discussed. The research summarised in this paper discusses the design of a CR-FSS for installation in a building corridor to electromagnetically separate two rooms, reducing the signal-to-noise (SNR) ratio and the potential for co-channel interference at 2.4 and 5 GHz, commonly used frequencies for Wi-Fi transmissions

An initial design study using CST Microwave Studio is conducted to understand the performance of the CR-FSS (Fig. 1) for various angles of incidence and both TE and TM polarisations. The period, height, and thickness parameters are optimised so both TE and TM bands overlap, as shown in Fig. 2. Harmonics in the 5 GHz region can be utilised to reduce specular scatter in this Wi-Fi band also. Further simulations are completed to understand the variation of the response with respect to angle of incidence.

Finally, the surface is applied to an in-building scenario where comparisons at different frequencies are observed. Cumulative distribution function (CDF) plots are used to quantify the differences between a normal building, and a building with the CR-FSS installed. Reductions of E-field level in the required areas will mean that co-channel interference is reduced and thus the SNR of these areas is also increased.

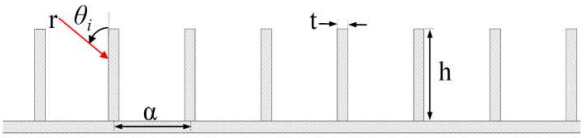

Figure 1: The CR-FSS structure optimised at 2.4 GHz with parameters: height, $h = 70$ mm, period, $\alpha = 80$ mm, $t = 4$ mm.

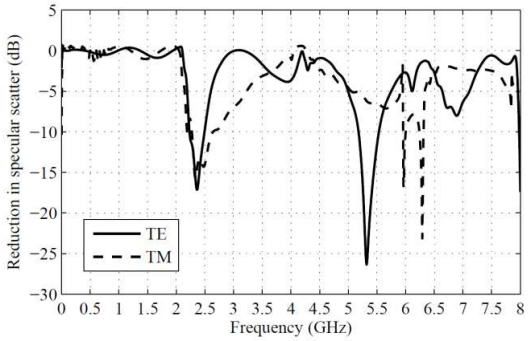

Figure 2: Frequency characteristics of the 2.4 GHz optimised CR-FSS at $\theta_i = 50°$.

Abstract— The objective of this study is to analyze the radar response of soil moisture and to develop a method for retrieving soil moisture using ALOS-2 data based on the advanced integral equation method (AIEM) model which was proved to be one of the most valid surface microwave scattering models. However, retrieval of soil moisture from SAR data is not straightforward as it may seem, for it is profoundly affected by numerous factors such as surface roughness, vegetation cover, and soil texture, to certain extent depending upon the probing wavelength. The AIEM model was used to simulate the radar scattering characteristics of the soil surface to analyze the coupling effects of the surface parameters including the root mean squared (rms) height, correlation length, soil moisture as well as the radar system parameters including the incident angle and polarization. For ALOS-2 SAR, four components decomposition method by Yamaguchi was first applied to decompose the total response into volume, surface, double bounce, and helix scattering components, from which the sensitivity of soil moisture scattering response due to polarimetric properties was investigated. Yellow River delta, one of the largest deltas in China formed by the silts from the Yellow River in Shandong province, was selected as test site. Influence of radiometric quality including speckle and calibration accuracy will be discussed in regard of soil moisture.

Electronic Counter-countermeasures in Bistatic Radars

Faran Awais Butt[1], **Ijaz Haider Naqvi**[2], **and Madiha Jalil**[3]

Abstract— Bistatic configuration of radars has become a topic of great interest for Electronic counter-countermeasures designers. The paper emphasized the need for bringing about a trend of employing bistatic radars in place of traditional monostatic radars which are no more useful under the hostile environment that is created by the electronic counter measures effect. It has been shown that noise and deception jamming can be countered using bistatic configuration of the radar system. Moreover, low observability of the target threat can also be dealt with using this.

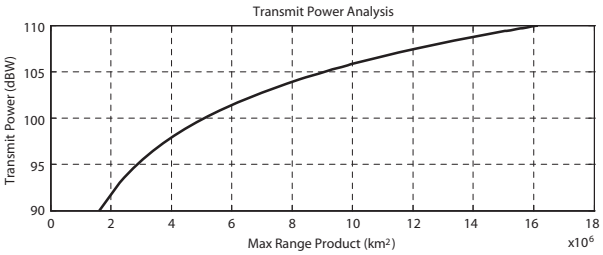

Figure 1: Transmit power analysis for bistatic angle of 10 degrees and RCS of 20 dBsm.

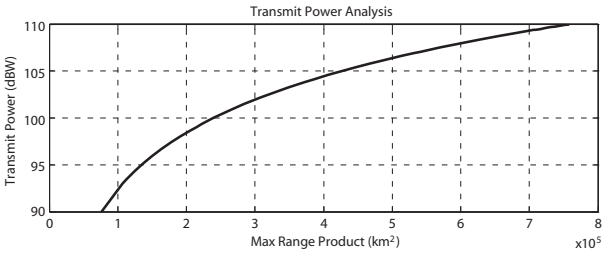

Figure 2: Transmit power analysis for bistatic angle of 20 degrees and RCS of 10 dBsm.

Figures 3 and 4 show the signal to noise ratio analysis of bistatic radar corresponding to max range product. From these figures, it can be concluded that if the bistatic angle is increased, the corresponding SNR is reduced. The bistatic angle, i.e., positioning of transmitter and receiver has a big role to play in the overall working of the system.

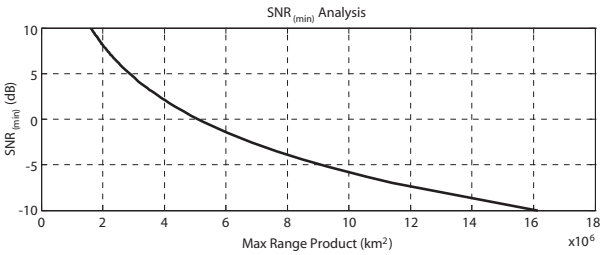

Figure 3: SNR analysis where angle is 10 and RCS of the target is 20 dBsm.

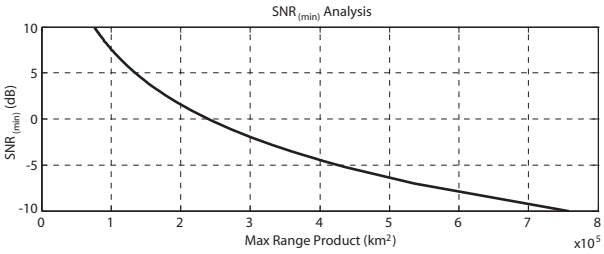

Figure 4: SNR analysis where angle is 20 and RCS of the target is 10 dBsm.

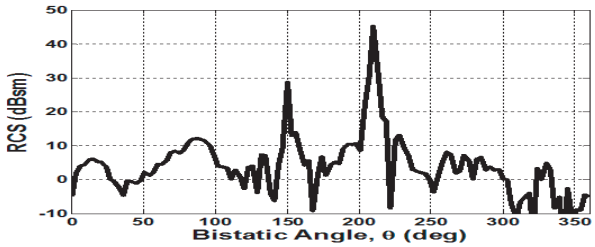

Figure 5: RCS vs. bistatic angle.

The paper has shown the advantages that the radar designers can exploit from a bistatic radar approach, courtesy of the geo placement of the distant receiver. Similarly bistatic approach

allows simultaneous accomplishment of ECCM techniques which improves the probability of detection. Bistatic radars can also give the liberty to designers of employing MIMO functionality by making an intelligent transceiver system on both the sites. Low observable stealthy targets which scatter the incoming transmitted wave in various directions can be best dealt with if there is a corresponding receiver or a transceiver system in best probable direction. Moreover for such targets, there is a range of aspect angles which can be exploited by using bistatic system. In addition to this, jammers which target the antenna sight of the radar for a typical monostatic system, no longer remains effective if there is a receiver at a distant sight.

Polarimetric SAR Simulations of Bare Soil and Vegetated Surfaces Using Scattering and Coherency Matrix from 3-D Numerical Solutions of Maxwell Equation (NMM3D)

Abstract— Polarimetric synthetic aperture radar (PolSAR) images have been widely studied to classify target and retrieve target information in microwave remote sensing. Scattering matrices ($S_{VV}, S_{HH}, S_{VH}, S_{HV}$) calculated from numerical 3D solutions of Maxwell equations (NMM3D) have been shown to be capable of simulating polarimetric SAR signature of bare soil at L-band [1]. In this paper, we made two extensions to the previous work . 1) We extend Pol-SAR simulations of scattering matrices of bare soil up to C-band, and 2) we simulate the Pol-SAR signature of coherency matrices for vegetated surface.

For polarimetric signatures of bare soil at C-band, results of scattering matrices from NMM3D are computed. Comparisons are made with theoretical speckle distributions, including amplitude, phase difference, and amplitude ratio. Surface roughness dependence with entropy, anisotropy, and alpha angle from the ensemble average of coherency matrix. We calculate polarimetric statistics of rough surface at C-band (5.4 GHz) with 40 degree incidence. Surface rms heights are from $1 \sim 4$ cm ($ks = 1.13 \sim 4.52$) with correlation length to rms height equal to 15 and the dielectric constant is $9 + 2.5i$.

Using distorted born approximation in conjunction with NMM3D we compute the coherency matrix for vegetated surface. Averages are taken to compute the coherency matrix of volume scattering and double bounce. These are then combined with the NMM3D coherency matrix. The following shows examples of terms from coherency matrix of volume scattering and double bounce. α and β stand for orientation of vegetation which will be averaged out to give ensembled results for coherency matrix. The scattering matrix elements for surface scattering with attenuation, rough surface under vegetation (RV), is also shown.

$$\begin{aligned}
\left\langle S_{vv}^{vol} S_{hh}^{vol^*} \right\rangle &= n_0 A d \frac{1 - e^{-d[-i2(Re(k_{ivz}) - Re(k_{ihz})) + Im(k_{ivz}) + Im(k_{ihz})]}}{-i2(Re(k_{ivz}) - Re(k_{ihz})) + Im(k_{ivz}) + Im(k_{ihz})} \\
&\quad \langle f_{vv}(\theta_s, \phi_s; \pi - \theta_i, \phi_i) f_{hh}^*(\theta_s, \phi_s; \pi - \theta_i, \phi_i) \rangle_{\alpha,\beta} \\
\left\langle S_{vv}^{DB} S_{hh}^{DB^*} \right\rangle &= n_0 A d \left[R_v(\theta_i) e^{2ik_{ivz}d} R_h^*(\theta_i) e^{2ik_{ihz}^* d} \right] \\
&\quad \langle f_{vv}(\pi - \theta_s, \phi_s; \pi - \theta_i, \phi_i) f_{hh}^*(\pi - \theta_s, \phi_s; \pi - \theta_i, \phi_i) \rangle_{\alpha,\beta} \\
S_{hv}^{RV} &= e^{ik_{ihz}d} e^{ik_{ivz}d} S_{hv}^R \\
S_{vv}^{RV} &= e^{ik_{ivz}d} e^{ik_{ivz}d} S_{vv}^R \\
S_{vh}^{RV} &= e^{ik_{ivz}d} e^{ik_{ihz}d} S_{vh}^R \\
S_{hh}^{RV} &= e^{ik_{ihz}d} e^{ik_{ihz}d} S_{hh}^R
\end{aligned}$$

Abstract— Wave propagation and scattering inside dense media such as snow has been extensively studied with the partially coherent approach of dense media radiative transfer (DMRT). In DMRT, one accounts for the coherent wave interaction only within few wavelengths as represented by phase matrix. Multiple volume scattering beyond a few wavelengths and volume-surface interactions are included through the radiative transfer theory by propagating the specific intensity. Such approach ignores the cyclical terms in Feynman diagram which give rise to the characteristic phenomenon of backscattering enhancement in active remote sensing [1]. On the other hand, the backscattering enhancement is inherent in the fully coherent approach. The fully coherent approach can also be applied to coherent radar observations such as interferometric and tomographic applications by simulations of the scattering matrices of the snowpack.

In this paper, we calculate the scattering matrix of the terrestrial snowpack over a flat ground by solving Maxwell's equations directly. The snow microstructure is represented by the bicontinuous media as a continuous representation of interfaces within a two-phase medium [2, 3]. The bicontinuous media could be quantified in terms of correlation function and specific surface area (SSA), and could be compared to field measurements of snow grain size distribution and SSA [4–6]. The effects of the ground are modeled by the half space Green's function. The dyadic half space Green's function is decomposed into a primary component of the free space Green's function and a response component expressed as Sommerfeld integrals. The kernel of the response part depends only on two independent variable, viz. the horizontal displacement between the field point and source point, and the sum of the offset of the field point and source point above the bottom interface. Lookup tables are built to expedite the evaluation of half space Green's function. The volume integral equation is then solved by the discrete dipole approximation (DDA). The matrix vector multiplication is accelerated by FFT taking advantage of the symmetry of both parts of the Green's function [2, 7].

The computation domain in this study is significantly increased. It increases from a ~ 8 cubic wavelengths cube size as used in the phase matrix calculations [1–6], to a much larger size in the calculation of the scattering matrix of a snowpack. The high computation demand is carried out by using parallel computing on high performance computing clusters.

The scattering matrix of the snowpack is computed for each realization. The statistical distribution property of the scattering matrix and backscatter are then computed using Monte Carlo simulations. The results of the snowpack backscattering and bistatic scattering coefficients are compared with the results of the DMRT approach with or without cyclical corrections [1].

All-optical Mitigation of Non-linear Gain in SOA

Cristiano De Mello Gallep[1], **Peterson Rocha**[2], **and Evandro Conforti**[2]

[1]School of Technology — FT, University of Campinas, Brazil
[2]Fac. Electrical and Computing Eng. — FEEC, University of Campinas, Brazil

Abstract— The intrinsic non-linear gain of semiconductor optical amplifier is mitigated in a simple all-optical scheme that enables transparent, quasi-linear response. Operation with advanced modulation formats such as n-PSK and n-QAM, presented good performance for access networks (< 30 km) up to 5 WDM channels.

The always increasing demand of high speed services have pushed for the new generation of optical carriers employed in long haul links, with 100 Gbit/s to 400 Gbit/s capacity per lambda [1]. Up to Terabit/s transmission can be accomplished in supper channel configurations [CPQd^2]. The more efficient use of spectra is achieved by multi-level modulation formats and optical polarization multiplexing, with addition of high speed digital signal processing to enable coherent detection and error correction, usually with base-rate of 25 Gbaud/s. These high capacity channels will run over fiber links together with carriers of the past generations — 40 Gbit/s (PSK) and 10 Gbit/s (OOK), that are simpler to generate and detect, and will continue to be used for small-metro and access networks for some time. With maturity of low-cost Tx/Rx for coherent detection, this technology tends to push over access network, with link solutions at lower rates, as 20 G and 10 Gbaud/s.

The semiconductor optical amplifier (SOA) is a noisy, non-linear device that can be employed to compensate splitting/switching losses, and other minor attenuation in the last-mile links, and also to detect and remodulate carriers in PON schemes [3]. The SOA is an attractive solution for integration and reduction of costs. But its small carrier lifetime — in nano-second range, and high non-linear gain index, make the use of SOA a trick problem: gain saturation can easily lead to cross-talk, and even single channel operation can suffer, by self-phase modulation. In multilevel formats such (D)QPSK and n-QAM, different amplitude transitions induce different phase delay, in non-linear response that impacts over the constellation diagrams as non-linear phase rotation — the n-point star rotates un-equally and single spots turn to arches, even connecting to of them. So, used as it is, SOA is not compatible with the new high capacity channels.

To solve the non-linear gain of SOA we proposed a new, all-optical regeneration scheme based on a second SOA working as non-linear absorber, in such a way that the two SOA give a reasonable gain (> 20 dB) with small phase distortion. The technique may mitigate non-linear phase noise up to 50%, even for multi-channel operation, and can still be an attractive solution for medium and small fiber links working with both old and new modulation schemes.

The Nonlinear Fiber-optic Channel: Modeling and Achievable Information Rate

E. Forestieri and M. Secondini
TeCIP Institute, Scuola Superiore Sant'Anna, Italy

Abstract— The evaluation of channel capacity in nonlinear fiber-optic systems is still an open issue. The main difficulty is due to the unavailability of an exact and mathematically tractable channel model. In fact, most of the results obtained so far either refer to highly simplified models or provide loose bounds to the capacity. A useful and practical approach to lower bound the capacity is that of evaluating the achievable information rate for an arbitrarily fixed input distribution (modulation format) and a suboptimal decoder optimized for an approximate version of the channel (mismatched decoding). In this context, the capacity problem can be seen as a joint optimization of the achievable information rate over both the input distribution and the channel model.

According to the popular Gaussian noise (GN) model, nonlinearity is simply modeled as additive white Gaussian noise: it cannot be compensated for, but it can be easily accounted for in the evaluation of channel capacity, leading to the conclusion that capacity vanishes at high powers. This result, however, is not supported by theory and is contradicted by some counter examples. Though it is now clear that the GN model has some limitations, it is still unclear whether these limitations are only of theoretical interest or do have a practical value.

After properly defining the fiber-optic channel — indeed, not a trivial task due to its highly nonlinear nature — and reviewing the main characteristics of the GN model, we consider a few alternative models and discuss their suitability for system design and performance evaluation. The choice of the right model depends on the problem at hand: while numerical methods, such as the split-step Fourier method, are suitable for compensating deterministic nonlinearity through the back-propagation technique, analytical approximations — based, for instance, on perturbation methods or Volterra series expansion — are more suitable for modeling stochastic effects such as signal noise-interaction and inter-channel nonlinearity. Finally, an exact analytical model, accounting only for dispersion and nonlinearity, can be obtained by employing the inverse scattering (nonlinear Fourier) transform. It is still unclear, however, whether this approach is competitive with the split-step Fourier method in terms of computational complexity and whether it can be used for modeling stochastic nonlinear effects.

By employing the aforementioned models, it is possible to show that the optimum modulation and detection strategies differ from those designed according to the GN model and typically used in fiber-optic systems. Therefore, in the second part of the talk, we consider different modulation and detection schemes aimed at providing higher robustness to nonlinear effects and investigate their actual advantage over GN-model-based strategies in terms of achievable information rate. Depending on the considered scenario, a non-negligible improvement is achieved. However, at high powers, the gap between lower and upper bounds to channel capacity remains large and does not allow to establish whether capacity is bounded or not. Possible directions for reducing the gap are finally discussed.

Flex-grid All-optical Interconnect Supporting Transparent Multi-hop Connection in Data Centers

Abstract— The demand of higher capacity and lower power consumption in data centers makes optical interconnects become an attracting solution. Many existing optical switching schemes [1, 2] employ optical-electrical-optical (O-E-O) conversion for multi-hop connections and hence have relatively low power efficiency. In this paper, a novel flex-grid all-optical interconnect architecture is proposed for data centers. All-optical interconnects between servers in different racks are realized with an optical switch matrix and flex-grid WSSs. Transparent multi-hop connections can be implemented by using optical bypass rather than going through O-E-O conversion. Compared with the O-E-O based multi-hop scheme, a higher energy efficiency is achieved with the proposed one. By employing flex-grid WSSs and advanced modulation formats, the elastic spectrum allocation [3] can be achieved, which greatly improves the resource utilization and scalability. Transmission performance evaluation has been carried out to verify the feasibility of our scheme.

Strong Quadrupole Light-molecule Interaction and the Dipole-quadrupole Theory of Surface Enhanced Spectroscopy

V. P. Chelibanov[1] and A. M. Polubotko[2]

[1]State University of Information Technologies, Mechanics and Optics

Abstract— Surface Enhanced spectroscopy is associated with such optical processes as Surface Enhance Raman scattering (SERS), Surface Enhanced Hyper Raman scattering (SEHRS) and Surface Enhanced Infrared absorption (SEIRA). The essence of these effects is that the cross-sections of these processes increase strongly for molecules adsorbed near rough metal surfaces and the enhancement can achieve huge values. For example for SERS it is 10^6, for SEHRS — 10^{12} and for SEIRA — 10^2–10^3. From our point of view these effects are associated with very strong dipole and especially quadrupole light-molecule interactions, arising in surface fields strongly varying in space near rough metal surfaces [1]. As can be shown the electric field near the roughness with a very large curvature enhances very strongly. Therefore there is the enhancement of both of the electric field and its derivatives in such regions and the dipole and quadrupole light-molecule interactions increase very strong. In order to check the validity of this mechanism one can analyze the spectra of the above processes in symmetrical molecules. The major regularity of these spectra is appearance of forbidden lines in molecules with sufficiently high symmetry. In SERS these lines are caused by the vibrations transforming after a irreducible representation, which describes transformational properties of the d_z moment which is perpendicular to the surface, while in SEHRS and SEIRA spectra they are the lines, caused by the totally symmetric vibrations transforming after a unit irreducible representation of the molecule symmetry group. Analysis of the surface enhanced spectra of various symmetrical molecules such as ethylene, benzene, 1,3,5 trideutereobenzene, hexafluorobenzene, 1,3,5 trifluorobenzene in SERS, ethylene in SEIRA and pyrazine and phenazine in SEHRS, reveals existence of such lines and another regularities of the enhance spectra that strongly support our theory of the surface enhanced processes

Femtosecond-scale Polarization Fluctuations of Light Measured by Two-photon Absorption

A. Shevchenko[1], **M. Roussey**[2], **A. T. Friberg**[2], **and T. Setälä**[2]

[1]Department of Applied Physics, Aalto University, Aalto FI-00076, Finland
[2]Institute of Photonics, University of Eastern Finland, Joensuu FI-80101, Finland

Abstract— Most natural and artificial light sources radiate unpolarized or partially polarized light, and the degree of polarization measures the time-averaged fraction of the polarized part. However, two optical fields can possess the same degrees of polarization, but their polarization fluctuations can have different speeds. Previously, to be able to characterize the polarization dynamics, we have proposed a certain polarization-correlation function $\gamma(\tau)$. It is equal to a statistically averaged fraction of the field intensity that at some delayed instant of time $t + \tau$ remains in the original polarization state of time t [1–3]. The maximum value of this function is $\gamma(0) = 1$. A particular value of τ at which $\gamma(\tau)$ decreases, say, to $1/2$ determines a time interval τ_p within which, on average, the field polarization remains essentially unchanged. Hence, the time τ_p can be called the polarization time.

In this work we introduce a method to experimentally investigate the dynamics of ultrafast polarization fluctuations and measure the polarization time τ_p of optical beams. The method is based on second-order interference and two-photon absorption in a semiconductor photo-multiplier tube. It is independent of the polarization fluctuation statistics and can be used regardless of the origin of the fluctuations. In the experiments, we use a Michelson-type interferometer with a polarizer and a quarter-wave plate inserted in each of its arms. The wave plates and the polarizers allow us to select the polarization components of interest from the incident light beam. The photomultiplier is used at the interferometer's output as a counter of photon pairs. It operates in the two-photon absorption regime at the wavelengths from 900 to 1800 nm. The time resolution of the measurements is limited by the lifetime of the virtual state via which the photon pairs are absorbed. For our detector, it is on the order of 1 fs. We have applied the technique to an unpolarized amplified spontaneous emission of an erbium-doped fiber amplifier (the peak wavelength is 1530 nm and the bandwidth is about 40 nm) and to a beam obtained by superimposing two independent single-longitudinal-mode laser beams operating at 1525 nm and 1615 nm wavelengths. The polarization time for the first source was measured to be 115 fs and for the second one 15 fs. The beams can therefore be considered as polarized within the propagation distance of 35 μm for the first and 4.5 μm for the second light source.

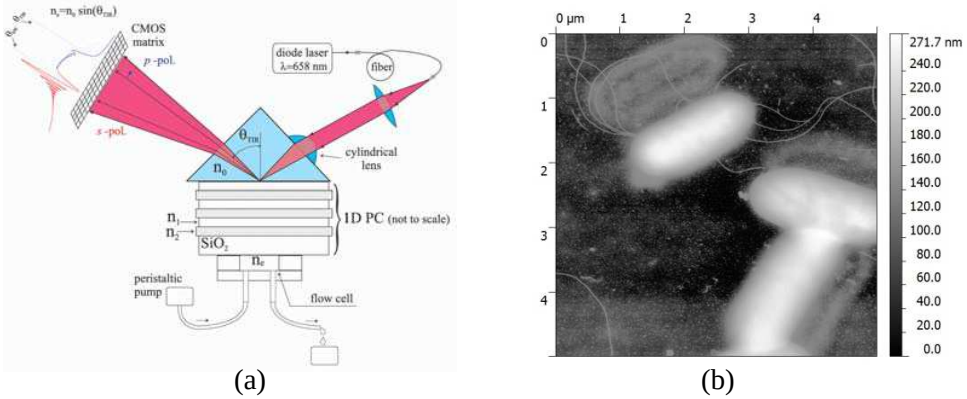
Ultrasensitive Label-free Biosensor Based on Photonic Crystal Surface Waves: A Tool to Study Dynamics of Receptor-ligand Interactions with Living Bacteria and Cells

Ekaterina Rostova, **Sergey Sekatskii**, **and Giovanni Dietler**
Laboratory of Physics of Living Matter, EPFL, Lausanne, Switzerland

Abstract— Although different types of optical biosensors are widely used to study kinetics of biomolecular interactions among a variety of macromolecules including antibodies, enzymes, hormones, low-molecular-weight molecules, toxins, cancer markers, drugs, etc., large biological objects with highly inhomogeneous refractive index such as cell suspensions impose significant difficulties.

A surface wave is an electromagnetic wave propagating along an optical interface, strongly confined there, and decaying exponentially away from the interface. In the utilized biosensor [1] such an interface is formed between a functionalized photonic crystal chip and a suspension of a biological sample under investigation. Angular interrogation of the surface wave resonance is used to detect changes in the thickness of an adsorbed layer, while an additional detection of the critical angle of total internal refection provides independent data on the liquid refraction index, see Fig. 1. Besides segregation of surface and volume effects, the exploitation of a photonic crystal supporting long-range surface waves enables to achieve mass sensitivity at the level of $0.3\,\mathrm{pg/mm^2}$ and refraction index (RI) sensitivity at the level of $10^{-7}\,\mathrm{RIU/Hz^{1/2}}$.

Another characteristic feature of this biosensor is large, in the order of $1\,\mu\mathrm{m}$, surface wave penetration depth into an external medium, which enables to study not only binding kinetics of interactions between macromolecules, but also with such large objects as viruses, bacteria, and cell organells. Here we report the first steps in this direction. We elaborated a chitosan-based protocol of surface modification of the sensor chip enabling to produce sufficiently dense and homogeneous (mono)layers of live *E. Coli* bacteria (see Fig. 1). The attached bacteria have been exploited as a target to study binding kinetics of different ligands onto a bacterial surface.



(a) (b)

Figure 1: (a) Schematic of the biosensor. (b) AFM image of a (mono)layer of *E. Coli* bacteria used as an immobilized target in the sensor.

Nanoplasmonics for Control over Localized Emission and Heat Generation

Stefan A. Maier
Imperial College London, London SW7 2AZ, UK

Abstract— Metallic nanostructures allow for the generation of spatially structured optical near-fields and near-field gradients, and have been heavily employed in surface-enhanced sensing and spectroscopies. Here we will present two new studies, namely control over quantum dot emission in extended hot spots of ring nanocavities, and the controlled heating of a solid state nanopore for molecular translocation studies.

Via engineering the photonic density of state on the nanoscale, metallic nanostructures allow the modification of the radiative properties of nanoscale emitters such as molecules and quantum dots. We will present a study of a hybrid quantum dot — plasmonic system with the hallmark of a spatially extended hot spot, based on ring nanocavities. Controlled placement of quantum dots via a dual-step electron beam lithography process allows high control over their radiative properties [1], and we will discuss extensions of this system towards higher field enhancement and more complex multi-emitter systems.

The second part of the talk will focus on controlled heating of a solid state nanopore [2] used for studies of molecular translocation. Localized heating at the nanopore centre occurs via controlled surface plasmon focusing based on a bull's eye geometry (see Figure 1). Changes in ionic conductivity directly allow for the assessment of local temperature in the pore region, in good agreement with full-field electrodynamic simulations.

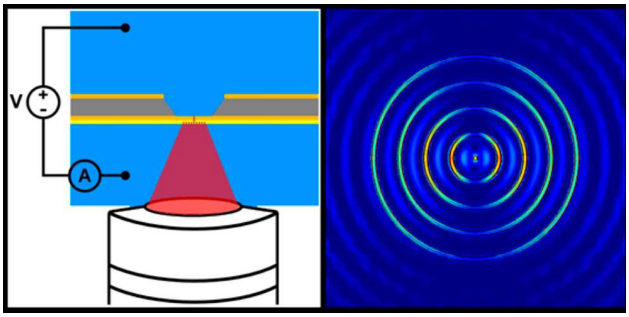

Figure 1: Localized plasmonic heat generation in a solid state nanopore [2].

Abstract— Dielectric multilayers sustaining Bloch surface waves (BSWs) are considered as a novel platform for two dimensional (2D) integrated optics. The dielectric platform is exploited to manipulate surface waves by patterning 2D dielectric optical components on top of it. BSW shows a potential of higher propagation length and large resonance strength because of low loss characteristics of dielectric materials. Taking the advantage of high field confinement on the surface, the platform has also applications in sensing.

In order to excite a BSW, momentum of incoming beam should match with the momentum of the BSW. Therefore, we use Total internal reflection configuration for this purpose, which consists of BK7-glass prism. The schematic of the configuration and the platform is presented in Figure 1. New design of multilayer platform consists of periodic stacks of alternative SiO_2 and Si_3N_4 layers. It has been fabricated to work around the wavelengths of 1.5 µm.

In this paper, we study the key parameters, propagation length and the effective refractive index (n_{eff}), of BSW. They play an important role in characterizing losses associated with the multilayer platform and propagation of surface modes. Effective refractive index contrast (Δn) is introduced by depositing an additional layer of high refractive index material on the top of platform. It is basically the difference between n_{eff} of additional layer and platform. It plays a key role in determining the optical properties of the 2D surface photonic devices and hence their capability to manipulate the BSW most essentially. High refractive index materials, as an active material to pattern 2D optical elements on the top of the platform, have been investigated in near field and far field. These material include titanium dioxide (TiO_2), for the time being, and Graphene.

We obtained propagation length of around 2 mm for 15 nm thickness of additional TiO_2 layer with the aid of multi-heterodyne scanning near-field optical microscopy (MH-SNOM). It is around 25 times longer compare to the recently obtained "Long-Range SPPs" studied by Lin et al. [1]. We achieved Δn of around 0.2 measured in the far field with 100 nm thickness of TiO_2. It is around 3.5 times higher than the Δn obtained for same thickness of Photoresist [2].

In near future, we aim to characterize different optical components on the top of multilayer platform with the aid of MH-SNOM, for example, Ring resonators and Interferometers for the time being.

Abstract— Near-field scanning optical microscopy is expected to overcome the diffraction limit, realizing a spatial resolution far beyond the wavelength of light. However, the spatial resolution, image contrast, and imaging repeatability obtainable using conventional aperture or apertureless probes do not currently satisfy the requirements for research or engineering applications. Here, we describe an optical imaging technique based on plasmonically-excited near-field to near-field coupling that has the potential to achieve a resolution of a few nanometers. Far-field near-infrared light is focused on the front edge of an Au-coated tetrahedral Si tip on the free end of a Si cantilever used as a plasmon waveguide (Fig. 1(a)). By coupling the scattered light to the Au wedge, the far-field light is converted into propagating plasmons that generate an optical near field at the top of the Si tip used as an excitation source (Fig. 1(b)). The excitation near field is coupled to a wear-resistant multiwalled carbon nanotube with a sharpened end, attached to the top of the Si tip (Fig. 2). This nanotube is used as both an optical nanoantenna and nanoprobe. The electric field is concentrated at the 4-nm-diameter conical end of the nanoprobe, so that it generates a second optical near field with the same spot size as the nanoprobe tip (Fig. 1(c)). By scanning the near-field probe spot over the sample surface, this plasmon-excitation cascaded-near-field coupling technique can achieve extremely high-resolution optical imaging. At a wavelength of 850 nm, an ultrahigh spatial resolution of less than 3 nm was achieved for a cross-sectional Au/SiO_2 superlattice sample (Fig. 3).

Abstract— Optical nanomaterials are artificial or natural materials which contain nanoscale-size structural units. Optical waves interacting with such materials are not Bragg-diffracted, since the material's unit cells are small compared to the light wavelength. The waves can therefore be considered as interacting with a homogeneous medium that has designable macroscopic characteristics.

At visible-light frequencies, nanomaterials with non-trivial and relatively large structural units (say, $> 50\,\mathrm{nm}$) are spatially dispersive, as a result of non-negligible excitation of higher-order electromagnetic multipoles in the unit cells [1]. Hence, the effective refractive index (n) and wave impedance (Z) evaluated or measured for any plane wave interacting with the material will depend not only on the polarization, but also on the direction of propagation of the wave [2, 3]. Since optical beams are composed of intercorrelated plane waves, spatial dispersion will necessarily affect the beam propagation characteristics in such nanomaterials [4].

In this work we introduce a proper theoretical basis for treating the interaction of optical beams with spatially dispersive optical nanomaterials. The method is based on a vector form of the angular-spectrum representation and a technique to evaluate the parameters n and Z for any required direction of plane-wave propagation. The parameters are retrieved from numerically evaluated transmission and reflection matrices that take into account possible changes of polarization of each plane-wave component upon interaction with nanomaterial layers. We apply the method to several particular examples and demonstrate (1) unexpected changes of light polarization in an anisotropic nanomaterial, (2) unidirectional diffraction-free propagation of optical beams in a designed spatially dispersive nanomaterial, and (3) spatial filtering of a focused optical beam by a flat nanomaterial slab.

Twin-beam Optical Parametric Generation and Cascaded Processes in Hexagonally Poled Nonlinear Lattices

Katia Gallo[1], **Martin Levenius**[1], **and Matteo Conforti**[2]

[1]KTH — Royal Institute of Technology, School of Engineering Sciences, SE-106 91 Stockholm, Sweden

Abstract— We review recent experimental and theoretical progress in the study of optical parametric generation and cascaded frequency up conversion in two-dimensional purely nonlinear lattices, relying on acoherent coupling of multiple resonances in the quadratic lattice.

Since their original proposal [1], two dimensional (2D) nonlinear photonic crystals in periodically poled materials have been the subject of a number of experimental and theoretical investigations, exploring the enhanced possibilities to engineer the nonlinear dynamics of quadratic interactions afforded in such structures [2, 3]. Most of the studies have concerned frequency up-conversion, until the recent demonstration of twin-beam optical parametric generation (TB-OPG) in 2D hexagonally poled crystals [4, 5].

TB-OPG experiments in hexagonally poled MgO:$LiTaO_3$ lattices demonstrated enhanced parametric gains as well as a rich spectral and angular response underpinned bythe coherent coupling of concurrent nonlinear processes throughshared signal or idlermodes. They provided evidence forrich interaction scenarios, generating multiple outputs in the infrared as well in the visible and encompassing also self-phase modulation and cascaded upconversion processes arising from the interplay of multiple lattice resonances.A good agreement was found with a simple model involving the cross-seeding of two non-collinear OPG processes via a common signal (idler), while the development of advanced ad-hoc simulation tools enabled to fully account for the complex nonlinear dynamics in the 2D lattices and faithfully reproduce the rich spectral-angular response seen in the experiments [6].

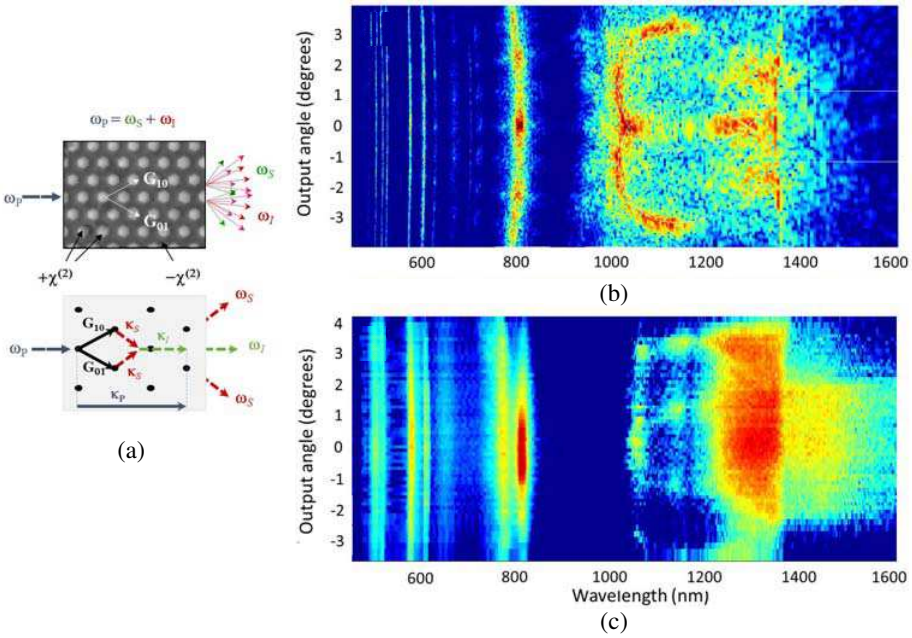

Figure 1: (a) Twin-beam parametric generation in a hexagonal nonlinear lattice. Spectral and angular mappings of the response in the visible and near infrared obtained in: (b) simulations and (c) experiments with a pump at $\sim 800\,\mathrm{nm}$.

Abstract— Compared to oxide based glasses, vitreous materials composed of chalcogen elements (S, Se, Te) show large transparency windows in the infrared. Indeed, chalcogenide glasses can be transparent from the visible up to 12–15 µm, depending on their compositions. In addition, chalcogenide glasses contain large polarisable atoms and external lone electron pairs which induce exceptional non-linear properties. Consequently, the non-linear properties can be 100 or 1000 times as high as the non-linearity of silica. An original way to obtain single-mode fibers is to design microstructured optical fibers (MOFs). These fibers present unique optical properties thanks to the high degree of freedom in the design of their geometrical structure. Our group has prepared various chalcogenide MOFs operating in the IR range in order to associate the high non-linear properties of these glasses and the original MOF properties. Indeed, chalcogenide MOFs might lead to new devices with unique optical properties in the mid-infrared domain like multimode or endlessly single-mode transmission of light, small or large mode area fibers, non-linear properties for wavelength conversion or generation of supercontinuum sources. Optical fiber sensors for the mid-IR region between 2 and 14 µm are another promising area of applications. The IR signatures of most molecules, including biomolecules, are located in this spectral domain, which allows in situ, non-invasive and real-time detection of gaz or organics molecules.

Playing Billiard in Laser Micro-cavities: A Test-bed for Semi-classical Physics

Joseph Zyss, Clément Lafargue, Stefan Bittner, and Mélanie Lebental
Laboratoire de Photonique Quantique et Moléculaire
Institut d'Alembert, Ecole Normale Supérieure de Cachan, France

Abstract— The generic "billiard problem" is a well-known paradigm of nonlinear mathematical physics, which connects to deep issues in quantum and wave physics all the way to quantum chaos. It can be implemented in mechanics, optics or electromagnetism, either in classical or quantum mechanics, depending on experimental configurations and on the billiard length-scale. The elusive borders between wave and geometric optics on the one hand, and between quantum and classical mechanics on the other, exhibit deep analogies which can be both addressed in actual billiard-like physical systems. We will show the relevance in this context of micro-billiard shaped lasers [1–4], thanks to new experimental and technological advances in the realm of polymer based photonics at micron and submicron scales. In such configurations, confinement of light in resonators can be considered by analogy with that of a quantum particle in a well (the 2-D quantum or wave billiard). Spatially distributed modes can be connected to classical orbits within the frame of semiclassical physics approximations, by use of a celebrated "trace theorem", herein generalized to open and chaotic cavities. A beneficial feature of dielectric cavities, in contrast with their more investigated metallised contour counterparts, is the ability for the electromagnetic wave to spread-out of the cavity by refraction, diffraction, evanescent tunnelling or a combination of these, allowing to simplify the otherwise hidden physics and eventually lending itself to sensor applications. However, such "open cavities" are more challenging from a theoretical and modelling point of view, giving raise to non-Hermitian operators and imaginary eigenvalues accounting for a finite modal excitation life-time in lossy cavities. Analytical solutions such as available for the metallized 2-D rectangle are not valid for the equivalent open structures which demand to resort either to full fledged solutions of the Maxwell-Helmholtz equations with continuity conditions on the contour, or to application of semi-classical orbit methods. We will show consistence between those two avenues and experimental findings. Particular attention will be paid to recent advances: systematic investigations of triangular cavities [5] and extension to 3-D micro-billiards [6]. The role of contour singularities will be evidenced and the related diffractive orbits evidenced. The technological precision required for such studies is reached by advanced e-beam patterning methods applied to dye-doped polymer structures, down to the required nanoscale precision.

Our investigations illustrate an approach whereby, contrary to the more academic pathway from upstream mathematical predictions down to experimental applications, experimental findings may help provide guidelines towards otherwise elusive mathematical problems, such as the diffraction of light by a dielectric prism that the lasing property allows to illuminate from its inside.

Liquid Crystals for Nonlinear Optics with Femtoseconds — CW Lasers

I. C. Khoo
Electrical Engineering Department, Pennsylvania State University, University Park, PA 16802, USA

Abstract— A critical analysis of various all major mechanisms for optical nonlinearities of nematic as well as Blue-Phase liquid crystals is presented, along with feasibility demonstrations of femtoseconds pulse compression, all-optical switching with nanoseconds — CW laser and tuning/modulations of micro- or nano-photonic structures [1–3]. Specifically, we will delve into individual molecular electronic nonlinearities with femtoseconds [4] response speed as well as slower (nanoseconds-milliseconds) collective molecular responses such as laser induced crystalline axis rotation, lattice reorientation and distortion, c.f. Fig. 1. The merits and limitation of nematics are discussed together with some recent results with Blue Phase liquid crystals that could circumvent some of the limitations.

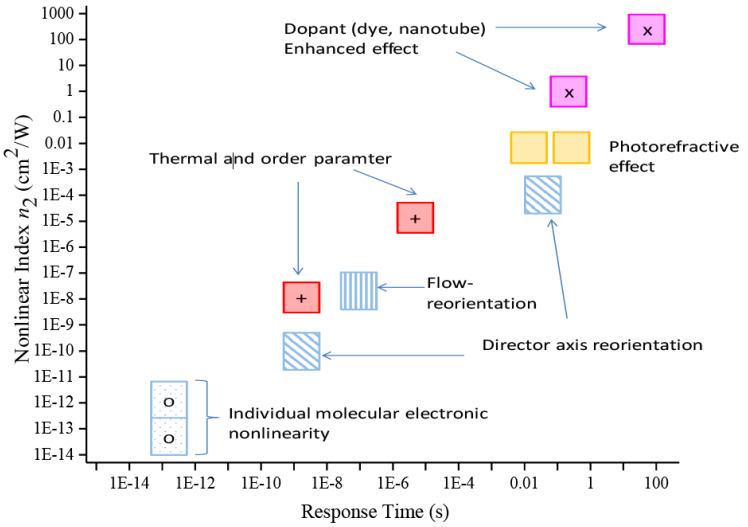

Figure 1: Nonlinear index coefficients and response speed of some exemplary nonlinear optical mechanisms in NLC.

Nonlinear Optical Imaging with Unconventional Light Fields

Godofredo Bautista, Mikko J. Huttunen, Jouni Mäkitalo, and Martti Kauranen
Department of Physics, Tampere University of Technology, P. O. Box 692, FI-33101 Tampere, Finland

Abstract— Nonlinear optical (NLO) microscopy, which embraces all imaging techniques that endow contrast based on nonlinear optics, has allowed unprecedented characterization of natural and artificial materials. Most past works, however, utilized linear, elliptical or circular polarization, where the state of polarization (SOP) is uniform across the beam cross-section. Recently, there has been a renewed interest in the unique focusing properties of beams that exhibit rotationally symmetric SOPs, and their novel imaging applications [1]. For example, when azimuthal and radial polarizations are focused, the intensity distributions of their transverse electric-field components preserve the doughnut-shaped intensity patterns and corresponding polarizations. However, when all the electric-field components are accounted for, the radial polarization exhibits a Gaussian-like intensity distribution due to the presence of a strong electric-field component along the beam axis, usually referred to as the longitudinal component.

In this talk, we show that NLO microscopy techniques equipped with unconventional polarizations provide completely unique capabilities in the characterization of the structural properties of three-dimensional nano-objects such as nanocones and nanowires, at microscopic resolution [2–5].

Our samples consist of either metal nanocones or semiconductor nanowires. For sample characterization, we used a custom-built point-scanning NLO microscope powered by a femtosecond laser (wavelength 1060 nm, pulse duration 200 fs, repetition rate 82 MHz). Upon routine beam cleaning, we directed the excitation beam onto the sample using a strainfree microscope objective (numerical aperture 0.8). We collected the respective NLO signals in reflection and/or transmission using photomultiplier tubes equipped with appropriate dichroic and optical filters. To generate azimuthal or radial polarizations, we used a polarization mode converter (ARCoptix).

We found that the introduction of azimuthal and radial polarizations in second- and third-harmonic generation microscopy allows us to directly determine the orientation and anisotropy of individual nanocones and nanowires. In essence, any deviation of the image pattern can be correlated with subtle structural features of the nano-objects.

Beam Bistability in Nematic Soft Matter

A. Piccardi[1], **A. Alberucci**[1,2], **N. Kravets**[1], **O. Buchnev**[3], **M. Kaczmarek**[3], **and G. Assanto**[1,2]

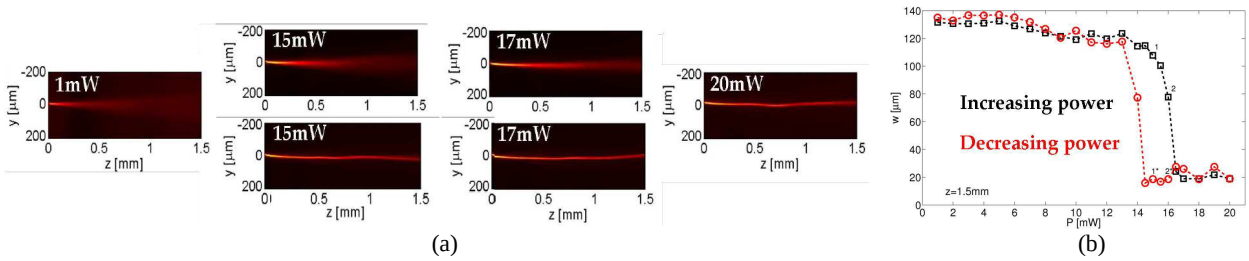
Abstract— We investigate optical bistability with diffracting and self-trapped beams in nematic liquid crystals. We demonstrate the coexistence of dispersive and solitary beams in an interval of $\approx 2\,\mathrm{mW}$. Bistability stems from the reorientational response in the presence of a threshold.

Optical bistability is a classic topic in nonlinear optics [1]. Two key ingredients for bistability are a nonlinear response and a feedback mechanism. Nematic liquid crystals (NLC) are birefringent dielectrics featuring a large reorientational nonlinearity, the latter based on molecule rotation in the presence of electric fields [2]. When launching a bell-shaped (extraordinary polarized) light beam, the molecular (angular) distribution becomes inhomogeneous: The beam itself defines a transverse gradient of the refractive index, leading to self-focusing at high enough powers [3]. When the molecules at rest are perpendicular to the beam electric field, this reorientation undergoes the so-called optical Freedericksz threshold (OFT), with threshold power depending on the beam width. Thus self-focusing, altering the beam size, changes the OFT threshold and can leads to a hysteretic behavior versus input beam power. Starting from a diffracting beam and increasing the excitation, above the OFT nonlinear reorientation takes place until a self-confined beam — a nematicon — is formed. Such self-localization in turn lowers the OFT below the initial value, so that when reducing the power the spatial soliton is supported at powers smaller than initially required for its formation.



(a) (b)

Figure 1: (a) Acquired images of beam propagation for increasing (top, left to right) and decreasing (bottom, right to left) power. (b) Beam width vs power along a cycle. Hysteresis is observed between 15 and 17 mW.

We launched a $2\,\mu\mathrm{m}$ wide beam at $\lambda = 1064\,\mathrm{nm}$, with linear polarization perpendicular to the NLC optic axis, thus enabling the OFT. At low power the beam diffractes as reorientation did not occur. Self-confinement was observed from $P = 17\,\mathrm{mW}$, leading to a solitary wave. When power was then diminished, the nematicon was maintained down to $P = 15\,\mathrm{mW}$: The system exhibited a hysteresis loop about 2 mW wide, with the two stable states associated to dispersive and localized wavepackets, respectively [4]. The observed bistable behavior stems from the inherent feedback provided by the reorientational nonlinearity between the beam profile and the self-focusing threshold, in agreement with Kaplan's recipe [5] despite the observation of only one soliton state.

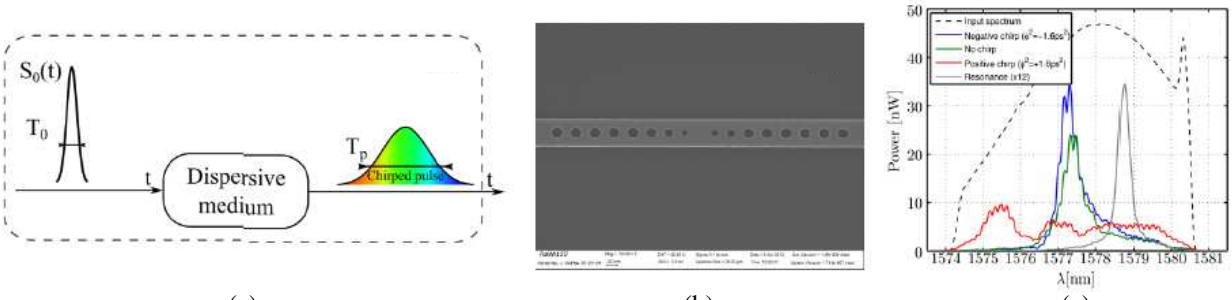
Abstract— The strong light confinement achieved in photonic crystal microcavities allows the enhancement of light-matter interactions and the reduction of the energy required to control nonlinear optical devices, like for instance low energy optical switches operating under the control of a resonant pulse. Although nonlinear refractive effects assist the switching operation, the imparted frequency shift dynamics of the cavity resonance tends to limit the coupling efficiency of the control pulse. As a result, the cavity enhancement effect is not maintained for the entire pulse duration, even if the latter is longer than the cavity photon lifetime.

To overcome this problem, a technique inspired by the coherent control of molecular and atomic systems [1] has been implemented to enhance the nonlinear behaviour of silicon-based optical resonators. In a silicon cavity, the optical resonance mainly experiences a frequency blue-shift driven by the refractive index variation induced by the free carriers generated by two-photon absorption (TPA). By delaying the blue spectral components, under a tailored linearly chirped pulse, we show that the benefit of light localization can be maintained throughout the pulsed excitation despite the cavity resonance dynamic frequency shift. This approach has only been theoretically investigated [2–4].

The fabricated cavity whose the SEM picture is presented in Fig. 1(b) has a mode volume of $0.8(\lambda/n)^3$. It exhibits a linear transmission spectrum, shown in Fig. 1(c) (grey line $\times 12$), with a narrow peak at 1578.8 nm. The measured linewidth of 0.3 nm corresponds to a quality factor $Q = 5260$ and a cavity photon lifetime equal to 4.4 ps. Optical pulses delivered by a mode-locked Erbium doped fibre laser are sent through a grating based pulse stretcher, which delimitates the spectral linewidth to 6.5 nm (spectrum shown by the black dashed-line in Fig. 1(c)) and introduces an adjustable 2nd order dispersion coefficient $\phi^{(2)}$. For $\phi^{(2)} = 0\,\mathrm{ps}^2$, the measured auto-correlation pulse duration is 2 ps.

The transmission spectra achieved with two opposite chirps + and $-1.6\,\mathrm{ps}^2$, both coinciding to a pulse duration (5.7 ps) longer than the cavity photon lifetime are shown in Fig. 1(c). Compared with the $-1.6\,\mathrm{ps}^2$ chirped pulses (green curve), the transmission spectrum for $\phi^{(2)} = +1.6\,\mathrm{ps}^2$ (red curve) leads to a broader transmitted spectrum, which almost matches the input pulse bandwidth. The increase by a factor 2 of the blue shift, achieved with the red curve of Fig. 1(c), means that TPA generated carrier density is twice higher and proves an enhanced nonlinear interaction in the silicon material thanks to the coherent excitation of the cavity. A coupled mode theory model that includes all the silicon nonlinearities has been implemented and the results are in good agreement with the experimental results.



(a) (b) (c)

Integrating Single Photon Sources and High-efficiency, Low Dark Count Single Photon Detectors Using Photonic Crystal Microcavities in Silicon-on-insulator Waveguides

Ellen N. Schelew, **Mohsen K. Akhlaghi**, **and Jeff F. Young**
Department of Physics and Astronomy, University of British Columbia, Vancouver V6T 1Z1, Canada

Abstract— Scalable photonic quantum technologies are sought after for applications in quantum communication, computing and sensing. One promising approach involves integrating key components, including single photon sources, single photon detectors, and conventional optical components like beamsplitters and filters, in planar lightwave circuits. Silicon-on-insulator (SOI) is an attractive host-material, as it benefits from ongoing advances in classical integrated silicon photonic technologies. Recent progress has been made towards realizing both single photon sources and detectors for wavelengths near 1550 nm. We describe a photon pair source integrated with a superconducting nanowire single photon detector, to form a heralded single photon source in SOI. The photon pairs are generated through a third order nonlinear process — Spontaneous Four-Wave Mixing (SFWM) — in a planar two-dimensional photonic crystal (2D PC) triple-cavity system engineered to resonantly enhance the nonlinear interaction, and strategically filter generated photons into a single output waveguide. This design improves on previously reported 'photonic molecule' designs by taking advantage of the high Q modes, and flexible waveguide and cavity coupling schemes, supported by 2D PCs. We also report on our novel approach to single photon detection in SOI which employs a superconducting nanowire lying on the surface of a 1D PC nanobeam cavity designed for coherent perfect absorption (CPA) of photons. While many competing designs require a large volume of superconducting material to achieve high-efficiency absorption, in the CPA implementation, a short (8.5 μm long) and narrow ($8 \times 35\,\mathrm{nm}^2$) nanowire achieves near unity quantum efficiency, together with a low dark count rate (< 0.1 Hz) and favorable speed and timing accuracy at 2 K.

First-principle Models of Light-matter Interactions for Large-scale Computer Simulations in Extreme Nonlinear Optics

M. Kolesik[1, 2]

[1]College of Optical Sciences, The University of Arizona, Tucson, USA
[2]Arizona Center for Mathematical Sciences, University of Arizona, Tucson, USA

Abstract— Computer simulations in modern nonlinear optics need to has to address two basic issues. The first is a transformation of the Maxwell equations into a one-way pulse propagation system. The second issue is the implementation of a light-mater interaction model that is based on first principles, and is sufficiently effective computationally to allow realistic simulations. White the first issue has been successfully addressed in the form of pulse-propagation equations, the second is still a subject of intense research work. I will describe a novel approach to nonlinear medium modeling that is based on metastable electronic quantum states. Rather than the stationary quantum states, i.e., eigen-states of the given Hamiltonian, the meta-stable electronic states provide a most natural tool to describe the dynamics in strong optical fields. They possess the properties of both bound and continuum-energy wavefunctions, and exhibit non-perturbative response to the driving optical field. As such they allow to construct an extremely economic implementation of a nonlinear medium model; I will demonstrate that even the lowest-order approximation can provide semi-quantitative results. The rest of this talk will briefly discuss the mathematical aspects of the method, describe numerical methods to obtain necessary characteristics of the metastable quantum states, and demonstrate that the framework makes it possible to perform large-scale simulations of the coupled Maxwell-Schrödinger system. The method is most suitable for high-intensity nonlinear optics which often deals with regimes in which both bound and free electronic states contribute to the medium response.

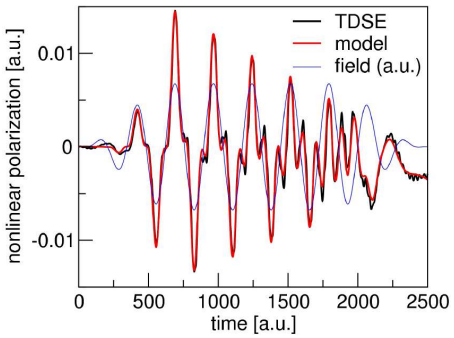

Figure 1: Illustration of the metastable electronic state approach for calculation of the nonlinear polarization and ionization induced by a strong optical pulse (arbitrarily scaled electric field is shown as the blue line). The black line shows the numerically exact solution obtained from the time-domain simulation of the Schrödinger equation. The red line represents the result obtained with the new method: It shows the nonlinear response, i.e., the atom dipole moment, obtained from a single resonance state, combined with the current induced by ionized electrons. In this example, the atom response is initially dominated by the self-focusing (optical Kerr) effect, while at later times, de-focusing effects of freed electrons prevail. Similarly accurate results are obtained across a wide range of regimes.

Instabilites and Rogue Waves in Optics

G. Genty
Optics Laboratory, Tampere University of Technology, Tampere FI-33101, Finland

Abstract— The emergence of high amplitude events that occur with low probability has been observed in many physical systems. Ocean rogue waves that emerge unexpectedly from the sea with massive destructive power is the most striking example of extreme events. Recently, the observation of extreme events in optical systems has attracted significant attention with the possibility, for the first time, to study in real time the dynamics of extreme-value phenomena. More specifically, a wide range of studies have shown how extreme spatio-temporal localization of light waves can occur in various optical systems including the nonlinear growth of a weak perturbation present on top of a plane wave or the generation of short pulses in laser cavities. Common features to many (although not all) of the systems where extreme localization has been observed in optics is the presence of noise and nonlinearity in the system. In this context, the nonlinear Schrodinger equation (NLS) describing nonlinear waves localization dynamics in weakly nonlinear media plays a particular role and it has been extensively studied in various contexts in nonlinear science [1, 2]. A particular class of solutions of the NLS that possess extreme localization characteristics are the solitons on finite background which have been proposed as a possible mechanism underlying the formation of extreme amplitude waves on the surface of the ocean [3, 4]. In an optical context, these structures have been shown to emerge spontaneously in noise-seeded modulation instability and play a central role in the observation of extreme events in optical fibers.

Here, we review the recent progress on extreme events in optics with particular emphasis on optical fiber systems. Experiments and modelling of localization dynamics are constantly providing new insights into how noise drives the dynamics of nonlinear optical systems. As research continues to progress in this field, it is likely that the noise properties in a wide range of optical systems may find analogies with areas of physics other than oceanography, allowing the use of a convenient optical testbed with which to study a wide range of different physical processes.

Abstract— Tight rocks may provide most of the world's future fossil energy. New production methods that allow hydrocarbons to be produced directly from tight source rocks such as shale gas and shale oil systems have changed the world's energy outlook. We are now at a stage where the technology for recovery of gas by CO_2 injection has advanced beyond our scientific understanding of the underlying processes. Much fundamental research focuses on molecular physisorption/chemisorption and meso-scale transport processes in nanostructured shales. The aim of such research is to understand carbon dioxide (CO_2)-methane (CH_4) conversion processes and trends of adsorption of CO_2 in model porous media and hydrofractured shale [1]. Standard simulation parameters on modeling near interfaces are based on intermolecular forces in bulk media. Using the formalism of Sambale et al. [2], we demonstrate that the attractive part of the Lennard-Jones parameters of intermolecular interaction in bulk media, i.e., the van der Waals parameter C_6 ($U_{vdW} = -C_6/\rho^6$) where ρ is the distance between the two molecules, is strongly modified by the presence of surfaces. We explore the retarded van der Waals interaction of two CO_2 molecules near an amorphous SiO_2-water interface and near a vapor-water interface. Different models for effective polarizabilities in water [3] and the corresponding dispersion forces between dissolved molecules are explored in bulk water and near interfaces. The interaction energy depends on the surface material, polarizability model of the molecule used and the relative orientation of the molecules near the interface, and shows considerable deviation from intermolecular interaction in the absence of surfaces. The dielectric properties of amorphous SiO_2 are computed using density functional theory (DFT) and Born-Oppenheimer molecular dynamics (BOMD).

The C-method as an Initial Value Problem: Application to Multilayer Gratings

Cihui Pan[1, 2, 3], **Richard Dusséaux**[1], **and Nahid Emad**[2, 3]

[1]Laboratoire LATMOS, 11 Boulevard d'Alembert, Guyancourt 78280, France

[3]Laboratoire Maison de la Simulation, Bâtiment 565, Gif-sur-Yvette Cedex 91191, France

Abstract— We study our approach of the C-method [1, 2] as an initial value problem for the efficient calculation of the N-dimensional scattering matrix of a grating. We apply this method to multilayer gratings with an arbitrary number of interfaces. The interfaces can have different functional form and amplitude and can be parallel or not.

For each interface separating two homogeneous media, we consider two horizontal planes above and below the interface, and define a coordinate system such that the interface and both horizontal planes correspond to coordinate surfaces. Inside the area delimited by the two horizontal planes, the Maxwell's equations lead to an initial value problem which can be solved with initial conditions satisfying the boundary conditions. Outside this area, the fields are represented by Rayleigh expansion. The scattering matrix between two consecutive media is obtained by using continuity relations between different components of fields on the horizontal planes [3].

We consider a $n+1$ layer diffraction grating, thus there are n interfaces separating the layers. From the uppermost to downmost, these layers are composed of medium 1 to medium $n+1$. Each medium has a constant optical index. Thus we can calculate the scattering matrix $S_{1,2}$ which associate the incoming and outcoming waves from medium 1 and 2. Then we collect all the scattering matrix of adjacent medium, $S_{i,i+1}, i = 1, \ldots, n$ and obtain the global matrix $S_{1,n+1}$ by combination of elementary matrices $S_{i,i+1}, i = 1, \ldots, n$.

The proposed method gives the efficiencies with a good accuracy. Experiments are performed on a three layer grating with interfaces described by Trigonometric functions. We also study the anomalies of coated dielectric gratings [4].

Efficient Numerical Solution for Time-domain Volume Integral Equations

J. Zhang and M. S. Tong
Department of Electronic Science and Technology
Tongji University, 4800 Cao'an Road, Shanghai 201804, China

Abstract— Integral equation approach is widely used for solving electromagnetic (EM) problems. For inhomogeneous penetrable structures, the volume integral equations (VIEs) are indispensable, and furthermore the time-domain version (TDVIEs) should be applied when a transient interaction with the structures exists. The TDVIEs are usually solved by combining the method of moments (MoM) with a well-designed basis function like the Schaubert-Wilton-Glisson (SWG) basis function in spatial domain and a march-on-in-time (MOT) scheme in temporal domain. The MoM requires conforming meshes in geometric discretization and also needs to perform two-fold integrations in evaluating matrix elements, resulting in certain inconvenience. On the other hand, the MOT has a well-known stability problem which has not been fully solved yet although various improvements were proposed.

In this work, we propose a different scheme to solve the TDVIEs for transient EM problems with penetrable objects. Unlike the conventional approach, the Nyström method is used in the spatial domain while the MoM with Laguerre basis and testing functions is employed in the temporal domain. The Nyström method uses a point-matching procedure to discretize integral equations and does not use any basis and testing functions so that the implementation can be simplified. Also, the method does not require conforming meshes and can endure low-quality meshes, leading to much convenience in geometric discretization. In temporal domain, the expansion of Laguerre basis function can naturally enforce the causality and also the Galerkin's testing procedure can fully solve the numerical stability problem in a march-on-in-degree (MOD) manner, so it is very suitable to solve transient problems. Numerical examples for transient EM scattering by a dielectric cube are presented and the merits of proposed approach has been demonstrated.

Analysis of EM Emission Characteristics by Arbitrarily Oriented Microstrip Lines Based on TEM Cell Electric and Magnetic Coupling Fields

Jung-Yeol Park[1], **Jin-A. Choi**[1], **Jae-Kyung Wee**[1], **In-Chae Song**[1], **Boo-Gyoun Kim**[1], **Hyok Lee**[2], **and Seung-Real Ryu**[2]

Abstract— In this paper, we analyze the electromagnetic (EM) emission characteristics of the arbitrarily oriented microstrip lines and PCB board makes it possible to predict the radiation characteristics by using a library of normalized line modeling. Figure 1(a) shows the test environment on various microstrip lines which are prepared to consider with thickness, length and current direction. The measurement method based on a transverse electromagnetic (TEM) cell rotates DUT. The test results by using a vector network analyzer (VNA) is different from that of direction DUT. The coupling factor by the direction of the DUT are all affected by the electric field. But the magnetic field is affected in different ways between TEM cell and DUT. In the Figure 1(b), when the DUT direction of a 180 degree (far end), the magnetic field is cancelled between DUT and Septum of TEM cell. And when the DUT direction 90, 270 degree magnetic fields are same results because magnetic fields are that it does not affect.

The method of lines (MoL) is used to calculate the capacitance matrix with the measured S_{12} of microstrip lines. Some simulations such as HFSS and ADS are carried out in order to improve the accuracies of extracting capacitances and inductances. For accurate coupling factors, the measured and simulated E and H powers on TEM cell as shown in Figure 1(b) are used for coupling capacitance and an inductance. A library based on the well-proven line parameters is established for evaluating a real PCB EMC including the accurate coupling factor models. In addition, the prepared library will be applied to evaluate its accuracy where the simulated EMIs will be compared with measurements of their EMIs predicted from those generated from line patterns on the tested PCB board as shown in Figure 1(c).

Algebraic Function Approximation for Eigenvalue Problem in Rectangular Waveguide Partially Filled with Transversely Magnetized Ferrite

Oguzhan Demiryurek[1] and Namık Yener[2]

[1]Technical Education Faculty, Kocaeli University, Izmit, Kocaeli 41380, Turkey
[2]Technology Faculty, Kocaeli University, Izmit, Kocaeli 41380, Turkey

Abstract— In this work, a lossless and closed rectangular waveguide partially filled with a slab of transversely magnetized ferrite without assuming vanishing of the derivative in the direction of the dc biasing field, has been analyzed using Method of Moment (MoM). Generally, there are basically three types of modes in the waveguide: propagating, evanescent and complex modes. To support evanescent mode, the waveguide must be bidirectional. But a rectangular waveguide filled with a slab of ferrite transversely magnetized is not bidirectional, if there exists no symmetry with respect to the rotation by π about an axis perpendicular to propagation direction. So such a waveguide does not support the evanescent waves. Propagation constant is complex or pure imaginary. Our waveguide is filled with a transversely magnetized gyrotropic medium and does not satisfy the condition of symmetry with respect to the rotation by π about an axis perpendicular to propagation direction. So it is not bidirectional and hence does not support evanescent modes. Results of the MoM are consistent with this situation. In a lossless and closed rectangular waveguide partially filled with a slab of transversely magnetized ferrite Maxwell's equations, consisting of partial differential equations, are transformed into an infinite linear algebraic equation system by application of the Galerkin version of Moment method. As the result of algebraic operations, from the transmission line equations a quadratic eigenvalue problem is obtained whose eigenvalue corresponds to the propagation constant. The determinant of the coefficient matrix of the quadratic eigenvalue problem is a monic polynomial of the propagation constant whose coefficients are rational functions of the complex frequency. If the polynomial is set equal to zero and is multiplied by the common denominator of the coefficients, an algebraic equation is obtained. The roots of this equation are the propagation constants. In this work as the contribution, using algebraic function theory the solution of the algebraic equation (propagation constant) for the waveguide filled with transversely magnetized ferrite medium, is expressed by means of a Puiseux series in the neighborhood of the algebraic branch point. Puiseux series coefficients are solved using transmission line equations and the propagation constant is computed from this series expansion. Puiseux series results are compared and found to conform with MoM results and the exact solution.

The Transmittance of Electromagnetic Waves and Field Correlations in Multilayered Microspheres with Quasi-periodic Structures

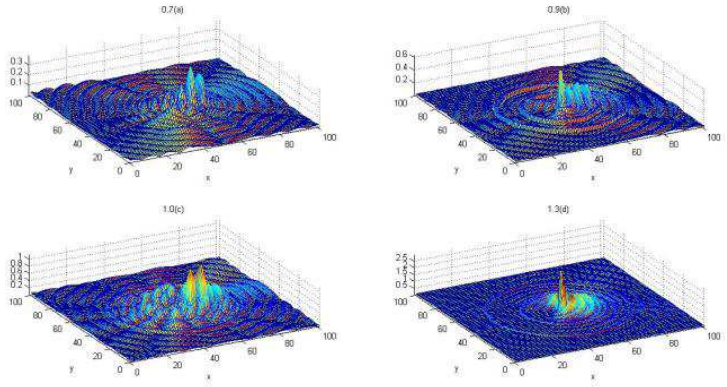
M. Nájera-Villeda and G. Burlak
Centro de Investigación en Ingeniería y Ciencias Aplicadas
Universidad Autónoma del Estado de Morelos, Cuernavaca, Mor., México

Abstract— The dielectric spheres have a complex spectrum of electromagnetic eigenoscillations with low Q-quality factor because of the power leakage in outer space. The case of the compound structure: the dielectric sphere coated by an alternative stack, is richer. The Q-factor of such oscillations strongly depends on the properties of the stack. It has a large value in the frequency regions of high reflectivity, and beyond these regions Q remains small. The combination of factors makes a variety of optical properties of microspheres with a multilayer stack. Particularly, a system of this type can serve as a symmetrical spherical photonic band gap structure (PGC), which has strong selection transmittance properties, and can arrange photon emitting nanoscale.

Researched the transfer matrix approach and the Green function technique we numerically study the electromagnetic properties (narrow peak positions) of the transmission spectra for microspheres coated by a multilayered stack with the generalized Cantor and Pascal structure (fractal). Quasi-periodic design structures allow obtaining the photonic band gaps in the field radiation. The location of light in disordered systems offers range of applications in optoelectronic applications.

In a microsphere, only narrow resonance spectrum (eigenfrequencies) peaks can be observed in the frequency spectrum of radiation. We show that the wave phase interference in such a fractal pattern leads to formation of very narrow electromagnetic transmittance resonances that can be used in modern optoelectronics.

It is of great interest investigate how a stack is modified with a quasi-periodic spherical structure, the working frequency spectrum numerically in sequence Pascal and Cantor set in a microsphere SI and SiO_2 multilayer. To do that we explore the transmission spectra and frequency resonances of such structures deposited on surface of a dielectric microsphere. Besides we calculate the structure of the field correlations in such a multilayered microsphere with incorporated nanoemitters. It is well-known that due to the fluctuation-dissipation theorem the correlation function of the photon states in the absorbing environment for temperature T and frequency ω can be written with the help of the macroscopic Green function (GF) as follows $\langle \mathbf{E}(r)\mathbf{E}(r')\rangle_\omega = \frac{\hbar\omega^2}{c^2}\coth(\frac{\hbar\omega}{2T})\mathrm{Im}(\mathbf{G}(r, r', \omega))$. For our purposes it is sufficient to give more attention to the imaginary part of GF to study a specific interaction between the field resonances in points r and r'. Figure below displays the results of such simulation of $\mathrm{Im}(G)$ in the radial section of a coated microsphere.



Such study allows using the multilayered microsphere to effective management of the photon properties in modern informational industry.

Evaluation of Power Transistors Figure of Merit for Hard Switching Commutation Mode through Experimental Analysis

Michal Frivaldsky, **Pavol Spanik**, **Boris Kozacek**, **and Marek Piri**
Faculty of Electrical Engineering, Department of Mechatronics and Electronics
University of Zilina, Univerzitna 1, Zilina 010 26, Slovak Republic

Abstract— Nowadays demand for efficiency and high density of electronic device is high. Therefore, great emphasis is placed on the properties of electronic components such as diodes, transistors, transformers and more. Hence the scientific discipline was created Figure of Merit (FOM) which is dealing with this issue.

The proposed article will deal about the analysis of FOM of several power MOSFETs, whereby main parameters are taken into consideration for calculation purposes. In order to verify faithfulness of FOM, the parametrical simulation analysis of hard-switching commutation mode for given parameters of target application (front-end converters) will be done. Consequently, experimental measurements for determination of switching as well as conduction losses of selected transistors will be performed. The aim of simulation and experimental analysis of commutation process shall be confirmation of the accuracy of simulation models due to fact that simulation analysis can be very useful during investigation of set of suitable transistors for improvement of the qualitative indicators (rapid prototyping) of switched mode power supplies (efficiency, power density, hold-up time etc.. . .).

Almost simulation analysis represents time-consuming process for evaluation of transistor switching performance. Therefore various FOM methodologies will be described taking into account main parameters for the FOM evaluation (transistor parasites, gate charge, switching frequency, parameters of target application, e.g., voltage — current ratings). Comparisons between the amount of transistor's losses and its FOM indicator will be provided.

FoM Evaluation for Power MOSFET Transistors: The development of switching power supply significantly moved forward. Requested parameters of switched mode power supplies (SMPS) are reduction of the size and reduction of power losses (increase of efficiency). In this article we decided to analyze several methods of FOM for the power MOSFET transistors. These methods are:

- Switching FOM
- Conduction FOM
- Detailed FOM
- Johnson FOM

Selected transistors for FOM evaluation as well as for simulation and experimental analysis of hard-switching commutation mode are CoolMOS IPW60R165CP, CoolMOS, SPP20N60C3 and MOSFET IRF840. The last mentioned device represents older technology of MOSFET transistors, whereby CoolMOS transistors exhibits currently best in class performance for power applications (for example solar inverters, renewable energy, telecom/servers, front-end converters etc.. . .).

The simulation and experimental analysis as well as FOM evaluation will be made parametrically, i.e., in dependency on the parameters that are influencing hard-switching commutation mode in the most manners (switching frequency, load current).

Poster Session 3

A Hybrid Trefftz Finite Element Analysis of Eigen-modes Propagating in a Holey Fiber

Yoshihito Morita, Shingo Sato, and Koji Hasegawa
Muroran Institure of Technology, Japan

Abstract— Hybrid Trefftz finite element method (HTFEM) is developed for a fast eigen-mode solver of electromagnetic waveguides with symmetric cross-sections such as photonic crystal fibers and micro-structured optical fibers. HTFEM divides the cross-sections of waveguides into Trefftz finite elements (TFEs) whose interpolation functions are fundamental solutions of vector wave equations of electric fields in infinite spaces and conventional vector finite elements (VFEs) with polynomial interpolation functions. Numerical dispersion of TFEs, therefore, is expected lower than VFE dispersion in the same element size. But complex element shape of TFEs requires more computational cost than simple element shape, HTFEs are suitable for modeling homogeneous disc and complementary disk parts of the waveguide cross-sections such as the fiber cores and jackets of holey fibers, and the remaining ring parts which include holes of the holey fibers should be divided by VFEs.

We had demonstrated advantages of HTFEM over conventional FE method with VFEs and perfect matched layers by analysis of holey fibers with six air holes: (1) HTFEM computation time of the whole cross-section of the holey fiber is shorter than the conventional FE analysis of a quarter of the cross-section at the same accuracy of the propagation constant, (2) HTFEM can analyze a quarter of the cross-section of the holey fiber under symmetric or asymmetric electric field conditions on the symmetric boundaries, and HTFEM can compute the eigen-modes faster and more accurately than the conventional FE method under the same number of total unknowns. When we compute specified eigen-modes, analysis of the whole cross-section or a quarter of the cross-section gives the propagation constants of the required eigen-modes and other eigen-modes that we should discard by inspecting the symmetry of electric field distributions.

To compute only specified eigen-modes, in this paper, we presented an HTFEM with electric field distributions restricted to the specified symmetry. We confirmed the validity of the modified HTFEs from the numerical results of a holey fiber with six air holes. The method ensures to compute only specified eigen-modes and needs no distinction by the distribution of the electric fields.

Using Microwave Radiation for Porcelain Tableware Sintering

T. Santos[1, 4], **L. Hennetier**[2], **V. A. F. Costa**[3], **and L. C. Costa**[1]

[1]Department of Physics and I3N, University of Aveiro, Aveiro 3810-193, Portugal
[2]Technological Center for Ceramic and Glass Industries, Coimbra 3025-307, Portugal
[3]Department of Mechanical Engineering, University of Aveiro, Aveiro 3810-193, Portugal
[4]CICECO, University of Aveiro, Aveiro 3810-193, Portugal

Abstract— This work presents an improved microwave multimode cavity developed for the sintering of porcelain tableware. It includes 6 magnetrons operating at 1 kW with a nominal frequency of 2.45 GHz. The way as the electromagnetic field propagates and is absorbed by the materials is very important for the control of the heating process. For a better understanding of the process, the distribution of the electromagnetic field inside the cavity was calculated using COMSOL Multiphysics software, with different magnetron configurations and sample positions. The improved automated control system comprises the usage of a pyrometer that allows the analyses of the thermal delay between the temperature given by a thermocouple and the real temperature in the material. The tip of the thermocouple lies fairly close to the material sample, approximately 1 cm from its surface, and for the maximum temperature its reading is nearly 35°C lower than the temperature measured by the pyrometer. Although this difference is not very high, it is significant to produce the bloating phenomenon. The best porcelain characteristics were achieved for sintering temperatures around 1355°C, in accordance with the industrial practice effective porcelain temperature. We exclude the existence of the so-called non-thermal microwave effect in the microwave porcelain tableware sintering.

The pyrometer was been calibrated with the thermocouple used in the experiments to guarantee the correct measurements. The calibration was been made in a conventional electric oven. Some physical properties such as the rupture energy, impact resistance and porosity of the obtained porcelain have been measured and compared with those of similar porcelain pieces obtained by conventional methods. The improved microwave oven allows a better temperature measurement, with a faster sintering (and thus higher production rates) with the same quality standards than the conventional sintered porcelain.

Design of Complex Metal-dielectric Diffraction Gratings

Alexander Lerer[1], **Stepan Vyhlidka**[2, 3], **Galina Kalinchenko**[2], **Daniel Kramer**[2], **and Bedrich Rus**[2]

[1]Physics Department of Southern Federal University

[3]Faculty of Mathematics and Physics, Charles University, Ke Karlovu 3, Prague 2, 121 16, Czech Republic

Abstract— Mathematical and computational methods in electromagnetic theory have been attracting an increasing attention of scientific community because of recent progress in integrated photonics, metamaterials and laser optics. Better understanding of light diffraction and propagation ensures effective design of nanoscale structures. To proof a design accuracy, the same object needs to be simulated by different methods.

The majority of mathematical methods for calculation of electromagnetic fields can be split in two groups. The first group — the methods based on direct solution of wave equations with defined boundary conditions — includes finite-difference time-domain, the finite element method, and the finite integration technique. In the second group of methods, the boundary problem is reduced to the solution of integrals, the integral-differential, pairs of integrals, and pairs of sum equations. The advantage of the first group of methods is their versatility. Their disadvantages are high requirements for a computer processing power, long calculation time, the need to digitize not only the scattering object, but also the space around the scatterer, and difficulties with simulations of small-scale elements. In addition, there is a problem with satisfaction of boundary conditions for radiation to open space. For the second group of methods these problems do not exist. The choice of the integral equation (IE) type is defined by the structure of the object under investigation. Therefore, the methods based on the IE solution are not as universal as the methods in the first group, but computer programs based on them work several orders of magnitude faster. Here we compare the results obtained by commercial numerical software and self-developed analytical method.

A Volume Integral Equation (VIE) Method was developed to simulate optical wave diffraction on metal-dielectric one and two dimensional diffraction gratings based on flat multilayered structures with regular inhomogeneity in each layer. Exact solution of the equation is obtained with the Galerkin method, taking into account the complex dielectric permittivity of metals and semiconductors in optical range. The Method is applicable for s and p polarized waves.

As examples of photonic crystals we simulated sieve-looking diffraction grating placed on multilayer dielectric substrate and metal forest-looking grating placed on multilayer dielectric substrate. Dispersion characteristics with windows of opacity are found out. The results are compared to the simulations done by commercial numerical software Ansoft HFSS. Also VIE Method was applied for a design of broad-band multilayer reflective diffraction gratings for compression of high-energy ultra-short laser pulses Tolerances for groove depth and angle of incidence are estimated, optimal duty-cycle parameters are found out. Electric field distribution inside of the gratings is also numerically studied. The results were compared to the simulations by numerical Fourier Modal Method in LightTrans Virtual Lab. The methods show excellent agreement.

Comparative Study of Different Dielectric Function Fitting Model for Gold, Silver, Copper, Aluminum in Visible Bandwidth by Using PSO

Dong Liu[1, 2] and Krzysztof A. Michalski[2]

[1]School of Electrical Engineering
Southwest Jiaotong University, Chengdu 610031, China
[2]Departmentof Electrical and Computer Engineering
Texas A&M University, College station, TX 77840, USA

Abstract— FDTD is one of the most common choice used in optical device simulation. In FDTD, the dielectric value of dispersive material in a continuous frequency range must be known. Because the dielectric value are measured by experiment at discrete frequency, we need to use dielectric function fitting to find an expansion to fit the tabulated dielectric constant in a wide frequency range. There are several dielectric model widely used in FDTD method, such as Debye, Drude, Lorentz, Complex-conjugate pole-residue pair, Citical points, Rational-Fraction and Partial-Fraction models. In these models, the parameters corresponding to different material are different and unknown, so we need to use a certain method to find the suitable parameters for each material. In fact, the process of finding the suitable model parameters for selected material can be seem as a optimization problem, so the optimization algorithms is naturally used. Many local and global optimization algorithms are adopt in dielectric function fitting, such as Nelder-Mean algorithm (NM), Levenberg-Marquardt algorithm (LM), Simulated Annealing algorithm (SA), Genetic Algorithm (GA), Particle Swarm Optimization (PSO), etc.. In our work, we use PSO to optimize the parameters of different dielectric model for several common materials, such as gold, silver, copper and aluminum. The frequency range of model fitting is the visible bandwidth. The accuracy of different model with different orders on different materials are compared, and the computational time costs are also compared. For optimization algorithms, the fitness function is very important. There are several fitness functions used in dielectric function fitting and the different fitness may get different parameters with different accuracy. In this paper, we also discussed the different fitness function used by optimization algorithms and recommended a appropriate fitness function for all selected materials.

In Re Electric Switching Sense of Microwave Magnetic Field Rotation near Varactor-loaded Dipole Excited by a Plane Wave

Valery Butylkin[1, 2], **Galina Kraftmakher**[1], **and Yuri Kazantsev**[1]

[1]Kotelnikov Institute of Radioengineering & Electronics RAS, Moscow, Russia
[2]Moscow Institute of Physics & Technology, State University, Dolgoprudnyi, Russia

Abstract— It is theoretically investigated movement of the microwave magnetic field near dipole, which is excited by a plane electromagnetic wave. The total magnetic field $\vec{H}$ being the superposition of incident and scattered fields of waves is under consideration. Until now a superposition of the incident and scattered fields near dipole has been not treated because, probably, dipoles were used generally as elements of antennas and the emphasis was radiant properties. But in recent years, there has been increasing interest in studies of metastructures on basis of resonant dipoles. As an example, one can point to nonreciprocal metamaterials, containing combination of ferrite and dipole elements [1]. These metamaterials are of interest for development of microwave devices such as filters, nonreciprocal isolators and circulators. In this case microwave nonreciprocity is due to different absorption of waves whose sense of rotation of magnetic field $\vec{H}$ coincides with sense of precession of the ferrite spins, and waves possessing the opposite sense of magnetic field rotation. That is why it is important to study properties of the microwave magnetic field in the neighborhood of the dipole. In this paper it has been shown that projections of the field $\vec{H}$ of electromagnetic wave near dipole satisfy canonical ellipse equation (in general case). This field rotates in one direction at frequencies above dipole resonance (DR) and in the opposite direction below the DR. Besides senses of rotation are opposite on opposite sides of the dipole (on the right or on the left of the dipole). Fig. 1 presents time-dependent normalized magnetic field $\vec{h}(t) = \vec{H}/H_{x0}^{inc} = \vec{e}_x h_x + \vec{e}_y h_y = \vec{e}_x \cos\omega t + \vec{e}_y g\cos(\omega t + \alpha)$. Here: $\vec{e}_j$ are the orts; $g = Z_0 l^2/4\pi Z a^2$; $\alpha = \tan^{-1}[(1-\omega^2/\omega_0^2)/\omega RC]$; Z and Z_0 are impedances of the equivalent oscillator simulating the dipole and of free space; capacity C, inductance L, and resistance R of the equivalent oscillator; $\omega_0 = (LC)^{-1/2}$ and ω are the dipole resonant frequency and the wave frequency; l and a are the dipole's length and distance between the dipole and ferrite. Parameters: $\alpha = \pi/4$, $g = 1$ and 0.5.

One can see that left-handed h-field takes place at frequencies $\omega > \omega_0$ while right-handed h-field corresponds to $\omega < \omega_0$. When dipole break is loaded with varactor one can change the capacity C by application of bias voltage to varactor. It results tuning the DR. Electrically tunable DR can provide controlled sense of rotating magnetic field and, in the end, switchable nonreciprocity in metastructures ferrite/varactor loaded dipole.

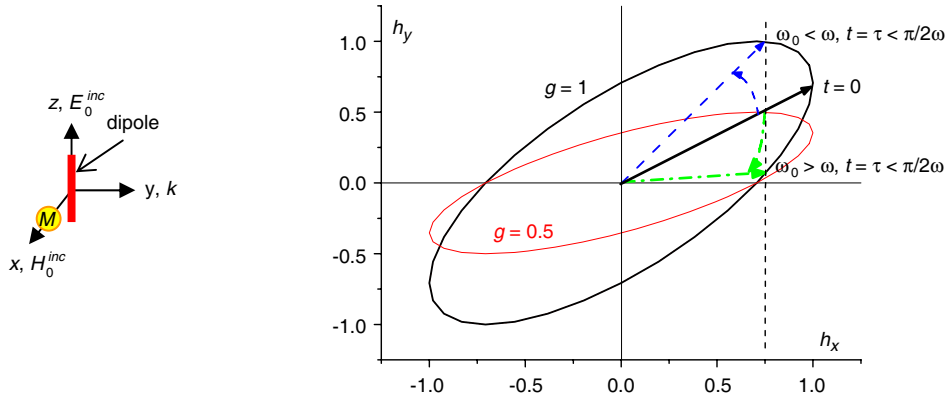

Figure 1: Disposition of dipole and ferrite with respect to incident wave and movement of normalized total microwave magnetic field h. M denotes point of location of ferrite, k, E_0^{inc}, H_0^{inc} are wave, electric and magnetic vectors of incident wave. Straight arrows depicts field h in instants of time $t = 0$ (black) and $t = \tau < \pi/2\omega$ (color). Bent arrows point sense of rotation of h. Blue lines correspond to $\omega_0 < \omega$. Green lines correspond to $\omega_0 > \omega$.

Analysis of EMG Waves from a Pulse Source

R. Kadlec, D. Nešpor, P. Fiala, and E. Gescheidtová
Department of Theoretical and Experimental Electrical Engineering
Brno University of Technology, Technická 3082/12, Brno 616 00, Czech Republic

Abstract— The authors report on an analysis of conditions on the boundary between layers having varied electromagnetic properties. The research is performed using consistent theoretical derivation of analytical formulas, and the underlying problem is considered also in view of multiple boundaries, including the effect of the propagation of electromagnetic waves exhibiting different instantaneous speed.

The paper includes a theoretical analysis and references to the generated algorithms. The main algorithm was assembled to enable simple evaluation of all components of the electromagnetic field in relation to the speed of the wave propagation in a heterogeneous environment. The proposed algorithms are compared by means of different numerical methods for the modelling of electromagnetic waves on the boundary between materials; moreover, electromagnetic field components in common points of the model are also subject to comparison.

The article describes the obstacles in comparison of different principles based analyses. Thus, analysis using numerical modelling performed via the wave equation in the ANSYS and the applied methods in the Matlab program.

When in conjunction with tools facilitating the analysis of material response to the source of a continuous signal, the algorithms constitute a supplementary instrument for the design of a layered material. Such design enables the realization of, for example, recoilless plane, recoilless transition between different types of environment, and filters for both optical and radio frequencies. This phenomenon occurs in metamaterials.

Propagation of Fluorescence Radiation through μ-capillary Holes of Glass Micro-channel Plate

Mikhail Mazuritskiy[1], **Alexander Lerer**[1], **Alexander Ezovtsov**[1], **and Galina Kalinchenko**[2]

[1]Physics Department, Southern Federal University, Zorge St. 5, Rostov-na-Donu 344090, Russia
[2]ELI Beamlines, Fyzikální ústav AV ČR, v.v.i. Na Slovance 2, 182 21 Praha 8, Czech Republic

Abstract— Propagation of X-rays through microcapillaries is of great interest due to the high efficiency of radiation transportation by holes of microcapillaries, and, as a consequence, due to the possibility for creation of new optical elements conditioning the X-ray beams. In addition to the high practical importance, capillary optical systems represent a fine tool for studying fundamental features of radiation dispersion by a surface.

Diffraction phenomena at the entrance of a hollow x-ray waveguide with real and imaginary parts of permittivity (absorption by dielectric cladding layers) are investigated using the model (approximation) of transmission layer on the surface of microchannels. It is shown that the wave penetrating through cladding material substantially modifies the wave field near the waveguide surface. It results in a significant increase of total energy flux inside guiding layer and leads to additional spatial modulation of the electromagnetic field.

In this work, the features of soft X-ray fluorescence spectra of radiation propagating inside microchannel plates have been analyzed in the framework of wave approximation. X-ray and fluorescence yield due to the grazing incidence reflection phenomenon have been investigated with respect to the geometry of channel walls. We discussed experimental spectra collected at the exit of microcapillaries under total x-ray reflection condition and supported them with theoretical calculations taking into account a surface transition layer at sample surface. Also, we have presented results on X-ray transmission through microcapillary structures, aimed at the Research & Development of dedicated optics working in "water window" spectral region (energy 100–600 eV). Have been studied spectroscopic features of **phenomenon of interaction of channeling radiation with unoccupied electronic states**. In the future it may allow to identify optimal transport conditions for the fluorescence radiation excited inside of microcapillary structures. The fluorescence transport conditions optimization is very important for improvement of X-ray focusing properties and, in principle, for delivery of high flux density on a sub-micrometer area of sample.

Diffraction by Arbitrary-angled Dielectric Wedges: Closed Form High-Frequency Solutions

M. Frongillo[1], **G. Gennarelli**[2], **and G. Riccio**[1]

[1]D.I.E.M., University of Salerno, Via Giovanni Paolo II 132, Fisciano (SA) 84084, Italy

Abstract— The canonical problem involving the electromagnetic field evaluation inside and outside an arbitrary-angled dielectric wedge illuminated by an incident plane wave is here addressed in the frequency domain. The use of numerical techniques represents a possible solution, but they become very expensive at high-frequency, where asymptotic methods based on ray-tracing are more efficient. Accordingly, it is valuable to have efficient solutions for the diffracted field able to compensate for the discontinuities at the Geometrical Optics (GO) boundaries related to the incident, reflected and transmitted fields in the observation regions. Uniform Asymptotic Physical Optics (UAPO) solutions were proposed in explicit closed form for evaluating the field diffracted by right-, obtuse- and acute-angled lossless dielectric wedges in the inner and outer regions [1–3]. They were able to compensate the GO discontinuities and resulted easy to handle since expressed in terms of the GO response of the structure and the transition function of the Uniform Theory of Diffraction (UTD) [4]. On the other hand, the use of a PO approximation implies inaccuracies when operating at grazing incidence and in correspondence of the dielectric interfaces.

Note that the diffraction problem concerning an acute-angled wedge was limited in [3] to a specific case of plane wave incidence.

This contribution is devoted to extend the previous analysis to all possible cases of plane wave incidence and to provide generalized UAPO solutions, which can be applied to the diffraction by a wedge with arbitrary apex angle. Such solutions include those proposed in [1–3] as particular cases and are obtained accounting for the equivalent electric and magnetic PO current densities on the internal and external faces of the wedge. Multiple internal reflections and external transmissions are considered for their explicit evaluation varying direction and polarization of the incident plane wave. Numerical tests confirm the effectiveness of the proposed UAPO solutions for the field diffracted in the dielectric wedge-shaped region and the surrounding free-space.

Analysis and Design of a Wideband Low Phase Noise LC VCO

Xuemei Lei, Jianxin Zhang, and Jing Shi
College of Electronic Information Engineering
Inner Mongolia University, Daxuexilu, Hohhot 010010, China

Abstract— In this paper, a LC voltage-controlled oscillator (LC-VCO) design optimization methodology based on switchable capacitor array is presented. The study of the compromises between phase noise and tuning range permits optimization of the design for given specifications. According to analytical phase noise models and tuning range, it allow to get a design space map where the design tradeoffs are easily identified. The proposed VCO is designed with the proposed methodology and implemented in SMIC's 0.18-µm RF CMOS technology and the chip area is 650 µm × 500 µm including the test buffer circuit and the pads. Simulation results show that its tuning range is 36.4%, from 4.5 to 6.5 GHz The simulating phase noise is −112.8 dBc/Hz at 1 MHz offset from the 6.5 GHz carrier. The maximum average power consumption of the core part is 6.47 mW at 1.8 V power supply.

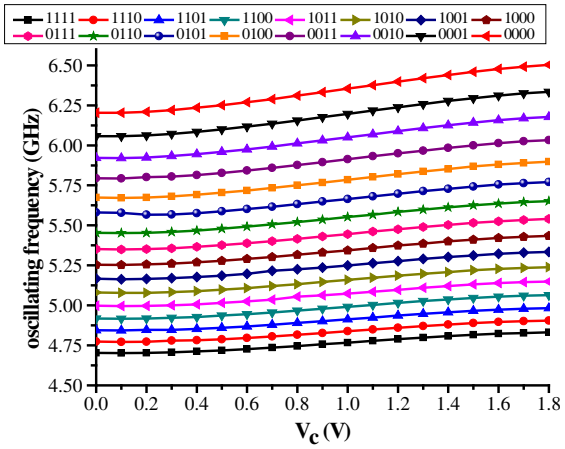

Figure 1: The simulated f-V curve of the proposed VCO.

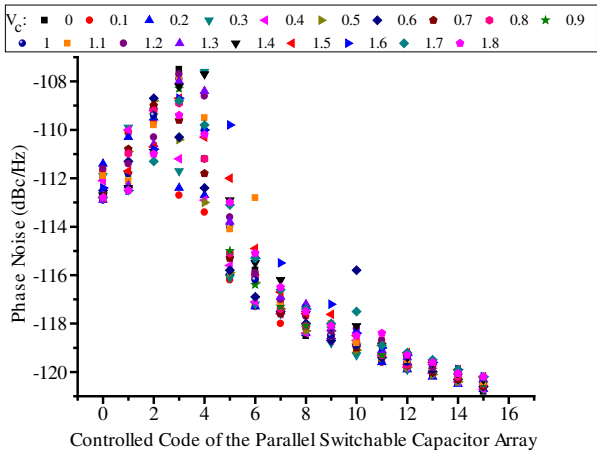

Figure 2: Simulated phase noise of the proposed VCO in different controlled code and different controlled voltage at 1 MHz offset.

Visualization of Electromagnetic Environment in Magnetic Confinement Fusion Test Facilities

Y. Kamimura[1], **S. Nakayama**[1], **and M. Tanaka**[2]

[1]Utsunomiya University, Japan
[2]National Instutute for Fusion Science, Japan

Abstract— The purpose of this study is to investigate the time varying (random and intermittent) properties of the leakage electromagnetic field that has specific broadband characteristics in the magnetic confinement fusion test facilities, and to establish worker's safety management method for particular leakage electromagnetic field (EMF) exposure. This study paid attention to the power supply room of coils and the surround of power amplifiers of ion cyclotron range of frequencies (ICRF) for plasma heating where workers may approach comparatively easily and the leakage EMF are generated. The visualization of the leakage EMF (i.e., EMF distribution measurement) has been performed using a position tracking device with IR camera of Wii-remote.

In the surrounding of the power amplifier for ICRF plasma heating, the visualization system for time varying leakage EMF distribution that had been developed recently is used [1]. In this system, two electric field meters (EMR-20 and EMR-300, Narda S.T.S.) are used. One field meter that adhered an IR marker has measured the E-field strength distribution. Another is fixed to a comparatively strong position of E-field for obtaining the time variance. The E-field strength distribution corresponding to the peak of the time-variance is obtained based on the measurement results of both meters. The leakage E-field that we measured was, however, very weak, and we can say that it hardly has potential hazard.

In the experiment in the coil power supply room, the compliance of the protection guidelines in the passage between power supply units was visualized and evaluated by the visualization system for low frequency leakage magnetic field distribution with magnetic field meter (ELT-400, Narda S.T.S.) [2, 3]. As a result, though the results of the instrument in accordance with the ICNIRP guidelines 1998 exceeded the reference level at the passage entrance between power supply units, the results by the instrument in accordance with the ICNIRP guidelines 2010 did not exceed it except the interior of the passage.

At present, the leakage EMF that exceeded the protection guideline has not been observed around the devices of ICRF plasma heating. It is confirmed that the visualization system for the low frequency magnetic field distribution can easily distinguish the compliance of protection guidelines of the leakage magnetic field in the power supply room of coils.

Helwan University, Cairo, Egypt

Abstract— Adaptive beam-forming capabilities for smart antenna arrays are nowadays used in different applications such as suppression and reduction of interference in wireless mobile communication, besides its effects on the overall quality of service. Several optimization techniques are considered in the previous literature to deal with Adaptive beam-forming for smart antennas. Particle Swarm Optimization (PSO), Central Force Optimization (CFO), Bacterial Swarm Optimization (BSO), and Gravitational Search Algorithm (GSA) are well known Global optimization techniques that are based on a nature-inspired heuristic. Recently hybrid PSOGSA technique was proposed and showed better performance than standard PSO and GSA in terms of computational speed.

In this paper, a novel algorithm that is based on the hybrid PSOGSA technique is developed for optimal beam-forming using ULA and UCA. The goal is to maximize the beam of the radiation pattern towards the intended user or Signal of Interest (SOI) and minimize the beam of the radiation pattern towards Signal Not of Interest (SNOI) based on controlling the complex weights (phase) of ULA or UCA.

Simulation results prove the directed power in terms of normalized array factor toward the intended direction (SOI) using UCA is better than ULA by approximately more than 6 dB, 3.5 dB, and 1.5 dB for different cases, on the other hand, directed null to SNOI better than ULA by approximately 35 dB, 5 dB and 14 dB for several cases. In addition, simulations of beam-forming showed accurate results even for a big set of simultaneously incident signals. It is found that hybrid PSOGSA is more attractive for beam-forming applications and better than GSA with approximately -3 dB in average besides it was demonstrated that hybrid PSOGSA achieves fast and robust global convergence over GSA.

Semiconductor Temperature Tunable Metameterial for Terahertz Applications

K. L. Koshelev[1, 2, 3] **and A. A. Bogdanov**[2, 3, 4]

[1]Saint-Petersburg State Polytechnical University, St. Petersburg 195251, Russian Federation

[3]Ioffe Institute, St. Petersburg 194021, Russian Federation
[4]The Academic University, St. Petersburg 194021, Russian Federation

Abstract— We introduce a new model of homogeneous temperature tunable THz metamaterial with controllable frequency range of hyperbolic dispersion based on semiconductor superlattice with doped quantum wells. We propose a method of thermal manipulating the shape of equal frequency surface in k-space. We discuss the phenomenon of permittivity tensor signature changing which results in transition from dielectric to hyperbolic regime of the material.

Hyperbolic metamaterials (HMMs) are one of the most developing branch of modern optics [1, 2]. HMMs represent uniaxial crystals. Dielectric function of uniaxial crystals is described by tensor with two different components corresponding to the directions along ($\varepsilon_{||}$) and across ($\varepsilon_{\perp}$) the optical axe.

Depending on the signs of these components, crystal represents a dielectric media ($\varepsilon_{\perp} > 0$, $\varepsilon_{||} > 0$), metal ($\varepsilon_{\perp} < 0$, $\varepsilon_{||} < 0$) or hyperbolic metamaterial ($\varepsilon_{\perp}\varepsilon_{||} < 0$). HMM's unique properties stem from the equal frequency surface of extraordinary waves.

We propose a new model of ultra homogeneous temperature tunable THz metamaterial based on semiconductor superlattice (SL) with doped quantum wells. Efficiency of thermal tunability is a result of high sensitivity of semiconductor conductivity to the temperature. Under term "ultra homogeneous" we mean that SL has tunnel transparent barriers and thickness of the wells is so small that that Drude-Lorentz model is inapplicable for a single layer. Here we use more accurate approach for dielectric function considering energy spectrum of carriers modified by SL potential and carrier distribution function. We show that away from interband transition and reststrahlen band each permittivity tensor component has Drude-Lorentz dispersion with modified plasma frequency:

$$\Omega_{\alpha}^2 = \frac{4\pi e^2}{\varepsilon_{\infty}} \frac{2}{(2\pi\hbar)^3} \iiint f(E,\mu,T) \frac{\partial^2 E}{\partial p_{\alpha}^2} d^3p, \quad \alpha = \perp, \| . \tag{1}$$

Here E is energy of carriers which depends on the momentum $\mathbf{p}$, $f(E,\mu,T)$ is the Fermi-Dirac distribution function, μ is the chemical potential, T is the temperature and ε_{∞} is a permittivity of the lattice without free carriers.

Tunability mechanism in proposed metamaterials is the following. Free carrier concentration and, therefore, plasma frequency of semiconductors is sensitive to the temperature in contrast to dielectrics and metals. Implementation of SL in semiconductors makes carrier spectrum and plasma frequency anisotropic. So, in SL we can distinguish plasma frequency along ($\Omega_{\|}$) and across ($\Omega_{\perp}$) the optical axis. Permittivity tensor signature and, therefore, optical properties of SL depends on the relation between frequency of the electromagnetic wave ω and plasma frequencies $\Omega_{\perp,\|}$. There are three cases corresponding to the different signatures of permittivity tensor: (i) dielectric case if $\omega > \Omega_{\perp,\|}$; (ii) hyperbolic case if ω is between $\Omega_{\perp}$ and $\Omega_{\|}$; (iii) metallic case if $\omega < \Omega_{\perp,\|}$. At fixed ω transition from one to another case can be realized by the manipulation with plasma frequencies which are easily controlled by thermal excitation.

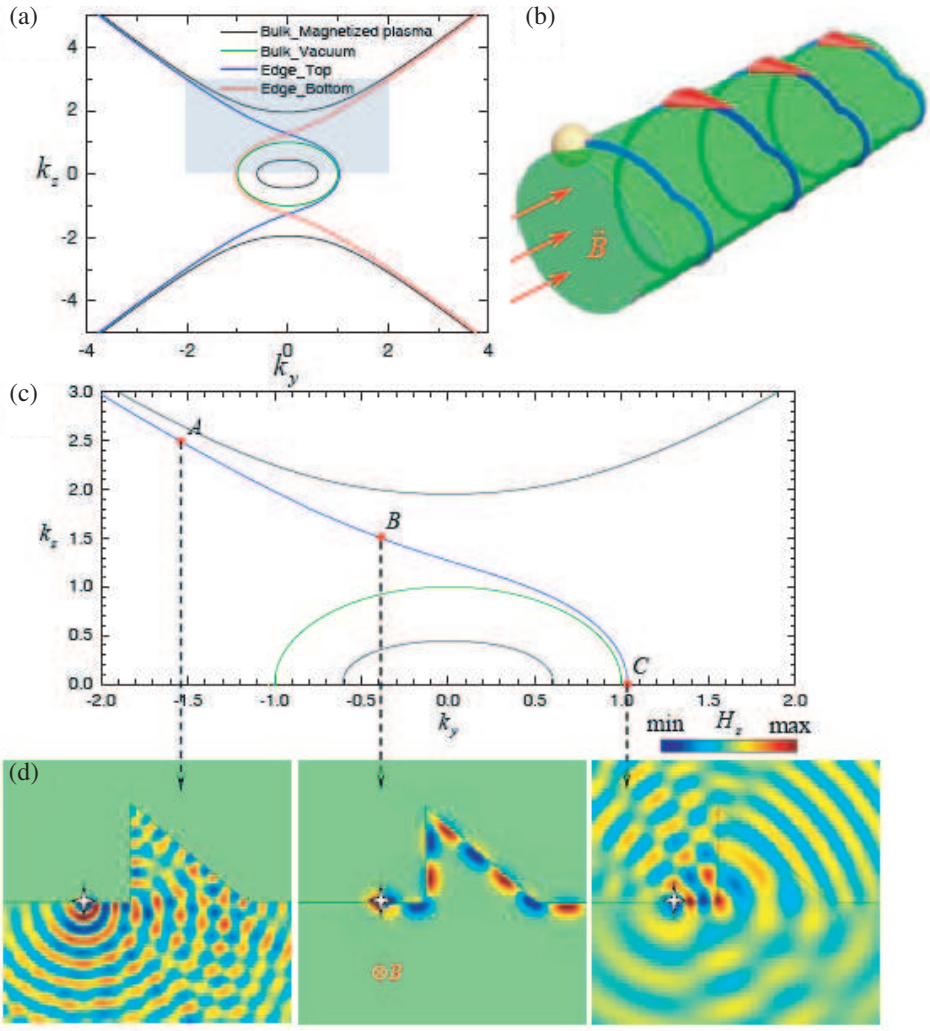
Abstract— In this paper we reveal the presence of photonic one-way helical surface states in a simple natural system — magnetized plasma. The application of an external magnetic field to a bulk plasma body not only breaks time-reversal-symmetry but also leads to separation of Equi-Frequency Contour surfaces (EFCs) to form topologically nontrivial gaps in k space. Interestingly, these EFCs support topologically protected surface states. We numerically investigate an interface between magnetized plasma, using a realistic model for parameter dispersion, and vacuum, to confirm the existence of one-way scatter-immune helical surface states. Unlike previous proposals for achieving photonic one-way propagation, our scheme does not require the use of artificial structures and should therefore be simple to implement experimentally.



This immunity to backscattering has been confirmed using full wave simulations shown in Fig. 1(d) in which a right moving surface wave propagates seamlessly around a sharp defect. The simulation is performed in the x-y plane for three different propagation constants k_z in the shadow area as indicated by 'A', 'B' and 'C' in Fig. 1(c). For point 'A' and 'C', since they are not located in the gap region, the electromagnetic wave can be scattered into the bulk states by z-invariant scatterers. On the other hand, at point 'B' where k_z is in the middle of the gap, the surface wave is immune from scattering by the sharp edges, and therefore the numerical simulation confirms that it is a topologically nontrivial surface state. As expected, when the direction of the magnetic field is flipped, the propagation of the surface wave is also switched to the opposite direction. This may enable topological surface states with dynamically reconfigurable properties.

The Properties of Surface Plasmon Polaritons at Linearly Graded Interfaces

Abstract— Plasmonic structures are a promising solution for overcoming the diffraction limit of light and for developing novel integrated optics devices. The advantage of using semiconductors is the possibility of tuning the semiconductor properties by changing the composition and doping of a given material. The inhomogeneous structures can be prepared.

New results are reported on investigation of dispersion curves for surface plasmon polaritons (SPPs) at an inhomogenously doped semiconductor/dielectric interface whereby the dielectric is represented by the same undoped semiconductor. The doped semiconductor is described by its frequency-dependent permittivity that varies with the depth. It is shown that a transition layer (TL) with a linear change in carrier concentration supports one branch dispersion curve regardless of the TL thickness. The obtained dispersion curves reach a maximum at a finite frequency depending on the TL thickness, and subsequently asymptotically approach the zero frequency in the shortwave limit. Therefore two surface plasmon modes are supported at a given frequency: a long-wave mode with a positive group velocity and a short-wave mode with a negative group velocity. It is shown that the conventional dispersion relation for SPPs at a TL with a zero thickness is an asymptotic solution, and the convergence of real dispersion curves is point-wise instead of an expected uniform convergence.

One stationary SPP exists for each thickness of TL. However, these modes differ in their potential for coupling with external source of light. Large modal index bandwidth is necessary to be able to couple practically to the slow light mode and also to enable the efficient energy accumulation without spatial spreading. It may be concluded that the narrow TL supports stationary SPPs with better MIB, but very short wavelengths [1].

Abstract— The authors discuss the application of broadband noise signal in the research of periodic structures and present the basic testing related to the described problem. The aim is to find a metrological method utilizable for the investigation of metamaterials in the frequency range between 100 MHz and 10 GHz; this paper therefore characterizes the design of a suitable measuring technique based on noise spectroscopy and introduces the first tests conducted on a periodic structure (metamaterial). In this context, the applied equipment is also shown to complement the underlying analysis.

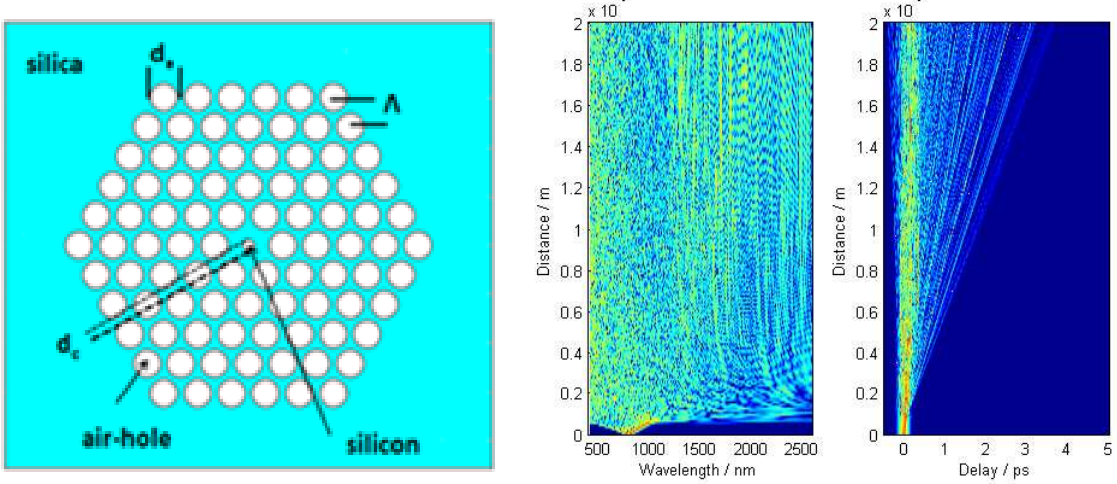
Abstract— The supercontinuum generation in photonic crystal fibers (PCFs) has been a topic of intense research ever since it was reported by Ranka et al.. To generate the supercontinuum (SC), the medium should at least exhibit a flat low anomalous dispersion with a small third order dispersion or zero dispersion. It is obvious that the PCFs operating near a zero dispersion wavelength (ZDW) with higher nonlinearity do not demand large input power for generating the SC. In addition, these desired conditions help smoothen the power spectra of SC. Therefore, highly nonlinear dispersion flattened PCF turns out to be the right candidate for generating SC. Nowadays, the generation of SC in photonic nanowire (PN) with sub-wavelength diameter has attracted significant interest due to its unique properties. Such a dielectric waveguide with a nanocore diameter possesses a tight mode confinement and as a result, it exhibits appreciable group velocity dispersion and nonlinearity. Very recently, a new fiber called nanowire embedded photonic crystal fiber has been introduced by exploiting the optical properties of both PN and PCF. Such a photonic device is termed as photonic crystal fiber nanowire (PCF-NW). This kind of small core PCF has been a good candidate for nonlinear applications such as soliton-effect pulse compression and SC generation In this paper, we demonstrate the supercontinuum generation in a silicon nanowire embedded photonic crystal fiber (SN-PCF) using fully-vectorial finite element method. The variation of supercontinuum is investigated by changing the fiber length, pump peak power and pump wavelength. The proposed fiber exhibits broad spectrum of more than 2200 nm within 2 mm length of fiber for peak power of 500 W of input pulse.

Design of the proposed SN-PCF and evolution of supercontinuum within a 2 mm length of SN-PCF:



Temperature Dependence of the Equilibrium Distance in Plane-parallel Thin Films at Thermal Equilibrium

Abstract— The Casimir force, which is especially intense between materials with separation distances at the nanoscale, may be attractive or repulsive depending on the geometry, temperature and the optical properties of the materials involved [1]. By a proper choice of a set of materials and slab thicknesses, this force gives rise to nanolevitation phenomena when the gravity force is taken into account at thermal equilibrium in planar geometries mediated by fluids [2, 3]. For a given geometry, the equilibrium separation can be adjusted by fine tuning of the volume occupied by each material in systems containing thin films, bilayers, or composite matrices with small inclusions inside. In addition, the equilibrium distance depends on the temperature through the Casimir force [2].

In this work we show that temperature dependence of the Casimir force is related to the difference between the static dielectric constants ε_0 of materials involved in the system. We analyse the temperature dependence of the Casimir force in terms of the transverse electric (TE) and transverse magnetic (TM) modes for realistic plane-parallel systems that show nanolevitation phenomena at thermal equilibrium. These systems consist of a thin film of Teflon, silica or polystyrene immersed in glycerol over a silicon substrate. Since the magnetic permittivity (which defines the TE modes) for all the materials considered is assumed to be unit at all frequencies, the largest variations with temperature come from the TM modes. Moreover, by splitting these contributions into two terms, that at zero frequency and that at non-zero frequencies, we prove that the main contribution to the temperature changes of the Casimir force is related to the term at zero frequency, which explicitly depends on the static dielectric constant ε_0 (see Fig. 1). Therefore the dependence of the equilibrium separation (and thus, of the Casimir force) with temperature can be controlled through the relation of ε_0 between materials.

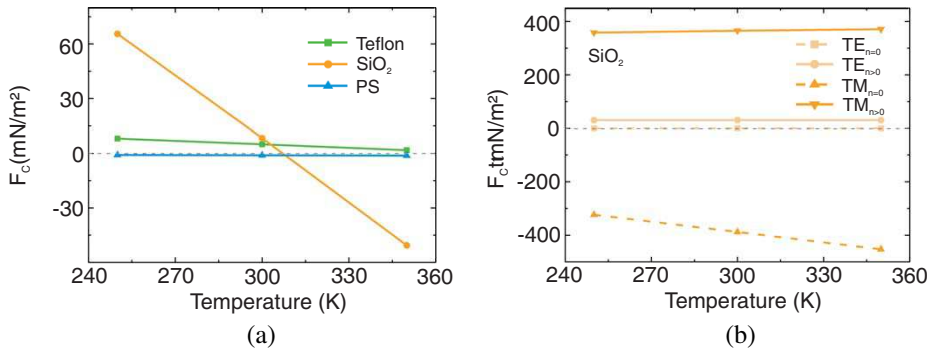

Figure 1: (a) Casimir force as a function of temperature for Teflon, silica (SiO_2) and polystyrene (PS) thin films of 500 nm thickness, at equilibrium distances 175, 60 and 450 nm, respectively, at $T = 300$ K, immersed in glycerol over a silicon substrate. (b) For a thin film of 500 nm of SiO_2, TE and TM contributions to the Casimir force for zero frequency ($n = 0$) and non-zero frequencies ($n > 0$).

Abstract— The propagation of electromagnetic waves in two-dimensional uniform arrays of zinc oxide (ZnO) nanorods of various diameters coated with a thin metal layer was studied by separation of variables method in cylindrical coordinates. The numerical results for single optical waveguide and two-dimensional array of waveguides are discussed in this paper. The dispersion of the dielectric constants of ZnO and metals are taken into account in the model because, as it is known, metals at optical wavelengths have a finite complex permittivity. The accuracy of results shown in this paper are ensured by comparison with results obtained by finite element method implemented in commercial software COMSOL Multiphysics, which is highly demanding to computing resources and slower than proposed method. As the advantages of finite element method may be distinguished its conservativeness, absolute stability, the possibility of constructing a finite-element approximations on unstructured grids, and calculating electrodynamic parameters of devices with complicated geometries. The dispersion characteristics calculated by finite element method are in good agreement with the results obtained by our method over all optical range and have minor deviations for the wavelength range close to the critical wavelength. Resonances located at the amplitude-frequency characteristics of optical nanoantennas may be interpreted as resonances of circular bilayer nanowaveguide segments with the ZnO core covered with thin metal shell. In this regard it is of interest to investigate the range of the optical characteristics of similar waveguides. The results may also be used to predict the resonant wavelength of two-dimensional periodic arrays of ZnO nanorods coated with a thin metal layer and grown on a dielectric substrate.

Dynamical Evolution of the Laser Linewidth at Switch-on

Abstract— Experimentally, the laser response is measured by following the time evolution of the light output by a laser, whether this operates in a single- or multimode regime. Frequency-selective detection is obviously possible, but typically cumbersome and avoided when several modes are simultaneously present. Integrated spectral features are easier to implement, as they do not require the simultaneous operation of independent fast detection over several wavelengths, but can result from the simple integration (e.g., on a CCD) obtained from a dispersive device (e.g., a grating). Traditional, rate-equation-based modelling of multimode semiconductor lasers coupling the modal intensities to the carrier reservoir have hinted to the presence of pronounced oscillations accompanied by slower modal relaxations [1].

We analyse the dynamical buildup of the laser intensity starting far below threshold and ending well above threshold. The total intensity quickly grows to the well-known peak and rapidly relaxes in oscillatory fashion towards its equilibrium value, accompanied by the quadrature oscillations of the carrier density. The individual modal intensities, however, display a much slower evolution which gives rise to a very slow convergence of the spectral distribution, which — as is well-known — differs strongly below and above threshold [2].

Our analysis illustrates the evolution between the two spectral distributions [3] thus showing how modulation schemes successfully applied to single mode lasers [4, 5] also improve the transient dynmaics in multimode devices [6], as experimentally verified [7].

Free-running Semiconductor Laser Dynamics: The Role of the Phase Instability

L. Gil[1, 2] **and G. L. Lippi**[1, 2]

[1]Institut Non Linéaire de Nice, Université de Nice Sophia Antipolis, France

Abstract— An unusual kind of spontaneous, multimode dynamics near the threshold of a semiconductor laser has been reported approximately a decade ago [1–4]. In some devices, it is characterized by a (nearly) constant total intensity, accompanied by regular modal jumps in orderly progression from the shortest to the longest wavelength of the lasing interval, followed by a jump to the shortest wavelength and cyclical repetition over the whole spectral interval at a constant, slow frequency (typically two to three orders of magnitudes slower than the intrinsic time scales) [2, 3]. Less regular behaviour is observed in all devices [1–4], including irregular, but not entirely stochastic, jumps and a residual modulation of the total intensity. The latter remains small compared to the modulation depth for each individual mode.

A heuristic interpretation of these observations was proposed on the basis of two completely opposing assumptions: A deterministic one, where the lasing modes are coupled either through Four-Wave-Mixing [1–4], Cross-Modulation or Self-Modulation [5]; or a stochastic one where noise is projected onto the ensemble of modes [6]. Curiously, both approaches produce predictions in qualitative agreement with the observations, thus hinting at the fact that the physics underlying this phenomenon must run deeper.

Performing a new derivation of the basic semiconductor laser equations [7], without ressorting to the usual approximations, and employing codimension 2 bifurcation theory, we obtain a new model for the laser dynamics near threshold which, without the need for introducing a projection onto cavity modes, shows the existence of a phase instability [8]. Its features are those of the well-known Benjamin-Feir instability of hydrodynamics and reconcile the deterministic description with an apparently stochastic one, where the role of noise is played by the underlying turbulence.

Abstract— A relativity simple and cost effective terahertz (THz) emitter can be realized on the base of optical transition between the levels of shallow impurities in semiconductors. Intracenter THz radiative transition takes place during the energy relaxation of nonequilibrium carriers created in allowed band at the impact ionization of impurities by electric field [1, 2] or at the photoionization of impurity centers by infrared laser radiation [3]. Recently we showed experimentally that intracenter THz radiative transition can appear under interband optical excitation of semiconductors doped with shallow impurities centers [4, 5]. Development of THz emitter based on silicon can allow direct integration of it with silicon electronic.

Here we report on the observation of intense THz emission under the interband photoexcitation of Si(Li) at low temperatures. The experiments were curried out on the float-zone n-Si samples doped with Li during the growth with the concentration $N_D - N_A \sim 1 \times 10^{16}\,\mathrm{cm}^{-3}$. The photoexcitation was provided by a 660 nm line of a continuous wave semiconducting laser with a maximal output power of 45 mW. Laser radiation modulated at a frequency of 75 Hz with a mechanical chopper was transmitted through a series of small diaphragms and filters, preventing penetration of the laser thermal background into the experimental setup, and then focused onto the sample surface to 2 mm spot size. The spectra were measured using a step-scan Fourier spectrometer at $T = 5\,\mathrm{K}$. The THz signal was detected using a liquid helium cooled Si-bolometer and a lock-in amplifier.

The THz PL is attributed to radiative capture of nonequilibrium carriers by charged impurity centers. These charged centers appear in the crystal due to the impurity-assisted electron-hole recombination at low temperatures. Intracenter optical transitions give the main contribution to the THz emission. THz photoluminescence (PL) spectra contain lines related to optical transition from first excited donor levels to ground state of Li donor. The observed experimental regularities will be presented and discussed.

The Effect of UV Laser Irradiation and Thermal Treatment on the Luminescent Properties of Silver-containing Glasses

V. S. Leonteva, **D. A. Klyukin**, **A. I. Sidorov**, **A. I. Ignatiev**, **and N. V. Nikonorov**
ITMO University, Russia

Abstract— The aim of this work is the investigation of transformations of silver in silver-containing silicate glasses under the influence of UV laser irradiation and thermal treatment and of the influence of this transformation on luminescent properties of glasses.

The glasses of the system Na_2O-ZnO-Al_2O_3-SiO_2-NaF-NaCl with addition of Ag_2O and Sb_2O_3 were synthesized in the ITMO University. The measured glass transition temperature was $T_g = 494°C$. It was shown in [1] that such glasses contain the charged silver molecular clusters (MCs) which have a very weak visible luminescence. For laser irradiation we used third harmonic pulses of YAG : Nd (Lotis TII) with $\lambda = 355\,\text{nm}$, $\tau = 5\,\text{ns}$, $E = 2.7\,\text{mJ/cm}^2$ and $f = 10\,\text{Hz}$. The laser irradiation led to the color changes in the irradiated zone and to the orange luminescence appearance under excitation by $\lambda = 400\,\text{nm}$ (Fig. 1(a)). This effect is caused by the photoionization of glass matrix by laser radiation, by trapping of free electrons by charged silver MCs and their transformation to the neutral ones.

The thermal treatment experiments were performed at temperatures below and above T_g. The thermal treatment below T_g led to the increase of the luminescence intensity (Fig. 1(b)). This effect can be explained by the increase of the concentration of neutral silver MCs as a result of trapping electrons from charged defects of glass net and Sb ions. The thermal treatment above T_g led to the decrease of luminescence intensity in the center if irradiated zone (Fig. 1(c)), because of the formation of silver nanoparticles there. The observed effects are confirmed by the optical absorption and luminescence spectra measurements.

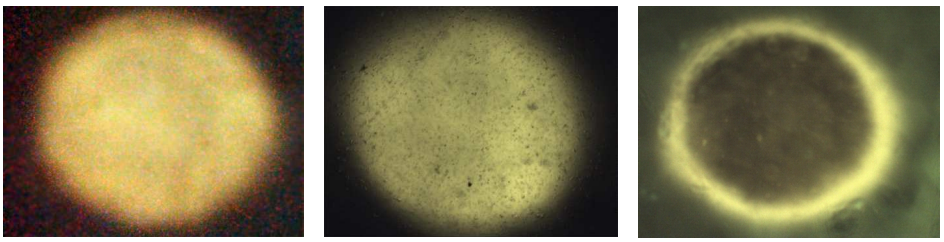

Figure 1: Luminescence of silver doped glass (a) after laser irradiation, (b) after thermal treatment below T_g, and (c) after thermal treatment above T_g. Excitation wavelength is 400 nm.

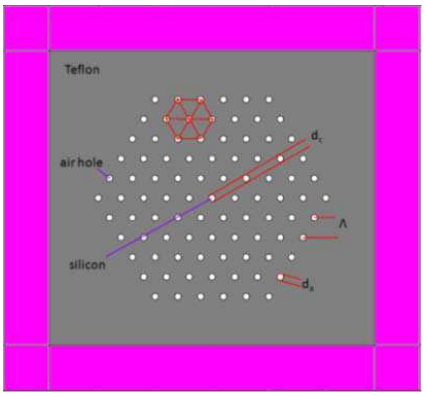
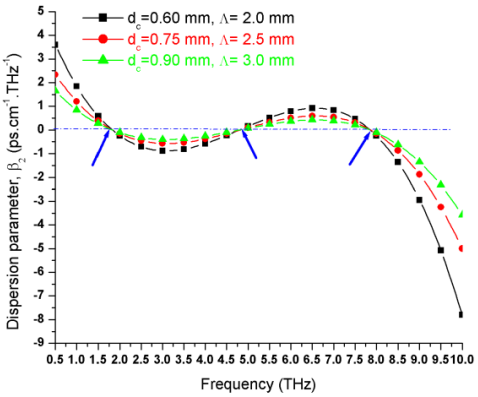
Abstract— Nowadays, the terahertz (THz) regime finds numerous applications in various important fields such as imaging, astronomy, communications, pharmaceutical quality control and security-sensitive areas, namely, monitoring drugs, explosives or weapons in a non-destructive manner and complex biological systems. In general, designing THz waveguides with low loss are essential for the successful implementation of THz systems. THz radiation lies between electronic and optical region in the electromagnetic spectrum with range of frequencies from 300 GHz to 10 THz. To date, most of the THz systems rely on free space propagation due to the virtual absence of low-loss waveguides at THz frequencies. In general, plastic, metallic ribbon waveguides and polymer PCF have demonstrated the THz guidance. These THz waveguides were fabricated by the drill and draw or stack and fuse technology.

In this paper, we design a novel photonic crystal fiber using finite element method which acts as a THz silicon waveguide. Here, the core is made of silicon material and the teflon is used in the cladding region wherein the air-holes are arranged in a triangular pattern. It is known that the silicon has excellent transmission properties compared to other guiding materials. It is known that the nonlinear index coefficient, n_2, of silicon is about 200 times larger than that of silica. The refractive index of silicon (around 3.5) is much larger than that of air which ensures a much tighter light confinement. Therefore, we study the important transmission properties, namely, group velocity dispersion, absorption coefficient, effective mode area and effective nonlinearity by varying the core diameter ($d_c = 0.6$, 0.75 and 0.9 mm) and distance between two consecutive air-holes, pitch ($\Lambda = 2$, 2.5 and 3 mm) for a wide range of frequency from 0.5 to 10 THz. The proposed THz silicon PCF exhibits three zero dispersions at 1.75, 4.8 and 7.8 THz frequencies and also report a low absorption coefficient of 10^{-4} cm^{-1} in the broad frequency region (2.5 to 10 THz). Further, we obtain a large mode area of 325000 μm^2 at 0.5 THz frequency for the core diameter of 0.9 mm and the pitch of 3 mm. These results show that the proposed THz silicon PCF would turn out to be a good candidate for THz waveguide compared to other plastic THz waveguides.

Design of the proposed SN-PCF and variations of dispersion with respect to frequency:





Minimally Invasive W-band Microwave Imaging

No-Weon Kang, Young-Pyo Hong, and Dong-Joon Lee
Center for Electromagnetic Wave, Korea Research Institute of Standards and Science
267 Gajeong-Ro, Yuseong-gu, Daejeon 305-340, Korea

Abstract— We present a minimally invasive microwave imaging technique for analyses of W-band transmission lines. Due to the high-frequency nature of the W-band (75 GHz–110 GHz), its power delivery generally requires millimeter-scale transmission lines. The industry-standard waveguide and co-axial schemes use WR-10 and 1.0 mm cable adaptors, as shown in Fig. 1(a). The physical dimensions of WR-10 are 2.54 mm × 1.27 mm, and 1 mm represents the outer conductor diameter of a coax adaptor. Owing to the minute embodiments of W-band mating components, mechanical precision of these components is crucial to determine the component grades. Their mating performances are usually evaluated by checking the field-transfer characteristic between mating ports. For a better characterization, it is desirable to measure the confined electric fields of each component directly, but this has not been feasible due to the finite areas of W-band components. To address this challenge, we have developed an extremely minute fiber-coupled optical probe for millimeter-wave sensing [1, 2]. The probe consists of an electro-optic wafer; its size is small enough to be directly mounted onto a bare fiber faucet. In addition, the wafer is virtually transparent to both millimeter-wave and near-infrared spectra. This probing scheme is a feasible solution to realize minimally invasive W-band imaging with (sub-) millimeter spatial resolutions. For instance, Fig. 1(a) shows the open ends of WR-10 and 1 mm-coax male connector. The minute fiber-coupled probe travels over the open ends on the x-y plane. The probe is sensitive to only certain directions, and we set it to measure the y-direction of the electric field. The field distribution, measured ∼0.3 mm above the metallic surface for the waveguide and connector, is shown in Fig. 1(b) and in the simulation illustrated in Fig. 1(c). We are currently working on imaging for on-wafer millimeter-wave calibration substrates. The field distribution over a co-planar waveguide which is launched by a 150-μm-pitch GSG probe is to be provided in a conference presentation.

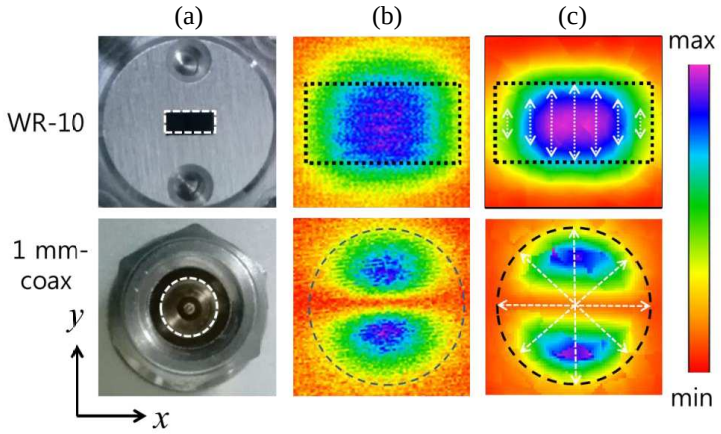


Figure 1: (a) Photograph of the W-band waveguide and coax adaptor, (b) measured electric field distribution at 94 GHz, (c) simulated electric field distribution at 94 GHz; most fields are concentrated within the dotted boundary.

Phase-stabilized Microwave Imaging Using Dual Electro-optic Probes

Young-Pyo Hong, No-Weon Kang, and Dong-Joon Lee
Center for Electromagnetic Wave, Korea Research Institute of Standards and Science
267 Gajeong-Ro, Yuseong-gu, Daejeon 305-340, Korea

Abstract— A highly stabilized electro-optic (EO) sensing technique for phase measurements in electric fields in a high-frequency transmission line is presented. For EO applications, a femtosecond mode-lock laser can be an effective source of microwave photonics, generating extremely high-order harmonics in its pulse repetition frequency [1]. These harmonic components can be utilized as a local oscillator (LO) to down-convert the radio frequency (RF) from a tested microwave device to an intermediate frequency (IF). The electromagnetic quality — especially the phase — associated with RF and LO processes directly affects that of the IF signal. The phase stability levels of both RF signals and LO signals tend to degrade rapidly at higher frequencies. The overall instability of the phase information associated with RF and LO processes can be monitored by coupling each LO and RF component with directional couplers with down-conversion to IF with a mixer [2]. However, this technique ultimately requires expensive microwave components for applications at higher frequencies. Here, we present a fairly simple and effective photonics-based technique which uses two probes to compensate for the phase drift which often occurs in high-frequency electro-optic sensing. In Fig. 1(a), one EO probe is positioned at a fixed position where strong electric fields are formed over a CPW line, while the other EO probe travels over the line on a programmed x-y plane. Both probes concurrently experience the overall phase drift associated with the unstable nature of W-band RF and LO sources. However, such phase instability can be corrected by subtracting the phases of each probe. This correction can be realized during scanning so as to provide phase-stabilized EO sensing for high-frequency microwave imaging. Figures 1(c) and (d) show electric field images of the amplitude and phase for an open-terminated CPW line at 220 GHz. A detailed experimental demonstration of the phase-stabilized imaging technique is to be provided at a conference.

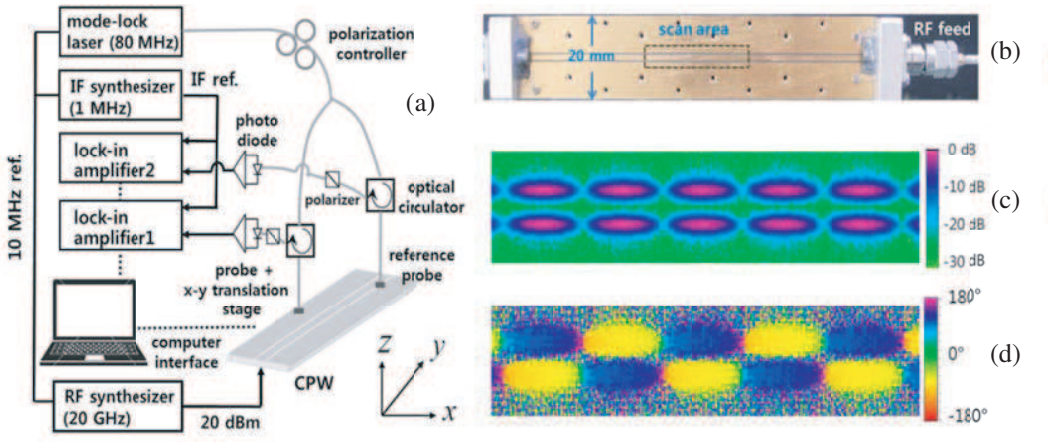

Figure 1: (a) Phase-stabilized EO imaging system, (b) CPW line for 20 GHz imaging, (c) amplitude of E-fields, (d) stabilized-phase of E-fields.

Field-calibrated Electro-optic W-band Power Sensor

Dong-Joon Lee, **Young-Pyo Hong**, **No-Weon Kang**, **and Jae-Yong Kwon**
Center for Electromagnetic Wave, Korea Research Institute of Standards and Science
267 Gajeong-Ro, Yuseong-gu, Daejeon 305-340, Korea

Abstract— We present a photonic-assisted microwave power sensor for W-band applications. For the evaluation of W-band (75 GHz–110 GHz) power delivery, a commercial power sensor with WR-10 waveguide is a widely used solution. However, most W-band power sensors show relatively limited sensing capability; their typical maximum power handling level is ∼20 dBm with ∼40 dB dynamic range. One solution to enhance the dynamic range of a sensor is employing a photonic technology. Electro-optic (EO) sensors have served as a good alternative for microwave field sensors. The EO sensors can be fabricated in an extremely minute scheme and they can be readily coupled with an optical fiber [1]. For instance, an optical fiber-scale EO sensor is shown in Fig. 1(b). The fiber is embedded along a 0.2 mm groove at one side on a narrow wall of WR-10 aperture. The sensor tip is placed in the center of the aperture where the electric field intensity is the strongest for TE_{10} mode of rectangular waveguides. We terminated this open-end with a WR-10 power sensor as shown in Fig. 1(a). The W-band power, delivered through a WR-10 waveguide, is read through a power meter. Knowing the power levels, the electric field intensity, where the EO sensor is located, can be attained analytically. The calculated electric field strength with respect to the power in the waveguide is shown in Fig. 1(c) with a dashed line. On the other hand, the EO sensors can measure millimeter-wave electric fields associated with a femtosecond laser which is electrically synchronized with microwave sources. By virtue of such laser-electronics synchronization, the EO sensors can interact with both optical and electronic units and yield microwave signals in terms of modulated light. The data points in Fig. 1(c) are the sensor signals with respect to the power in the waveguide at 94 GHz. These values are in arbitrary unit but can be calibrated in an absolute unit. The EO sensor shows excellent linearity up to 20 dBm level as in Fig. 1(c). Because the sensor's all-dielectric embodiment, its high field sensing capability is known as ∼ MV/m scale [2]. We believe this kind of photonicCassisted power sensor would show at least 80 dB of dynamic range. We are currently trying to enhance the sensor's capability. The improved data set is to be provided at a conference presentation.

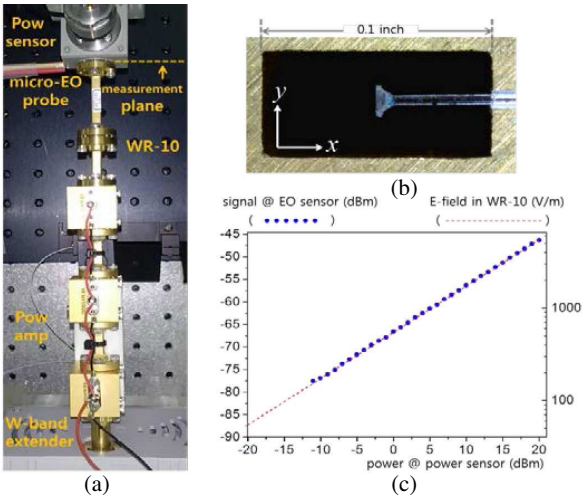

Figure 1: (a) Photonic-assisted W-band waveguide power measurement system, (b) field sensing geometry with a minute EO sensor, (c) field-calibrated performance of an EO sensor at 94 GHz.

Broadband Tunable Terahertz Metamaterial with Photoinduced Vanadium Dioxide Film

Shen Qiao and Yaxin Zhang
Terahertz Science Cooperative Innovation Center
University of Electronic Science and Technology of China, Chengdu 610054, China

Abstract— The composite structure of metamaterial and vanadium dioxide film is a novel way to realized active terahertz device within specific frequency band. By designing the resonant structure of metamaterial, there will be different frequency response in the applied spectrum. The vanadium dioxide is a reversible phase transition material due to its insulator-metal transition at a critical temperature or enough light intensity. Applying the photoinduced characteristics of vanadium dioxide, a dynamic resonant terahertz functional device is suggested to realize the ultrafast external spatial terahertz wave modulator. This paper carried out a broadband terahertz modulator at 0.21–0.53 THz with more than 80% modulation depth in typical frequency. In this modulator, the vanadium dioxide film is deposited on silicon substrate using sol-gel method. Then a dual-resonance metamaterial is patterned on the vanadium dioxide film using photo etching technology. Simulation results show that this dual-resonance metamaterial is a band-pass frequency selective surface with tunable band width by changing the dimensions of the split gaps and each resonance peak have its own resonant mode with different circular current. In the static test, the characteristics of the structure spectrum are performed using terahertz time-domain spectroscopy with different incident laser powers on the surface of this device. The transmission of the broadband spectrum is decreasing linearly with the increasing leaser power. The dynamic experimental result illustrate that this device realizes up to 1 MHz amplitude modulation by utilizing a 0.34 THz CW terahertz source. The simulation and experimental results show that this work may have many potential use in the design of modulators, switches, sensors, detectors and so on.

Generation Method for Bandwidth-limited Terahertz Pulses by Spectral Synthesis of Optical Comb Generated by a MZM-based Flat Comb Generator

Abstract— Terahertz (THz) time-domain spectroscopy (TDS) is a powerful tool for characterization of material properties. In general THz-TDS is performed using broadband THz pulses covering up to tens of terahertz generated by ultrashort optical pulses. However, in many cases, the frequency range of interest is relatively narrow, while the high dynamic range and the high frequency resolution are required. Bandwidth-limitation of THz pulses has an advantage in terms of the power modal density. In this presentation, we propose a generation method for bandwidth-limited THz pulses by using a Mach-Zehnder-modulator-based flat comb generator (MZ-FCG).

Our approach to bandwidth-limited THz pulse generation is based on the photomixing technique, in which a single-mode and a pulsed signal are mixed on a photomixer. Picosecond pulse trains generated by the MZ-FCG are halved by an optical splitter. They are launched into optical bandpass filters (BPFs), respectively. One BPF extracts a mode (single-tone), and the other BPF extracts several modes (multi-tone), which is a pulse train elongated from the original pulse in pulsewidth. By mixing them, the optical pulse trains are down-converted to THz pulse trains. The envelope of the optical pulses is preserved to THz pulses. The carrier frequency is corresponds to the frequency difference between the center frequencies of the filters, and the pulsewidth is proportional to the bandwidth of the multi-tone signal. Merits of our system are tunability of both the center frequency and the bandwidth (pulsewidth) of the THz pulses by changing the center frequency and the pass-bandwidth of the BPF, respectively. A typical bandwidth of the comb signal is several hundred gigahertzes, so that THz pulses with the center frequency of several hundred can be generated by the MZ-FCG.

The MZ-FCG, which is composed of a dual-drive-type MZM is driven by two RF signals, converted a cw light to a flat comb. By driving the MZ-FCG with 10 GHz signals, optical combs with mode spacing of 10 GHz and the 10 dB-reduction bandwidth of 330 GHz were generated. By chirp compensation using an SMF with a length of 1.1 km, the comb signal was converted to a 2.85 ps pulse train.

The optical combs were halved by an optical splitter; one is launched into a tunable bandpass filter (TBPF1) and extracted a single-tone signal from the comb. The other is launched into another TBPF (TBPF2), and an extracted multi-tone signal. The filtered signals were coupled by another coupler, and THz pulses were measured by the OSO with the temporal resolution of 1.1 ps. As a result, THz pulse trains were successfully observed. By tuning the center frequency and pass-bandwidth of TBPF2, tunabilities on frequency and bandwidth were also demonstrated.

Collapse of Nonlinear Terahertz Pulses in n-InSb

Abstract— The radiation of the terahertz (THz) range $f = 100\,\text{GHz}$–$30\,\text{THz}$ is used in spectroscopy, medicine, scanning, and environmental science. The interaction of THz radiation with narrow-gap semiconductors like n-InSb, n-InAs, and low dimensional structures is of great interest, because it gives a possibility to create both active and passive electromagnetic and electronic devices.

In the report there are investigated nonlinear electrodynamic phenomena in a volume narrow-gap semiconductor n-InSb $f \sim 1$–$5\,\text{THz}$. The nonlinearity of electron gas due to the Kane dispersion law is dominating here. The equation for the amplitude, which is slowly varying with respect to time only, has been derived. The dependence of the wave amplitude on the longitudinal coordinate z and the transverse one ρ is arbitrary. The saturation of nonlinearity is taken into account. Under a propagation of THz transverse limited electromagnetic pulses through the structure intrinsic InSb-n-InSb-intrinsic InSb with the electron nonlinearity both the longitudinal and transverse focusing occurs. This leads to the spatiotempotal collapse, or the formation of the electromagnetic wave bullets from the input pulses. The influences of the wave dissipation and the saturation of nonlinearity on the nonlinear wave dynamics are important. The optimum conditions for realizing wave collapse have been obtained for the carrier frequencies, transverse sizes of the input pulses, the input intensities, and the wave dissipation. A comparison with the layered structures that include the 2D graphene sheets or thin n-InSb layers jointly with linear dielectric ones is given.

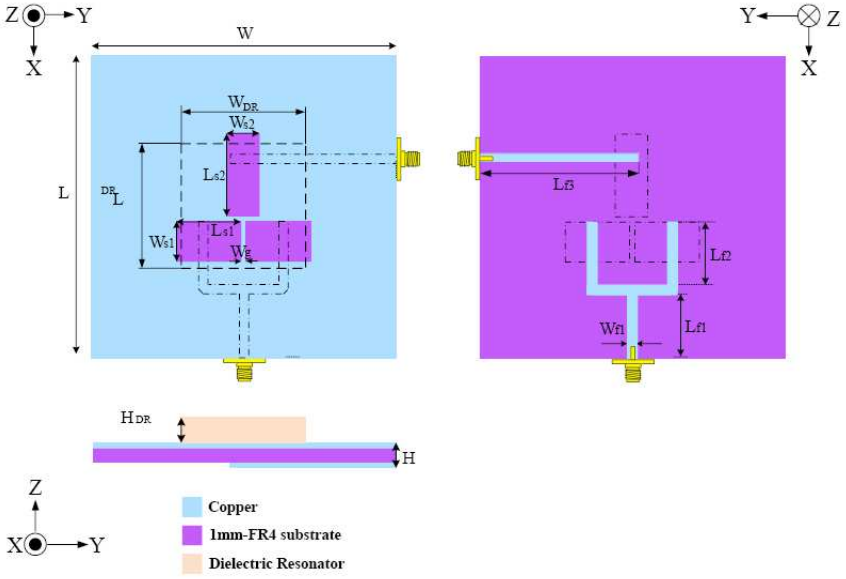
A Novel Dual-band Dielectric Resonator Antenna for WLAN Applications

Jwo-Shiun Sun, Chi-Yeh Kan, Hung-Wen Liu, Guan-Pu Pan, and Tsung-Lin Li
Department of Electronic Engineering, National Taipei University of Technology, Taipei, Taiwan

Abstract— A novel dual-band dual-polarized dielectric resonator antenna (DRA) is proposed to utilize a T-shaped slot with high isolation between two input ports to reduce the coupling effect between the excited modes. The proposed DRA offers measured impedance bandwidth for WLAN-802.11b (2400–2484 MHz) and WLAN-802.11a (5725–5825 MHz) applications with the peak gain 5–8.65 dBi. Simulated results of the return loss, isolation and gain of the DRA get fairly good agreement with those experimental ones.



Triple-band MIMO Antenna with Proximity Coupling Radiators

Abstract— This paper presents a triple-band mobile wireless MIMO antenna that meets GSM900/1800 and LTE2600 bands protocols. The antenna element is designed with three individual resonant Planar Inverted-L Antennas (PILs) with proximity coupling structures. The highest band is generated by the inverted-L structure fed by a transmission line, and the other two bands are produced by two meander lines, for which one is a coupling PIL construction for the lowest band and a parasitic element is located on the backside of the circuit board for the middle band. The MIMO antenna consists of two symmetric antennas with edge-to-edge separation of nearly one-tenth wavelength of the lowest band. The rectangular slot on the ground plane is implemented to enhance the isolation for the highest band, and the winded microstrip line inserting in the rectangular slot serves the purpose of isolation for the lowest band. Good isolation in middle band is achieved by its tilt unsymmetrical radiation pattern. The MIMO antenna measurement results show good impedance matching with low mutual coupling. The Envelope Correlation Coefficient is calculated to verify that the proposed antenna is suitable for wireless mobile applications.

A Planar Dual-band Antenna for WLAN MIMO Application

Li Ju Chen and K. H. Lin
National Sun Yat-Sen University, Kaohsiung, Taiwan

Abstract— A Multiple Input Multiple Output (MIMO) system has been one of the most promising wireless technologies for broadband communication systems. A planar dual-band antenna for WLAN MIMO application is proposed. The proposed antenna covers two operation frequencies at 2.4 GHz–2.5 GHz and 5.15 GHz–5.85 GHz for WLAM applications. To have good isolation between the antennas is difficult due to both strongly coupled between two and coupling currents of the surface in the ground plane. The mutual coupling increases the envelope correlation of the two ports and reduces the radiation efficiency.

The configuration of the proposed MIMO antenna was presented in Fig. 1. The MIMO antenna has two planar pitch antennas with slot on the top side and a notch filter on the bottom side. Fig. 1(a) shows the top view of the antenna and Fig. 1 (b) shows the bottom view of the antenna. The proposed antenna was implemented on the single layer FR4 substrate with a volume of 50 mm × 35 mm × 0.8 mm and relative permittivity of 4.4. Two symmetry antennas are placed at the top edge of the system ground. The dimension for the antenna is 17.5 mm × 14.5 mm. The dimension parameter is shown in Fig. 1 as well. The width of the feed line is 2.2 mm and the length of feeding line is 18 mm.

In order to improve the isolation at the lower band, a notch filter with meander line design was added at the bottom side. The dimensions of the notch filter are shown in Fig. 1(b). The simulation result of return loss (S_{11}) and isolation (S_{21}) were shown in Fig. 2. The return loss for proposed antenna covers 2.4 GHz–2.5 GHz and 5.15–5.85 GHz. The return loss is below −10 dB at two operation bands. The proposed MIMO antenna has the isolation of about 16 dB at the lower band and over 15 dB at the upper band. The proposed antenna provides two pass bands for dual-band application and also has good isolation between two single antennas for MIMO application.

Resonant Antenna Design Employing Equivalent Circuit Mode

Cheng-Nan Hu, Siam-Chen Huang, Jhih-Neng Yang, and Jen-Kai Hong
School of Communication Engineering, Oriental Institute of Technology, New Taipei 22061, Taiwan

Abstract— Utilization of the equivalent circuit model has shown more time-effective for designing RF circuits and antennas rather than Electromagnetic fields analysis. This study investigates equivalent circuit perspective on designing the resonant antenna. An equivalent π-network circuit is firstly proposed and de-embedded by using even-odd mode analysis to approach the electromagnetic fields coupling of a closely coupled two-element diversity antenna. Thus, the improvement on the isolation between antennae can be straightforward achieved by employing resonant and absorption method. Numerical and experimental study are presented herein.

Flexible PIFA Antenna Design for Wireless Sensor Networks in Wearable Healthcare Applications

I. Gil and R. Fernández-García
Departmentof Electronic Engineering
Universitat Politècnica de Catalunya, 08222 Colom 1, Terrassa, Spain

Abstract— In recent years, the Wireless Sensor Networks (WSNs) [1] have emerged as a communication technology to address applications such as healthcare monitoring, environmental sensing, industrial monitoring, etc.The WSNs consist of small communication nodes containing a sensing part, a microcontroller, communication components and a battery. Wearable WSN healthcare applications require compact size and optimized radiation patterns [2] and, therefore, antenna design play a fundamental role incustomized designs.The planar inverted-F antenna (PIFA) is a common antenna for portable devices because of its excellent balance between low-profile, low-cost and performance [3].

In this work an optimized PIFA including the textile and human skin effects has been designed, simulated and characterized for wearable WSN healthcare applications. The proposed PIFA has been designed by means of the commercial *Keysight Advanced Design Systems and Momentum* software.Fig. 1(a) shows the proposed substrate based on the implementation of the flexible PIFA in the commercial Pyralux (dielectric constant $\varepsilon_{rP} = 4.6$, thickness $h_P = 50\,\mu\text{m}$). A textile layer ($\varepsilon_{rT} = 2$, $h_T = 1\,\text{mm}$) has also been considered to emulate the outfit impact on the antenna. Finally, the human skin has been included as the lowest layer in the substrate ($\varepsilon_{rS} = 39$, $h_S = 1.5\,\text{mm}$) [4]. The antenna has been designed to operate under the Bluetooth 4 standard (2400–2483.5 MHz). The optimized PIFA ($20 \times 26\,\text{mm}^2$) considering the overall substrate is illustrated in Fig. 1(b). The antenna return losses (S_{11}) for several steps with regard to the optimization design process are depicted in Fig. 1(c). An original PIFA meandered antenna has been designed at the operation frequency in Pyralux substrate. Obviously, the introduction of the textile and skin layers increases the overall dielectric constant and, therefore, a reduction in the radiation frequency is expected. The redesigned antenna performance correspond to 300 MHz bandwidth at $S_{11} = -10\,\text{dB}$ and a maximum return losses of $-18\,\text{dB}$.

Dual-band Printed Antenna for WLAN Applications

Lanchao Zhang, **Tao Jiang**, **and Yingsong Li**
College of Information and Communication Engineering, Harbin Engineering University
Harbin 150001, China

Abstract— A dual-band printed antenna for wireless local area networks (WLAN) applications is presented in this paper. The proposed antenna is printed on a FR4-epoxy substrate with a dielectric constant of 4.3 and an overall size of $40 \times 40 \times 1.6\,\mathrm{mm}^3$. The antenna consists of two strips which locate at the top and bottom sides of the substrate respectively. The top one is fed by a $50\,\Omega$ microstrip line directly, and operates in 5.8 GHz band. The bottom is fed by the coupling current and operates in 2.4 GHz band. The two strips have overlapping parts in space, which have a good effect on improving impedance matching and expanding the bandwidth. Good return loss is achieved, higher than 25 dB in the low frequency band and 20 dB in the high frequency band respectively. It is shown that the proposed antenna is suitable for WLAN applications.

Compact Reconfigurable Antenna Design Based on Variable Capacitive Loading

Abstract— A planar frequency reconfigurable antenna is proposed with variable capacitors. The proposed one is designed of a planar monopole antenna with a controllable load as shown in Fig. 1. Resonant frequencies are adjusted by variable capacitive loading of a varactor diode [1]. To achieve compact design, the monopole is designed with meander shape, while the bias circuit isolates between RF and DC paths. For the performance analysis, the equivalent circuit has been constructed with a variable capacitor using the Agilent ADS [2]. In addition, electromagnetic (EM) simulation is conducted using the ANSYS HFSS. The proposed antenna has been implemented on an epoxy substrate with a size of $32 \times 35 \times 1\,\text{mm}^3$. The implemented frequency variable monopole antenna has been verified by comparing prototypes with designed capacitors and ones with biased varactor diodes. The experimental results show expected resonant frequencies corresponding to loading capacitors as shown in Fig. 2. Moreover, the measured radiation patterns keep almost the same shape and performance for variable resonances. The proposed antenna has presented the resonant frequency variations from 2.25 GHz to 2.42 GHz.

Unequal Power Divider Using Series RC Circuit for Improved Isolation

Young Kim[1], **Seok-Hyun Sim**[1], **and Young-Chul Yoon**[2]

[1]Kumoh National Institute of Technology, Republic of Korea
[2]Catholic Kwandong University, Republic of Korea

Abstract— This paper presents a high dividing ratio unequal power divider with improved isolation using a series RC circuit. To improve isolation, we used an isolation component composed of a series resistor and capacitor circuit. This circuit is placed at an arbitrary position in the quarter-wave transmission line to achieve power division. In addition, to achieve a high dividing ratio, the low impedance line is composed of a capacitive loaded transmission line with slow-wave characteristics. To validate the performance of the proposed unequal power divider, we simulated and fabricated the unequal power divider for an operating frequency of 1 GHz. The experimental results are in good agreement with the simulated results.

Microwave Amplifier Design for Solid State Radar Transceivers at X-band

Abstract— The next generation of military, civilian, and commercial radar transmitters (T/R) would rely on various distributed architectures employing solid state power amplifiers (SSPA) using gallium nitride (GaN) device technology that promise to play an important role. These devices can support systems with higher sensitivity, increased detection range and improved reliability with lower cost and weight. The GaN Monolithic Microwave Integrated T/R Circuit (MMIC) enables improved resolution and DC power distribution efficiency in Radar Systems. The first challenge for the T/R module that is presented in this paper is fitting all the components in a package designing a suitable amplifier. The analytical structure followed to create amplifier bias circuits is presented in this paper. A discrete GaN on SiC HEMT was used. Incorporating matching circuits to bias circuits, various simulations are extracted to find what bias circuits do not affect the overall behavior of the amplifier. Simulation results show good matching $S_{11} = -12.2\,\text{dB}$, $S_{22} = -14\,\text{dB}$ and a gain value at 15.4 dB, almost the maximum supported. With new values S parameters resulting from the design of this circuit, $K = 1.3$ and $D < 1$ which mean that the circuit is stable. In this paper, the single stage X-band amplifier design which uses only one MMIC amplifier has an excellent performance at 10 GHz and can be utilized in Solid State T/R module for advanced Phased Array Radar Systems.

Microwave Dielectric Properties of $(Bi_{1-x}Eu_x)NbO_4$ Ceramics

S. Devesa, **M. P. Graça**, **and L. C. Costa**
I3N and Physics Department, University of Aveiro, Aveiro 3810-193, Portugal

Abstract— Bismuth-based dielectric ceramics are well known as low-firing materials and have been studied for applications as multilayer capacitors. Various attempts have been undertaken to improve the dielectric properties of $BiNbO_4$, such as the addition of oxides or the substitution of bismuth by lanthanides.

In this work, $(Bi_{1-x}Eu_x)NbO_4$ ($x = 0.00$, 0.05, 0.10, 0.20 and 0.50) samples were prepared using the sol-gel method through the citrate route.

The solution was dried at 400°C for 48 h to evaporate the solvent and the obtained powders were thermally analyzed by differential thermal analysis.

The fine particles were pressed into cylinders and then treated at six different temperatures, between 400 and 1150°C, using a dwell time of 4 h, with a heating rate of 5°C/min. This heat treatments were performed in agreement with the differential thermal analysis results.

The structure was studied by X-ray diffraction and the morphology by scanning electron microscopy.

The measurement of the complex permittivity was made using the small perturbation theory, with a cavity operating in TE_{01n} mode, at resonant frequency of 2.7 GHz.

In this method, the resonance peak frequency and the quality factor of the cavity, with and without a sample, can be used to obtain the complex dielectric permittivity of the material. We measured the shift in the resonant frequency of the cavity, Δf, caused by the insertion of the sample, which can be related to the real part of the complex permittivity, ε', and the change in the inverse of the quality factor of the cavity, $\Delta(1/Q)$, which gives the imaginary part, ε''.

The inclusion of europium allowed an increase of the complex permittivity and a decrease of the dielectric losses.

THz Generation of Bloch Oscillators from SiC Structures due to Strong Electric Fields

V. I. Sankin, A. V. Andrianov, A. G. Petrov,
S. S. Nagalyuk, P. P. Shkrebiy, and A. O. Zachar'in
Ioffe Institute, 26 Politekhnicheskaya, St. Petersburg 194021, Russia

Abstract— In this work the experimental and theoretical studies of the THz electroluminescence (EL) were carried out on SiC natural superlattices (NSL) structures of 4H-SiC, 6H-SiC and 8H-SiC polytypes [1] at $T = 5$–10 K. Figures 1(a), 1(b), 1(c) show typical THz EL spectra for the 8H-, 6H- and 4H-structures. The results of experimental measurements can be summarized as follows: i) When electric field applied to natural SL exceeds certain threshold value single THz emission line appears in the spectra. The frequencies of these lines demonstrate increasing linear dependence on applied voltage. An integrated THz emission is linearly polarized along an axis of natural SL with polarization degree above 50%. For the polytypes 8H-, 6H-, 4H-SiC threshold electric fields required for observation of THz emission are 50, 85 and 170 kV/cm respectively. The current through the structure is proportional to a voltage in the degree 5/2 [2]. The THz emission peaks for hexagonal polytype family 8H-SiC, 6H-SiC, and 4H-SiC are located in accordance with increasing of the miniband width value [2]. These results are the first unambiguously demonstration of the Bloch Oscillation regime. ii) As is seen, new emission line at about 12.5–13 meV appears at higher electric fields and currents in the spectrum of the THz emission from 8H-, 6H- and possibly from 4H-SiC structures. We attribute this line to electron optical transitions between several Wannier-Stark ladders in the slightly higher second minimum due to current injection from n^{++}-n^{-} junction of n^{++}-n^{-}-n^{+} structure to this minimum. The THz emission power about 40 μW is a well basis for development of electrically tuned emitters with frequency 1.2–3 THz.

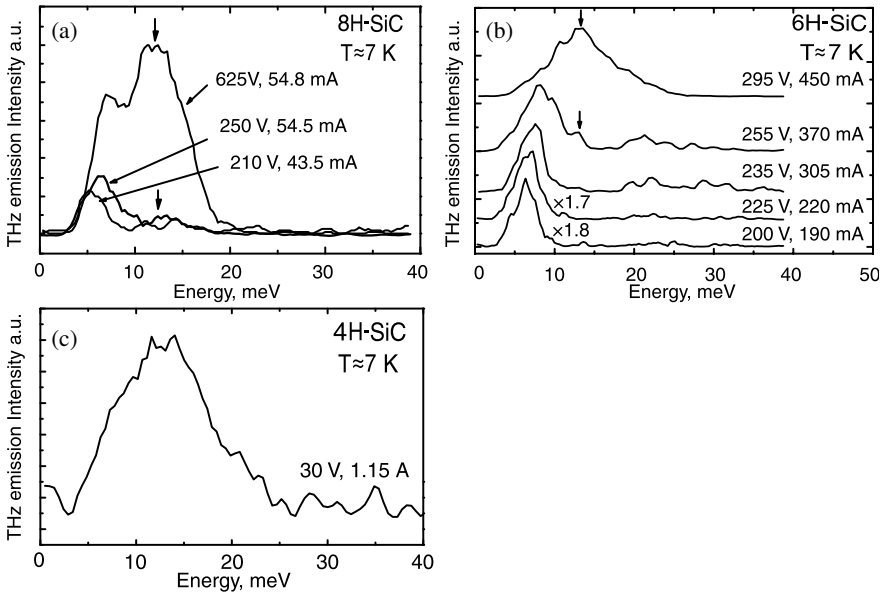

Figure 1: THz EL spectra of the structure with NSL (a) 8H-SiC, (b) 6H-SiC, (c) 4H-SiC.

Electromagnetic Emission Analysis of a Multiband EMI Filter Based on Sub-wavelength Resonators

J. M. Ruiz[1], **I. Gil**[2], **and M. Morata**[1]

[1]Escuela Universitaria Salesiana de Sarriá, Psg. Sant Joan Bosco 74, Barcelona, E-08017, Spain
[2]Department of Electronics Engineering, UPC Barcelona Tech, Colom 1, Terrassa, E-08222, Spain

Abstract— The increasing pollution of the electromagnetic emissions requires the design of electronic systems which are immune to electromagnetic interferences (EMI) and, more specifically, to radiofrequency interference (RFI). Recent developed solutions in order to reduce the cost and dimensions of conventional EMI filters consisting of strategies based on sub-wavelength resonator have been proposed [1]. However, these structures can provoke electromagnetic emissions that can affect to the nearly electrical components. This fact is especially critical in small electronic devices where analogue, digital and RF signals coexist in a reduced area, such as wireless sensor networks motes. In order to determine if metamaterial resonators can be used as EMI filter on these small electronic devices, in this paper the electromagnetic emission of sub-wavelength EMI filter based on SRR and CSRR resonator has been analysed by means of near E and H fields simulation with the FDTD SEMCAD [2] software. Fig. 1 shows the designed filter [3]. The target bands are 900 MHz (RFID UHF), 1.8 GHz (GSM) and 2.4 GHz (ISM, Instrumentation, Scientific and Medical). A 3-stages/5-stages rejection band filter was designed and fabricated in a PCB. The preliminary simulation results (Fig. 2) show that the more significant emissions take place at higher frequencies, the 1.8 GHz GSM band and ISM band (2.4 GHz) and are located at the resonators' surface.

Overhead and Cable Transmission Lines Magnetic Fields: Standardization, Estimation, and Design

N. B. Rubtsova and A. Yu. Tokarskiy
FSBSI "Research Institute of Occupational Health", Moscow, Russian Federation

Abstract— Main principles of power frequency (50/60 Hz) magnetic field (MF) occupational and general public safety are analyzed taking into account international approach to maximum permissible levels achieving.

Overhead and cable power transmission lines magnetic field strength estimation algorithm is presented. Example of 500 kV overhead transmission line power frequency MF strength distribution is presented in comparison with 500 kV cable transmission line MF distributions. Cable transmission line (CL) MF distribution considered on the example of two 500 kV CL parallel circuits alive to the same electric bus. According with the problem of general public electromagnetic safety maintenance is suggested the optimal circuits' arrangement with changed order of the phases that allow reducing the 50 Hz MF values to maximal permissible levels (hygienic standards of general public exposure).

It is shown that multiphase sources create the field of elliptic polarization, which most root-mean square strength value is on the ellipse major axis, whereas result values calculation by components with Pythagorean Theorem use lead to errors with the increase of real value to 41%. By the example of 500 kV lines is shown the differences between results of the applied calculation methods. For 500 kV cable lines the ways of MF value decrease to permissible levels under different kinds of it lying are examined.

In addition it is shown that muff coupling use with cables and muffs locations in the corners of equilateral triangle under correctly changed order of the phases as well as slight increase of cable depth gives the possibility to avoid the ferromagnetic screens arrangement, and to cut costs.

Electromagnetic Compatibility of Contactless Power Transfer Modeled in FEM Analysis Software

R. Fajtl and K. Buhr
Department of Electric Drives and Traction, Faculty of Electrical Engineering
Czech Technical University in Prague, Technická 2, 166 27 Prague 6, Czech Republic

Abstract— This paper deals with electromagnetic compatibility of Contactless power transfer (CPT) and its effects on the surrounding electric devices. In the first part of this paper there are mentioned mathematical equations which describe basic parameters of CPT. Most of these equations feature the CPT transformer which is the main part of CPT.

CPT operates at high frequency which causes growth of reactance value. With increasing value of reactance the efficiency of CPT highly decreases. In the second part of the paper are listed four basic electric circuits using capacitors to compensate reactive power and increase the efficiency of CPT. This part also shows basic equations describing parameters of compensated CPT such as efficiency, operational frequency and others.

The third section of this work is about creating a model of CPT transformer in a multiphysics FEM software. From analysis of the model of CPT transformer in this multiphysics software the basic parameters of electromagnetic field is derived. Layout of electromagnetic field is shown and described in this part.

The last part of this paper is about valorization of electromagnetic field and its effects on the CPT device and its surroundings. Electromagnetic compatibility of any electric device has to be explored because it may cause serious hazards to others electric devices. Operation of CPT can disrupt functionality of electric devices such as pacemaker, security electronics and others electric devices in its surroundings.

The whole paper is about basic principles of CPT functions and its effects on its surroundings. It shows layout of electromagnetic field of the CPT and it deals with possible interference with other electric devices.

Parallel Imaging Based on Multicore DSP for FMCW SAR

Chengfei Gu, **Wenge Chang**, **and Xiangyang Li**
College of Electronic Science and Engineering
National University of Defense Technology, Changsha, Hunan 410073, China

Abstract— The combination of frequency modulated continuous wave (FMCW) and synthetic aperture radar (SAR), which leading to compact structure and high resolution imaging sensor, has been a hot spot in recent SAR research. Predictably, FMCW SAR will have enormous potential application in remote sensing and mapping, whereas the main challenge of this light-duty and high-resolution sensor is the realization of real-time imaging, which limited to restricted load and time-consuming autofocus processing. A Ku-band FMCW SAR system is demonstrated which has the capability of real-time processing with the application of single high-performance multi-core DSP. The navigational data of platform movement, which particularly used for high precision motion compensation, is accurately measured by GPS and accelerometer. Furthermore, to realize the real-time processing, an effective parallel processing approach based on multicore DSP is presented in detail, also the time consumption of key steps are minutely listed. To verify the capability of real-time processing, an automobile experiment is campaigned, which has equipped a FMCW SAR system on the top of the car. The obtained results of real-time processing and post-processing are presented and compared, processed with 35 cm and 25 cm resolution, respectively.

The main content of this paper is organized as follows briefly.

1. The selection of imaging algorithm and motion compensation strategy are presented for FMCW SAR real-time processing.

2. Section 2 depicts the processing flow of real-time imaging, also the time consumptions are minutely listed. Fig. 1 shows the data flow of real-time processing.

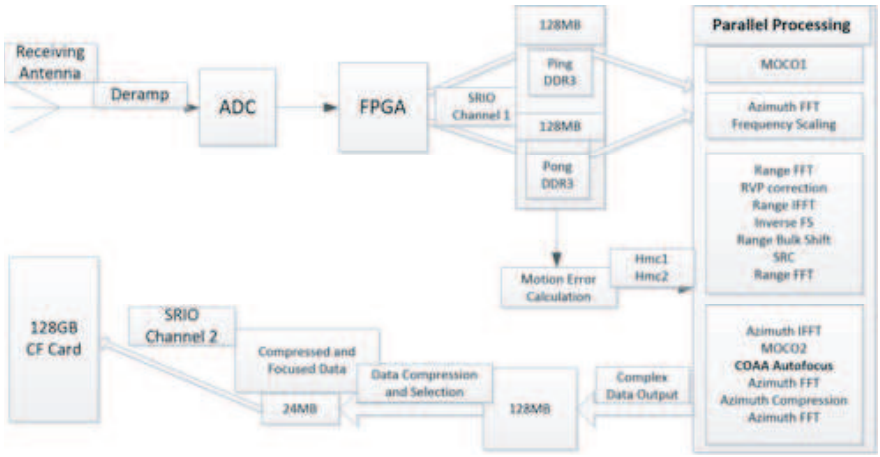

Figure 1: Data flow of real-time processing.

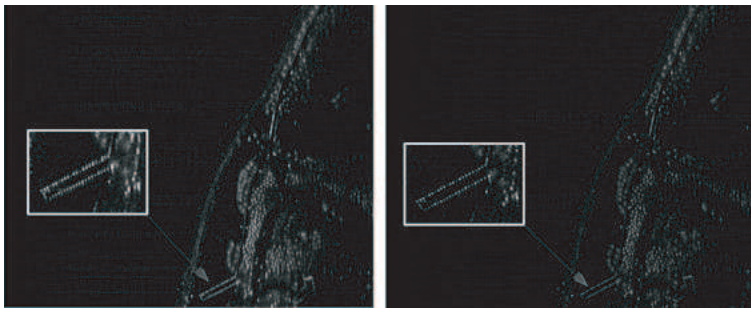

(a) (b)

Figure 2: Comparison of (a) real-time processed and (b) post-processed images.

3. In Section 3, the results of real-time and post processing are presented and compared, also the image performance for corner reflecters is analyzed in detail. The SAR images of the real-time processing and the post-processing are shown in Fig. 2 for resolution comparison.

4. Section 4 gives the conclusion of this paper.

A compact real-time processing SAR sensor is presented in this paper. On the foundation of this compact SAR system, the FSA which also contains high precision motion compensation and time-consuming COAA autofocus processing is efficiently realized in parallel with a single eight-core DSP. Furthermore, both the real-time processed result and the post-processed result of experiment are presented and compared, also the performance of SAR images are analyzed in detail.

Monitoring of Buoyancy Effects to Structures by Tsunami Water after Heavy Seismic Shocks

Shigehisa Nakamura
Kyoto University, Japan

Abstract— This work concerns on monitoring of structures under heavy seismic shocks. The author concentrates his interest to introduce some typical problems of structures. Specific references are found in the coastal zones at the event of the 201l Earthquake in the northwestern Pacific. It is discussed what could be the key in order to realizing the hazardous damages of the structures especially in the coastal zones.

Monitoring of Orographic Patterns in Relation to Tsunami Earthquake

Shigehisa Nakamura
Kyoto University, Japan

Abstract— This work is a note to problems on monitoring of orographic processes in relation to tsunami earthquake on the planet earth. The author is now in need to see a problem of a orographic patterns on the earth. For his convenience, Global orographic patterns are studied. The orographic patterns found in the geological surveys are selected as references. In a scope of any electromagnetics scope, it has been hard to consider any application can be effective for orography in the past. Now, the author has to notice about application of electromagnetic techniques for orography.

Reconstruction Algorithm through Laplacian Image in X-Ray Differential Phase-Contrast Computed Tomography

Tetsuya Yuasa[1], **Naoki Sunaguchi**[2], **and Masami Ando**[3]

[1]Yamagata University, Japan
[2]Gunma University, Japan
[3]Tokyo University of Science, Japan

Abstract— Phase-contrast CT reproduces a three-dimensional (3D) distribution of refractive indices in biological soft tissue with high contrast, and provides pathology and physiology with important information concerning biological soft tissues, e.g., breast cancer tissues. Typically, phase-contrast CT imaging system acquires the derivative of projections required for reconstruction. Then, a refraction-contrast CT image is reconstructed from the differential projections by convolving them with a signum function (i.e., $\mathrm{sgn}(\xi) = 1$ for $\xi \geq 0$, -1 for $\xi < 0$) and then applying a filtered backprojection (FBP) method. As, originally, FBP is an algorithm derived from a continuous model, the CT measurement must satisfy the sampling theorem for obtaining an artifact-free image. That is, $N_p \approx 2/\pi \cdot N_b$, where N_b and N_p are the number of bins in a single projection and of projections, respectively. When the number of detective elements in the horizontal direction of the two dimensional detector is assumed to 4000, the required number of projections is, indeed, 2500. In addition, due to the low photon count efficiency of the system, the x-ray exposure time to acquire a single projection is relatively long compared with the conventional CT. Therefore, use of FBP is disadvantage in terms of measurement time.

For this problem, we devised a novel reconstruction scheme for reduction of the number of projections to be measured. First, we obtain the second derivatives of the projections by numerically differentiating the differential projection measured. Then, we reconstruct the Laplacian of refractive-index image to be reconstructed from the second derivative projections using algebraic reconstruction technique with total variation regularization. Finally, we obtain the refractive-index image by solving the Poisson equation with the reconstructed Laplacian image being a source. In this presentation, we theoretically prove the reconstruction algorithm, and show its efficacy by demonstrating the experimental data.

An Efficient Approach of Lengthening Battery Age and Working Hours through Redistributing Battery Packs

L. Chen[1], **X. H. Feng**[1], **G. C. Wan**[2], **and M. S. Tong**[2]

[1]School of Electrical and Electronic Engineering, Shanghai Institute of Technology, Shanghai, China
[2]Department of Electronic Science and Technology, Tongji University, Shanghai, China

Abstract— The smart power management devices have wide applications in electric vehicles and energy storage systems. For the sake of facilitating battery management, individual batteries are generally grouped to form battery packs by serial and parallel connections and a complete power supply system consists of the battery packs in serial and parallel connections. Initially, the performance of each individual battery which constitutes battery packs is different and the difference between individual batteries will be gradually enlarged during the use of batteries, resulting in a significant degradation of the battery packs' performance. Because the released maximum power by a power supply system is determined by the minimum-power battery pack and the minimum-power battery pack will be seriously harmed if it continuously discharges and we must stop its discharging process. Similarly, if the maximum-power battery pack has a full charge, we must stop its further charge to prevent it from being harmed. When the difference of performance between battery packs is magnified, the working hours of power supply system will sharply reduce and the age of batteries will also be shortened greatly.

In this paper, we fully investigate a set of lithium-iron-phosphate batteries and propose an efficient approach for lengthening the working hours and age of the batteries by redistributing battery packs. The approach analyzes the data about the state of charge (SOC) and voltage of battery packs and then quantifies the level of their inconsistency between battery packs. The redistribution of battery packs will be automatically managed according to the level of inconsistency and we have designed a smart electronic device for controlling the process. The experimental tests show that the approach can significantly lengthen the working hours and age of the batteries. We will show the details of design and testing results in the presentation.

An Accurate Estimation for the State of Health of Lithium-ion Batteries by Using Fuzzy Logic System

L. Chen[1], **F. Q. Xiong**[1], **G. C. Wan**[2], **and M. S. Tong**[2]

[1]School of Electrical and Electronic Engineering, Shanghai Institute of Technology, Shanghai, China
[2]Department of Electronic Science and Technology, Tongji University, Shanghai, China

Abstract— Lithium-ion batteries have been widely used as a power source for electric vehicles and their performance significantly impacts the operation of electric vehicles. The state of health (SOH) and state of charge (SOC) are the two important indexes reflecting the state of batteries. However, the study on the SOH has not received a sufficient attention compared with the study for the SOC and there has not been a mature estimation method for the SOH. As the battery management system of electric vehicles gets constantly improved, seeking an accurate estimation method for the SOH of lithium-ion batteries has become more and more important. The SOH estimation belongs to a nonlinear problem which requires a highly accurate solution and the traditional linear estimation methods cannot meet the estimation requirements. The lack of accurate estimation for the SOH has seriously affected the practical applications of lithium-ion battery packs and it is very imperative to find a good solution.

In this paper, we propose an equivalent circuit model to accurately estimate the SOH for lithium-ion batteries. The residual capacity and equivalent DC resistance of the lithium-ion batteries under different SOHs can be easily obtained by charging and discharging experiments for the batteries and their relationships to the SOHs can be figured out to define the corresponding fuzzy rule table. Also, the static estimation and dynamic estimation are combined together so that the system reliability and the estimation accuracy can be improved. The simulated results show that the scheme can remarkably enhance the estimation accuracy for the SOH of lithium-ion batteries. We will show the details of the scheme and testing results in the presentation.

Estimation of Equivalent Model Parameters for $LiFeO_4$ Batteries Based on Particle Swarm Optimization

L. Chen[1], **T. Geng**[1], **Q. Zhang**[1], **G. C. Wan**[2], **C. H. Jiang**[2], **and M. S. Tong**[2]

[1]School of Electrical and Electronic Engingeering, Shanghai Institute of Technology, Shanghai, China
[2]Department of Electronic Science and Technology, Tongji University, Shanghai, China

Abstract— Power batteries are very important components in electric vehicles and they have a significant impact on the performance and security of a whole vehicleTo ensure the safe and reliable operation of batteries,designing an optimal battery management system (BMS) is very essentialThe BMS manages the batteries based on their states and instructions from a vehicle management system (VMS)The voltage, current, and temperature of batteries can be measured directly by sensors while other parameters such as the state of charge (SOC) has to be estimated indirectly by certain algorithms which usually rely on the battery model and its parametersThe battery model and parameters are essential because they form the basis of loop simulations for hardware and SOC estimation, and also provide a reference for the control of BMS

In this paper, we propose a unified form of equivalent circuit model for $LiFeO_4$ batteries based on the analysis of similarity between the internal mechanism and external characteristic of a chemical power source. A two-order equivalent circuit of $LiFeO_4$ batteries is built and their resistance and capacity are estimated with a least square method (LSM) and particle swarm optimization (PSO). By comparing the results from different estimation methods, we find that the relationship between the SOC and the electric motive force (EMF) or EMF-SOC can be significantly affected by the temperature. We also build a BP neural network in which the EMF and temperature are taken as inputs while the SOC works as an output and the results are used to estimate the SOC. The simulated and experimental results show that the proposed estimation method can accurately estimate the SOC for$LiFeO_4$ batteries.

Noncoherent Detection for Multi-hop Amplify-and-forward-based Multi-branch Cooperative Diversity Systems

Minghe Mao[1], **Ning Cao**[1], **Yunfei Chen**[1, 2], **and Haobing Chu**[3]

[1]School of Computer and Information, Hohai University, Nanjing 210098, China
[2]School of Engineering, University of Warwick, Coventry CV4 7AL, UK
[3]School of Engineering, UBC Okanagan, Kelowna, BC V1V 1V7, Canada

Abstract— Since the actual distribution of the received signals in multi-hop amplify-and-forward (AF) relaying transmission is no longer Gaussian, which is caused by the multiplication of fading gains and noise, a new fitted distribution named as logistic distribution is used to derive a novel noncoherent detector based on the maximum likelihood (ML) method. In order to get better performance of the receiver, one or more multi-hop AF links are added to form a multi-branch cooperative diversity system. Therefore, at the destination, combining method is applied to combine several signals together to obtain better diversity gains. Numerical results show that the new detector based on the logistic distribution outperforms the conventional energy detector. Also, it is shown that the performance of receiver is significantly improved when combining method is applied in the multi-branch cooperative diversity system especially when the number of branches increases.

Preliminary Numerical Results: Figure 1 shows the preliminary results for this work. Assume that, the number of hops is 5. Compared with the conventional energy detection on single branch, the new detector based on logistic fitting distribution has better bit-error-rate (BER) performance. One sees that the BER of the new detector can further decrease when the number of combined branches increases and the maximum ratio combining method is applied.

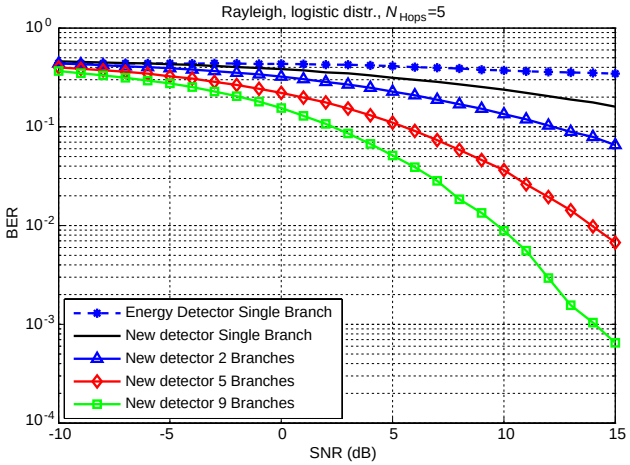

Figure 1: BER vs. SNR, new detector using logistic fitting parameters for combining different numbers of branches (single, $M = 2$, $M = 5$, $M = 9$), compared with the conventional energy detection on single branch with 5 hops AF relaying.

A New Design of High-speed Decimal Direct Digital Frequency Synthesizer

Guochun Wan, **Gui Zhu Yin**, **Jie Zhang**, **and Mei Song Tong**
Department of Electronic Science and Technology
Tongji University, 4800 Cao'an Road, Shanghai 201804, China

Abstract— Direct digital synthesizer (DDS) has been widely used in wireless communications due to its convenience and high frequency resolution. Although the resolution of the current design has been high, the binary operation phase accumulation restricts the minimum resolution of the DDS which is only $1/2^M$, where M is the number of accumulator bits, and this cannot meet a special output frequency requirement. In some applications, for example, in the terminal of very long baseline interferometry (VLBI) technology, more precise frequency signal is needed to adjust the received microwave signal. To satisfy this demand, the mixture of decimal and binary operation is used to enhance the DDS minimum frequency resolution to $1/(2^M 10^N)$, where M is the number of binary bits and N is the number of decimal bits.

The original DDS adopts a binary algorithm which limits the output frequency resolution in some cases and cannot switch the frequency and phase quickly. To solve this problem, the high-speed decimal DDS was proposed to replace the original DDS algorithm by using the mixture of decimal and binary algorithms and pipelined segment accumulator to realize the phase accumulation. It also uses a look-up table (LUT) to achieve a fast waveform output so that a high-speed and high-resolution performance can be achieved. We implement the new DDS design with VHDL language and its good performance has been demonstrated by simulations.

Coverage Impact for Data Traffic Profiling in WCDMA Networks

Karolis Žvinys, Darius Guršnys, and Evaldas Stankevičius
Department of Telecommunication Engineering
Vilnius Gediminas Technical University, Lithuania

Abstract— A packet data traffic volume and a packet switch related services climb upward in UMTS networks. Nowadays UTRAN is a key data carrier in mobile communications, while other generation networks are still implemented. Even serving a huge amount of customers and processing an enormous traffic quantity it is still required to ensure a sufficient quality of service (QoS) level. With rapid development of mobile networks, operators need to continually focus on quality. Quality of service (QoS) is a comprehensive reflection of the service capability of a WCDMA system. It defines how satisfied the users are with the services received from cellular networks. Therefore, the improvement of efficiency for provided services has become a major concern for operators.

One of the way to maintain differentiated services (DiffServ) for the large number of satisfied users is QoS management. Basically QoS can be managed for the main four UMTS traffic classes: conversational, streaming, interactive and background.

According to these classes three different user groups (Gold, Silver, Copper) are distinguished, which are formed by combining several network parameters related to QoS assurance. In such a way customers can be controlled in cellular networks providing them prioritized services. However could we already assume that the prioritization of individual user will ensure guaranteed priority service anytime and anywhere?

The goal of this study is to discover an impact for users received data services with individual QoS based on uneven network conditions. Therefore the study investigates three differently profiled customers which belong to background WCDMA traffic class. Main focus is paid for customers achieved uplink and downlink throughput evaluation regarding to variable radio network environment. Data transfer rate measurements are carried out in a commercial mobile network on heavy loaded cells in order to reach the results closest to reality. To draw an impact of radio conditions variation, a radio signal strength changes gradually for a user with a higher priority. The performance of the user experience is analyzed by the metrics of data rate and channel quality. Received benefits of the user service satisfaction related to radio environment changes is provided graphically. The drawbacks of prioritization the customers in cellular networks are introduced in the work also. On this study user profile QoS management over CN and UTRAN network has been applied only. It means that QoS profiling over Iub/Iur links was not involved into consideration.

The investigation process consists of analysis of related works on Section 2. Section 3 provides a determination of user profiles. The rest part of research presents the obtained results on Sections 4, 5 and 6. This includes NodeB selection, HSDPA and HSUPA users profiling topics. Finally conclusions are introduced in Chapter 7.

A Nyström-based Approach for Solving Time-domain Magnetic Field Integral Equation

W. J. Chen, **G. C. Wan**, **J. Zhang**, **and M. S. Tong**
Department of Electronic Science and Technology
Tongji University, 4800 Cao'an Road, Shanghai 201804, China

Abstract— Transient electromagnetic (EM) problems can be formulated by a time-domain integral equation approach. For conducting or homogeneously penetrable objects, the time-domain surface integral equations (TDSIEs) including the time-domain electric field integral equation (TDEFIE), time-domain magnetic field integral equation (TDMFIE), or their combination can be applied. Traditionally, the TDSIEs are solved by the method of moments (MoM) in spatial domain and a march-on in time (MOT) scheme in temporal domain. The MoM requires a well-designed basis function like the Rao-Wilton-Glisson (RWG) basis function which needs conforming triangular meshes in geometric discretization and double surface integrations in evaluating matrix elements. The MOT scheme, on the other hand, suffers from a late-time instability problem although some improved versions have been proposed in recent years. The instability and accuracy are still dependent upon the choice of time step.

In this work, we propose a hybrid scheme to solve the TDMFIE for transient scattering problems by conducting objects. Compared with the TDEFIE, the TDMFIE is thought of little more difficult to solve due to the nature of its integral kernel. We use the Nyström method to discretize the spatial domain while employ the MoM with Laguerre basis and testing functions to discretize the temporal domain for the TDMFIE. The merits of Nyström method in spatial domain includes the simple mechanism of implementation, removal of basis and testing functions, and allowance of using nonconforming meshes. Although the method requires an efficient treatment for hypersingular integrals, we have developed a robust technique to handle them. The time-domain MoM (TDMoM) with Laguerre basis and testing functions is superior to the MOT because the Laguerre function can naturally enforce the causality and also the Galerkin's testing scheme can fully eliminate the numerical instability with a march-on-in-degree (MOD) procedure. A numerical example for EM scattering by a conducting cylinder is presented to illustrate the scheme and its robustness has been verified.

A Hybrid Scheme for Solving Transient Electromagnetic Problems with Conductors

W. J. Chen, **G. C. Wan**, **J. Zhang**, **and M. S. Tong**
Department of Electronic Science and Technology
Tongji University, 4800 Cao'an Road, Shanghai 201804, China

Abstract— Solving transient electromagnetic (EM) problems is essential in many applications such as the design of radar cross section of aircrafts and design of some antennas or microwave circuits. The problems are usually of broadband, nonlinear, and time-varying characteristics and can only be described by time-domain governing equations. Although time-domain differential equations can be used to solving the problems, the time-domain integral equations (TDIEs) may be preferred in many situations due to their unique merits. The TDIEs could be in different forms and they are electric field integral equation (EFIE), magnetic field integral equation (MFIE), and combined field integral equation (CFIE), in a time-domain form, if objects are conducting or homogeneously penetrable.

Those TDIEs are usually solved by combining the method of moments (MoM) in spatial domain and a march-on-in-time (MoT) scheme in temporal domain. The MoM requires a well-designed basis function like the divergence-conforming Rao-Wilton-Glisson (RWG) basis function or curl-conforming edge basis function, resulting in an inconvenient implementation. On the other hand, the MoT scheme is conventionally inefficient and inherently unstable due to the low- and high-frequency modes of creeping into the solution. The late-time instability of MoT has not been fully solved albeit many improved versions have been developed in recent years.

We propose a novel hybrid scheme to efficiently solve the time-domain EFIE for transient EM problems with conductors. The Nyström method instead of the traditional MoM is used in spatial domain while the MoM instead of the conventional MoT is employed in temporal domain. The benefits of Nyström method in spatial domain include the simple mechanism of implementation, removal of basis and testing functions, and allowance of using nonconforming and low-quality meshes. In time domain, we use the MoM with Laguerre basis and testing functions which was proposed by Jung et al. and it is superior to the MoT scheme because the Laguerre function can naturally enforce the causality. Using a Galerkin's testing, we can eliminate the numerical instability through a march-on-in-degree (MoD) procedure. We present a numerical example to demonstrate the hybrid scheme and its robustness has been observed.

Influences of High Relative Humidity on Extremely Low Frequency Electric Field Measurements

Leena Korpinen[1], **Hiroo Tarao**[1, 2], **Rauno Pääkkönen**[1], **Oleksandr Okun**[3, 4], **and Lauri Sydänheimo**[1]

Kagawa National College of Technology, Kagawa, Japan
[3]LLC Soyuzenergoproekt, Kharkiv, Ukraine
[4]Department of Electrical Energy
National Technical University "Kharkiv Polytechnic Institute", Kharkiv, Ukraine

Abstract— An earlier study indicated that humidity can influence electric field measurement results; thus, it is important to take into account when these results will be compared to the values given in different exposure safety guidelines (e.g., the International Commission on Non-Ionizing Radiation Protection (ICNIRP) or Directive 2013/35/EU of the European Parliament and of the Council on the minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (electromagnetic fields). The aim of the study was to investigate extremely low frequency (ELF) electric field measurements in a climate room when the electric field meters were in a high-humidity environment before the measurements. We used the commercial three-axis meters EFA-3 and EFA-300, which contained a bandwidth ranging from 5 Hz to 2 kHz. We employed two methods: (1) the sensor was placed on a tripod; and (2) the sensor was fixed using a plastic clamp and was suspended by three fishing lines. With Method 1 (with both meters), the first experiment period included 7 measurements, when the relative humidity was 75% and temperature varied from 1°C to 25°C and the electric fields varied from 1 kV/m to 25 kV/m. Then, the meter measurements took over 3 hours, exposing it to humidity varying from 79% to 95%. Then, the second measurement period began. With Method 2, the protocol was similar; however, the time that the meters endured high humidity was over 5 hours. In the first periods of Method 1, the maximum percentage error was 5.6%, and in Method 2, it was 11.9%. In the second period, the maximum percentage errors were 14.5% (Method 1) and 24.4% (Method 2). We evaluated only two sensor types because there are a limited number of commercial sensors available for electric field measurements. Therefore, our material is quite limited. In conclusion, it can be stated that in the future it is important to also take humidity into account before the measurement period, not only during electric field measurements.

Examples of Variation in Measured ELF Electric Fields under 400 kV Power Lines

Leena Korpinen[1], **Rauno Pääkkönen**[1], **Hiroo Tarao**[1, 2], **Oleksandr Okun**[3, 4], **and Lauri Sydänheimo**[1]

[1]Tampere University of Technology, Tampere, Finland
[2]Department of Electrical and Computer Engineering
Kagawa National College of Technology, Kagawa, Japan
[3]LLC Soyuzenergoproekt, Kharkiv, Ukraine
[4]Department of Electrical Energy
National Technical University "Kharkiv Polytechnic Institute", Kharkiv, Ukraine

Abstract— The physiological effects and public exposures of electromagnetic fields have been studied at Tampere University of Technology (TUT). Parts of the earlier projects have also measured the electric fields in the same place under 400 kV power lines. The aim of the work was to investigate how the measured ELF electric fields fluctuate in the same measurement place when humidity varied. When we compare the measured values to the recommendations (e.g., guidelines of the International Commission on Non-Ionizing Radiation Protection (ICNIRP) or Directive 2013/35/EU), it is important to know how humidity influences the measured results. During three days, the electric field measurements were performed at three places near 400 kV power lines in Finland. The electric field strength was measured with two 3-axis commercial electric meters: EFA-3 meter (accuracy ±5%, RMS) and EFA-300 meter (accuracy ±3%, RMS). In Place A, nine electric field measurements were performed; in Place B, five measurements were performed; and in place C, two measurements performed. In place A, the electric fields varied from 6.8 to 12.5 kV/m when relative humidity was from 70.5% to 86%. In place B, the electric fields were 5.1–8.2 kV/m when relative humidity ranged from 67% to 76 %, and in place C, the electric field was 0.90–0.92 kV/m when humidity was 68–76%. The measured electric fields varied significantly. For example, in place A the lowest electric field (6.8 kV/m, relative humidity 70.5%) was only 54% of the maximum value (12.5 kV/m, relative humidity 86.0%). In the example, the difference in relative humidity was 15.5%. The measurement material is quite limited; however, it is possible to find examples where the measured electric fields were quite different, when the humidity also varied. In the future, humidity is important to take account in electric field measurements.

Possible Methods for Limiting Exposure to the Electric Fields of High Voltage Power Lines on Active Implantable Medical Devices in the Human Body

Oleksandr Okun[1, 2], **Leena Korpinen**[3], **and Lauri Sydänheimo**[3]

[1]LLC Soyuzenergoproekt, Kharkiv, Ukraine
[2]Department of Electrical Energy
National Technical University "Kharkiv Polytechnic Institute", Kharkiv, Ukraine
[3]Department of Electronics and Communications Engineering
Tampere University of Technology, Tampere, Finland

Abstract— According to earlier studies, the electric field (EF) under a 400 kV power line in some conditions may disturb active implantable medical devices (cardiac pacemakers, implantable cardioverter defibrillator, and others) in the human body and affect their functioning. Therefore, it is reasonable to consider possible ways to limit the impact of EF on medical devices. One of the known methods of limiting EF intensity under power lines without changing the design of lines is to plant trees and shrubs under the power lines. The second simplest method of limiting the field intensity of transmission lines is to install grounded wires (shields) under lines' wires. In this case, the induced charges on grounded wires partially compensate for the EF produced by line wires and limit the field intensity. It is economically feasible to connect shields under the line wires to a voltage source and thus ensure the effective utilization of the cross section. It is clear that the potential of each lower wire for the shielding effect must be the opposite of the upper wire potential. In this case, as with the grounded wires, the charge on the lower wire has the opposite sign to the charge on the corresponding wire. However, the presence of potential on the lower shield wire increases the charge and, consequently, the shielding effect. The aim of the study is to consider the shielding effect of additional wires (with and without voltage) to reduce the EF intensity under high voltage power lines. The field intensity under power lines at the height above the ground level in this case is calculated by geometrically summing the fields generated by each conductor and its image separately. The charges on grounded and line conductors are determined by solving the system of Maxwell's potential equations. In the final paper, more details of the study will be presented. Examples will be shown of the results of calculating the EF generated under a 400 kV power line with additional shielding wires. The shielding effectiveness and the possibility of its application will also be estimated.

Negative Permeability from Random Particle Composites

Shahid Hussain
Smart Technologies Group, QinetiQ Limited
Cody Technology Park, Farnborough, Hampshire, GU14 0LX, UK

Abstract— Artificial media, such as those composed of periodically-spaced wires for negative permittivity and split ring resonators for negative permeability have been extensively investigated for negative refractive index (NRI) applications [1, 2]. This paper introduces an alternative method for producing negative permeability: granular (or particulate) composites incorporating magnetic fillers.

Artificial media, such as split-ring resonators, are designed to produce a magnetic resonance feature, which results in negative permeability over a narrow frequency range about the resonance frequency. The position of the feature is dependent upon the size of the inclusion. The material in this case is anisotropic, such that the feature is only observable when the materials are orientated in a specific direction relative to the applied field. A similar resonance can be generated in magnetic granular (particulate) materials: ferromagnetic resonance from the natural spin resonance of particles.

Although the theoretical resonance profiles in granular composites shows the permeability dipping to negative values, this is rarely observed experimentally due to resonance damping effects. Results are presented for carbonyl iron in spherical form and in flake form, dispersed in insulating host matrices. The two particle shapes show different permeability performance, with the magnetic flakes producing a negative contribution. This is attributed to the stronger coupling with the magnetic field resulting from the high aspect ratio of the flakes. The accompanying ferromagnetic resonance is strong enough to overcome the effects of damping and produce negative permeability. The size of random particle composites is not dictated by the wavelength of the applied field, so the materials are potentially much thinner than other, more traditional artificial composites at microwave frequencies.

Programmable Fiber-based in-band OSNR Monitoring for Flexgrid Coherent Optical Communication System

Abstract— With the rapid development of ultra-dense large capacity coherent WDM optical communication networks, the monitoring of in-band optical signal-to-noise ratio (OSNR) plays an essential role to ensure signal qualities. Different from the classic polarization-nulling method, we proposed and experimentally demonstrated a novel fiber-based programmable in-band OSNR monitoring method for flexgrid coherent transmission system, the OSNR monitor is based on linearly chirped fiber Bragg grating (LCFBG) and commercial thermal print head (TPH). For the coherent communication system, when the output power of the pre-amplifier at the receiving terminal is constant, degraded OSNR leads to decreased signal power and elevated ASE noise. Therefore, if the central spectrum (signal and in-band noise) is filtered by an ultra-narrow bandwidth optical filter, the output optical power is in proportional to the OSNR value, the influence of the filtered in-band ASE noise will be negligible with relatively high OSNR and the ultra-narrow bandpass filter is the key element for this technique. Based on the thermo-optic effect of the LCFBG, we used the in-house developed driver circuits and a LabVIEW based software to implement a programmable ultra-narrow passband optical filter for OSNR monitoring. Linear monitoring range of 9–27 dB OSNR values with wavelength ranging from 1530.6 to 1538 nm is achieved. The OSNR monitor has advantages of low cost, low insertion loss, large wavelength tunability and compatible with current optical fiber communication system.

Abstract— GaN:Mn epilayers were grown on Al_2O_3 substrate uisng MBE. XRD data showed two phase; intrinsic GaMnN and precipitates including MnGa and MnN. PL transitions (e, Mn) and (D, Mn) related to Mn were remarkably activated. The clear ferromagnetic hysteresis loops were obtained in both samples, which means a good formation of ferromagnetic coupling. The M-T curves revealed two Tc of $140 \sim 170$ K which is originated to intrinsic GaMnN and above 300 K which is originated to precipitates MnGa and MnN. These results agree with the results of XRD and PL. In order to reconfirm the magnetic property, ESR was performed. The samples clearly display the magnetic resonance at around 200–400 mT. ESR data depicted the shift of H_{center} (i.e., $\Delta H_{\text{center}} = 337 - H_{\text{center}}$ [mT]) is greater than 20 mT for samples, and the appearance of H_{center} with positive ΔH_{center} is indicative of the samples having obvious ferromagnetism. The incorporated Mn ions are in a 2+ ionic state (i.e., Mn^{2+}) because Mn^{2+} with the spin state of $S = 5/2$ typically exhibits a magnetic resonance with $g \approx 2$ when Mn was doped in semiconductors. The trend of XRD and PL results totally coincides with that of the results of SQUID and ESR.

Laser Sensor for Monitoring Methane Emission in the Arctic Permafrost

Abstract— Over the past 100 years, the rate of the temperature change in the Arctic increased almost twice compared to the average rate of warming on the Earth. The advantages of laser sensor for monitoring of methane from the permafrost are to create an alternative to the conventional visual monitoring and sampling, which are more expensive and inefficient in the Arctic. We developed Raman laser sensor for monitoring of methane emissions from the permafrost. The laser sensor is based on Nd: YAG laser (266 nm, 50 mJ, 5 ns, 100 Hz) and hyperspectral resolution detection system for resolving the isotopic shifts in the Stokes spectra.

Over the past 100 years, the rate of the temperature change in the Arctic increased almost twice compared to the average rate of warming on the Earth. Preliminary estimations predict the fast and wide degradation of permafrost across the Arctic by the year 2100. Deconservation of 0.1% of the organic carbon from the upper 100 m layer of permafrost (about 10,000 Gt of carbon in the form of CH_4) may double the atmospheric methane with radiation activity about 20 times higher than that of CO_2.

The advantages of Raman laser sensor for monitoring of methane from the permafrost are to create an alternative to the conventional visual monitoring and sampling, which are more expensive and inefficient in the Arctic.

CH_4 frequency spectra are characterized by isotopic shifts, depend on the isotopic mass (and neutrons) and can be extremely fine. For example, C^{14} shifts from the relatively stable C^{12} by only $12.4 \cdot 10^{-3}\,\mathrm{cm}^{-1}$ and hyper/ultraspectral ($\lambda/\Delta\lambda \gg 100$) resolution measurements required for their identification. Hyperspectral resolution helps to avoid the overlapping of spectral lines, resolves the isotopic shifts in the Stokes spectra, and allows determine the isotopic composition. C^{14}/C^{12} ratio of the composition identifies the source of the carbon emission (permafrost or oil deposits).

We developed on-board Raman laser sensor which allows methane pockets detection, and classifies parameters (C^{14}/C^{12} ratio) of the permafrost anomalies. The laser sensor is based on Nd: YAG laser (266 nm, 50 mJ, 5 ns, 100 Hz) and hyperspectral resolution detection system for resolving the isotopic shifts in the Stokes spectra.

Dual Source Railway Vehicles

T. Lelek, V. Schejbal, and O. Sadilek
Department of Electrical and Electronic Engineering and Signaling in Transport Jan Perner Transport Faculty, Studentska 95, Pardubice 532 10, Czech Republic

Abstract— The paper will deal with research activities about technical aspects of dual source railway vehicles (DSRV) on the Czech railway traffic system. The thought vehicle uses for powered traction equipment the catenary and traction battery system. The battery system design is based on the traction and vehicular simulations.

The discussion about decrease of using fossils fuels is today more serious than last years. That problem is correlating with finding the alternative energy sources. The problems around of the electric car revolution in connection with energy sources has solved in the book Energy myths and realities from V. Smil. The publication has concluded that contemporary transmission system is not ready for age of the clear electric transport means. Therefore the first rational step lays in the expanding hybrid transport means for railway and road transport. It will help to progressive transition to independent traction vehicles and prepare national transmission systems for high energy flows. Presently the professional society explores possibilities of use electric independent vehicles.

The multisource railway vehicles are solving at the Department of Electrical and Electronic Engineering and Signaling in Transport. Research activities are focused on the traction and propulsion computer simulations and on the real measurement of the experimental vehicle. The paper will discuss a design of dual source railway vehicle with the trolley collector and the battery. At first the paper will deal with basic concept of DSRV, next step will be ideological proposal design of battery system, simulations of traction motors efficiency and final simulation of specific track with price calculations. It is expected that this vehicle will be operating in the Czech district.

The designed vehicle has a lot of advantages unlike conventional one. Among these advantages we might include operation in a short section without an electric line, elimination of combustion engine, using a principle of regenerative braking and recharging battery under catenary. Recharging in a station is not necessary. This realities lead to more effective vehicle using.

Design of Slot Plannar Applicator for Local Thermotherapy

Abstract— Microwave thermotherapy is form of treatment which profits from effect affiliated with higher than common temperatures in biological tissue, such as higher blood flow and thus improved oxygenation and faster cell metabolism. From these effects we profit both in rehabilitation applications and above all in adjuvant cancer treatment. It's well known fact, that hyperthermia used in combination with conventional oncological methods significantly improves results.

The aim of this work was to design and construct a suitable planar slot applicator for microwave thermotherapy. Planar slot applicator is very good solution for superficial treatment, but can also be used for intracavitary treatment, as it can be manufactured from elastic materials. As resonant structure the slot applicator poses very good solution for energy transfer to biological tissue. Crucial for it's function is optimal impedance matching between applicator itself and treated tissue to ensure that all the energy radiated from antenna aperture is delivered to treated area. To allow applicator operate in unshielded room, we set its working frequency to 434 MHz, which is designated for biomedical and industrial use.

To design and simulate optimal resonant structure we used CST MICROWAVE STUDIO software suite. The aperture dimensions were set to 45 mm × 45 mm. After the optimal solution was found, applicator was made by the same technique as printed circuit board to evaluate its real behavior on phantom. As biological tissue phantom we chose agar model as one the best models of muscular tissue, or generally tissue with high water content. To simulate dielectric properties of real biological tissue, we added to agar 3 g of salt (NaCl). Measurement of scattering parameters was performed on vector analyzer Agilent E5071C.

To analyze how heat is distributed in tissue model was used thermal analyzer FLIR P25. After $t = 300$ s of heating was phantom evaluated with thermal analyzer from above a then immediately cut in pieces to see heat distribution inside.

By analyzing realized applicator was confirmed, that the lowest energy loss is indeed on frequency 434 MHz. So that makes our applicator perfect for furthermore clinical testing. To prevent creating hotspots applicator should be always equipped with water bolus.

Our slot applicator is suitable for use in biomedical applications in human medicine, preferably for cancer treatment, as it is capable delivering high amounts of energy to target tissue.

Array of Spiral Applicators for Local Thermotherapy

Abstract— Hyperthermia, also called thermotherapy, is a type of cancer treatment in which body tissue is exposed to high temperatures (up to 43°C). It has been shown that high temperatures can damage and kill cancer cells, usually with lower injury to normal tissues. Damaging proteins and structures within cells is causing death of cancer cells by damaging proteins and their inner structures.

Hyperthermia is often used with other forms of cancer therapy, such as chemotherapy and radiation therapy. Hyperthermia may make some cancer cells more sensitive to radiation or harm other cancer cells that radiation cannot damage and it can also enhance the effects of certain cytostatics.

There are two main streams in hyperthermia thermotherapy depending on the area of the human body where the heat was applied. Thus, we have a local hyperthermia application and a whole body application.

In local hyperthermia, heat is applied to a small area, such as a tumor, using techniques that deliver energy to heat the tumor. Different types of energy may be used in this case including radiofrequency, microwave, or ultrasound.

Depending on the tumor location, there are several approaches to local hyperthermia: External approaches are used to treat tumors in superficial area, which means that the tumors are not more than 30 mm below the skin. External applicators are often positioned around or near the appropriate region, and energy is focused on the tumor.

Two-wire Archimedean spiral applicator configurations, when properly excited, have been shown to be circularly polarized radiators with wide broadband characteristic with respect not only to input impedance but also to radiation pattern. In practice, the configuration is excited from a transmission line connected to the center terminals of the configuration.

Such energized two-wire Archimedean spiral radiates a broad circularly polarized beam to each side of the spiral. Each radiated beam is normal to the plane of the spiral Accordingly, the radiated beams are identical except that the rotational sense of polarization of the radiated field on one side is the opposite of that on the other.

In most applications it is desirable that the spiral radiate to one side this is accomplished by appropriately backing the spiral on one side by a ground plane.

The matrix composition of the two-wire Archimedean spiral applicators is a very useful when we want to irradiate the larger area, which can be useful for example treating the tumors in thoracic region, e.g..

Our main aim was to discuss the array of four of the two-wire Archimedean spiral applicators. From the results based on the simulations in simulator of electromagnetic field we assume that this setup is the most suitable applicator for the superficial thermotherapy covering the largest area of tissue. Effective field size of the single applicator is 63%. The measured impedance matching to the biological tissue is less than −10 dB. When composed together in the shape of five spiral applicators, this setup is capable of effectively heating the superficially located tumors.

Development of Applicator for Microwave Hyperthermia System for Treatment of Mice

Abstract— A microwave hyperthermia treatment of mice is planned within the research project "Utilization of novel mouse strains for investigation of the natural killer cell regulatory role in development and therapy of cancer" supported by Czech Scientific Foundation.

For this purpose a microwave exposure chamber working at 434 MHz was designed and its configuration was optimized in numerical simulator in terms of SAR and temperature distributions created by electromagnetic waves irradiated by the applicator in a numerical mouse model. The considered mouse model is a high resolution anatomical model depicted in Fig. 1. The mouse model was created by IT'IS Foundation, Switzerland and consists of 50 different tissues. To every tissue dielectric and thermal material properties were assigned from IT'IS Foundation biological tissue material properties database. A numerical model of the exposure chamber was created in the SEMCAD X and the mouse model was imported to the numerical model as well. Such overall numerical model allowed estimation of 3D distribution of the power loss density as well as computation of temperature 3D distribution in a treated mouse. Even effect of blood flow on the 3D temperature distribution was taken into account. The chamber was integrated to an available clinical hyperthermia system ALBA ON 4000, ALBA Hyperthermia System, Italy. The exposure chamber consists of two radiating structures (LC resonators) and the exposed mouse is located between them in a well-defined position. Advantage of using the ALBA 4000 is that the system already includes all necessary components such as microwave power generator, water bolus, minimal invasive temperature sensors and control unit and allows performance of well controlled hyperthermia treatments of mice. Preliminary experimental validations of performance of the exposure chamber integrated into ALBA 4000 on agar mouse phantoms were performed and are discussed here.

Abstract— In this paper a numerical study of requirements on microwave components for breast microwave hyperthermia is performed. The main goal is to find information about ranges of system settings in terms of phases and powers of each channel for different parameters as working frequencies of the system, positions and sizes of tumors. This information will be used for specification of microwave components needed for system implementation. In this study, 8 balanced antipodal Vivaldi antennas, developed originally for microwave imaging, in the field of microwave hyperthermia for breast cancer treatment are used as radiating elements. The working frequencies considered here are 915, 1400 and 2450 MHz. Ability of the system to effectively focus electromagnetic power into a tumor region within a numerical breast phantom is investigated using numerical simulations of SAR and temperature distributions created by an electromagnetic waves irradiated by the system. A commercial full-wave electromagnetic numerical simulation tool SEMCAD X with a built-in thermal solver is used for this task. A simple homogeneous breast phantom with a skin layer considered here was adopted from [1]. For the purpose of this study, a spherical tumor of diameter $d = 10$; 20 and 30 [mm] is virtually placed into the breast phantom at one quarter, one half and three quarters of the breast radius (out of the longitudinal axis). Average value of relative permittivity ε_r and equivalent conductivity σ_e of the healthy breast tissue as well as of the malignant tumor tissue were adopted from [2]. Statistical evaluation of achieved results will be performed as well as discussed.

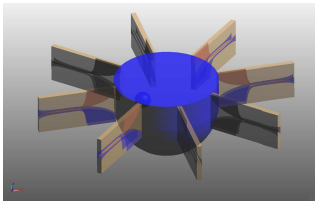

Figure 1: Schematic of 8-antenna configuration around the homogeneous breast phantom.

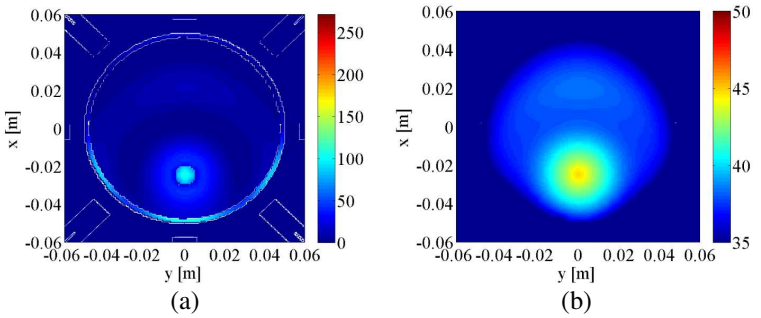

Figure 2: Optimized SAR distribution for 8-antenna configuration in the (a) numerical phantom at 1400 MHz and (b) corresponding temperature distribution, respectively.

Abstract— Microwave mixers perform the frequency conversion of electromagnetic signals and their operating principle is mostly based on the nonlinear behavior provided by the diodes or the transistors. The frequency translation is significant in numerous modern microwave systems applications ranging from radar and radio astronomy to microwave instruments and biological sensing. The selection of mixer's topology is based on its required performance. Transistor mixers are typically used in several applications where cost is the main driver rather than performance of the mixer. However, Schottky diode mixers utilizing hybrid couplers as their balun are used almost exclusively for the more challenging and high performance applications. For a diode mixer, the bandwidth limitation of the balun limits the overall performance of the mixer, which inspired the recent studies on design of wideband mixer topologies based on various types of baluns.

A new design of miniaturized single balanced diode mixer that comprises of a ring coupler as balun is presented in this paper for ultra wideband microwave applications. The ring structure of proposed mixer utilizes a pair of ultra wideband phase inverted transitions. To design analogous in-phase and inverted-phase transitions of ring coupler, consecutive transitions from parallel stripline to coplanar waveguide to parallel stripline are utilized. However, in order to interface ring coupler with diodes and to feed RF and LO signals, additional parallel stripline to microstrip line transition is introduced The diode matching circuit is designed after studying the nonlinear behavior and embedded impedance of diodes in nonlinear circuit simulator. Finally, the IF signal is extracted through external low pass filter. A favorable 3.1 to 10.6 GHz ultra wideband mixer performance has been achieved by optimizing the diode matching circuit with ring coupler. The proposed mixer exhibits flat conversion loss, good inter-port isolation of more than 20 dB, and compact size of 30% of the conventional ring mixer. The measured results show a conversion loss of 7.5 dB over 3.1 to 10.6 GHz ultra-wideband range of frequencies and also covers the IF frequency range of DC to 1 GHz. For optimal system performance, the proposed mixer can preferably be desirable for the high volume applications of UWB.

A Broadband Equiangular Spiral Antenna for UWB Ground Penetrating Radar (GPR) Applications
